$$\mathbf{p}_d = \mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}} + \mathbf{p}_d^{\text{fric}} = p_d \mathbf{e} + \alpha_d \boldsymbol{\sigma}_d \quad (4.157)$$

Hence, the total pressure of the dispersed phase might be approximated as the sum of the kinetic (4.107), collisional (4.127) and frictional (4.155) pressure contributions:

$$p_d = \alpha_d \rho_d \theta [1 + 2(1 + e)\alpha_d g_0(\alpha_d)] + p_d^{\text{fric}} \quad (4.158)$$

The total deviatoric pressure tensor might be written as a viscous stress tensor:

$$\sigma_d = -\mu_d \left( \nabla \mathbf{v}_d + (\nabla \mathbf{v}_d)^T \right) - \left( \mu_{B,d} - \frac{2}{3} \mu_d \right) (\nabla \cdot \mathbf{v}_d) \mathbf{e} \quad (4.159)$$

where the overall viscosity (4.152) might be approximated as the sum of the kinetic, collisional and frictional contributions.

The overall viscosity is then approximates as:

$$\begin{aligned} \mu_d = & \frac{2\mu_d^{\text{dilute}}}{\alpha_d(1+e)g_0(\alpha_d)} \left( 1 + \frac{4}{5} \alpha_d g_0(\alpha_d)(1+e) \right)^2 \\ & + \frac{4}{5} \alpha_d \rho_d d_{12} g_0(\alpha_d)(1+e) \sqrt{\frac{\theta}{\pi}} + \mu_d^{\text{fric}} \end{aligned} \quad (4.160)$$

It is noted that the kinetic viscosity, defined by (4.109) and the dilute regime viscosity (4.113), dominates in the dilute regime. The collisional viscosity, defined by the linear sum of the first (4.130), second (4.148) and the bulk viscosity (4.146) parts, usually dominate in the dense high shear flow regime. The frictional viscosity, defined by (4.156), normally dominates for the dense low shear flow regime.

#### 4.1.5.5 The Granular Heat Flux Vectors

The total granular heat flux vector,  $\mathbf{q}_d$ , is determined in about the same way as the total pressure tensor. The heat flux thus consists of a kinetic part,  $\mathbf{q}_d^{\text{kin}}$  and a collisional part,  $\mathbf{q}_d^{\text{coll}}$ .

The kinetic flux is determined by the Chapman-Enskog approach [25]:

$$\mathbf{q}_d^{\text{kin}} = \frac{1}{2} mn \langle \mathbf{c} c^2 \rangle = \frac{1}{2} m \int f \mathbf{c} c^2 d\mathbf{c} \quad (4.161)$$

In the first approximation term the density function  $f$  is approximated by the Maxwellian distribution function (4.40), thus the equilibrium microscopic particle velocity equals the peculiar velocity because the average macroscopic gas dynamic velocity equals zero, i.e.,  $\mathbf{c} = \mathbf{C} + \mathbf{v} = \mathbf{C}$ , thus the flux becomes:

$$\mathbf{q}_d^{\text{kin},(0)} = \frac{mn}{2} \int f^{(0)} \mathbf{C} C^2 d\mathbf{C} = \frac{mn}{2} \int \frac{\mathbf{C} C^2}{(2\pi\theta)^{3/2}} \exp \left[ -\frac{C^2}{2\theta} \right] d\mathbf{C} = 0 \quad (4.162)$$

That is,  $\mathbf{q}_d^{\text{kin},(0)} = 0$ , because the integral in  $\mathbf{C}$  is odd (see Chapman and Cowling [25] Sect. 1.42 and Gidaspow [49] Eq. (9.133)).

The second approximation term,  $\mathbf{q}_d^{\text{kin},(1)}$ , which is valid for dilute flows only [25, 49], is obtained by using the perturbation function  $\Phi$  defined by (4.111):

$$\begin{aligned}
\mathbf{q}_d^{\text{kin},(1)} &= \frac{1}{2}m \int f^{(1)} \mathbf{C} C^2 d\mathbf{C} = \frac{1}{2}m \int f^{(0)} \Phi \mathbf{C} C^2 d\mathbf{C} \\
&= -\frac{m}{n} \int f^{(0)} A(\mathbf{C}) \mathbf{C} \cdot \nabla \ln \theta \mathbf{C} C^2 d\mathbf{C} \\
&= -\frac{1}{3} \frac{m}{n} \nabla \ln \theta \int f^{(0)} A(\mathbf{C}) C^4 d\mathbf{C}
\end{aligned} \tag{4.163}$$

in which the integral theorem (E.1) has been employed.

Applying Eq. (7.31,6) in Chapman and Cowling [25],  $\int f^{(0)} A(\mathbf{C}) C^4 d\mathbf{C} = 0$ , the heat flux relation can be manipulated subtracting a particular zero term:

$$\begin{aligned}
\mathbf{q}_d^{\text{kin},(1)} &= -\frac{1}{3} \frac{m}{n} \nabla \theta \int f^{(0)} \mathbf{C} A(\mathbf{C}) \cdot f^{(0)} \left( \frac{C^2}{\theta} - \frac{5}{2} \right) \mathbf{C} d\mathbf{C} \\
&= -\frac{1}{3} \frac{m}{n} [\mathbf{A}, \mathbf{A}] \nabla \theta
\end{aligned} \tag{4.164}$$

where the granular conductivity  $\kappa_d^{\text{dilute}} = \frac{1}{3} \frac{m}{n} [\mathbf{A}, \mathbf{A}]$  is expressed in terms of a bracket integral. Such integrals can be evaluated by Sonine polynomials [25].

In analogy to Fourier's law of molecular heat conduction [25, 49], the granular kinetic heat flux is defined as:

$$\mathbf{q}_d^{\text{kin},(1)} = -\alpha_d \kappa_d^{\text{kin}} \nabla \theta \tag{4.165}$$

To estimate the kinetic conductivity,  $\kappa_d^{\text{kin}}$ , an analogy is frequently made to dilute gas flows. A first approximation of the dilute gas flow conductivity was given by Chapman and Cowling [25], Eq. (9.7,4). The kinetic conductivity,  $\kappa_d^{\text{kin}}$ , might thus be approximated in terms of the dilute flow conductivity as:

$$\alpha_d \kappa_d^{\text{kin}} \approx k_d^{\text{dilute}} = \frac{5}{2} \mu_d^{\text{dilute}} C_V = \frac{75}{384} \sqrt{\pi} \rho_d d_{12} \theta^{1/2} \tag{4.166}$$

where the  $\mu_d^{\text{dilute}}$  is defined by (4.113). An estimate of the specific heat at constant volume for a dilute granular fluid was deduced by Gidaspow [49] and presented in Table 9.5 in his book, based on a relation for the specific heat at constant volume for a dilute gas (2.232). The  $C_V$  for dilute granular fluid was approximated as:

$$C_V = 3/2 \tag{4.167}$$

The collisional part of the overall energy flux,  $\Phi(\frac{1}{2}mc^2)$ , decomposes into a collisional heat flux,  $\mathbf{q}_d^{\text{coll}} = \Phi(\frac{1}{2}mC^2)$ , and a work term,  $\mathbf{v}_d \cdot \mathbf{p}_d^{\text{coll}} = \Phi(m\mathbf{C} \cdot \mathbf{c})$ , as shown by (4.71). Moreover, the macroscopic kinetic energy flux,  $\Phi(\frac{1}{2}mv_d^2)$ , vanishes because the macroscopic fluid velocity does not change due to a microscopic particle collision as stated by (4.74). In the sequel, the required closure for the overall collisional granular heat conduction flux,  $\mathbf{q}_d^{\text{coll}}$ , is derived by substituting  $\psi = \frac{1}{2}mC_1^2$

into the flux relation (4.26):

$$\begin{aligned} \mathbf{q}_d^{\text{coll}} = & \Phi \left( \frac{1}{2} m C_1^2 \right) \approx \\ & - \frac{d_{12}^3}{4} m g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} ((\mathbf{C}'_1)^2 - \mathbf{C}_1^2) \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) d\mathbf{z} \\ & - \frac{d_{12}^4}{8} m g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} ((\mathbf{C}'_1)^2 - \mathbf{C}_1^2) \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(0)}(\mathbf{r}, \mathbf{c}_2, t) \mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(0)}} d\mathbf{z} \end{aligned} \quad (4.168)$$

where the set of integration variables is defined as  $d\mathbf{z} = (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2$ .

By use of (4.50), this relation can be expressed in terms of the peculiar velocity instead of the microscopic particle velocity because the macroscopic velocity,  $\mathbf{v}$ , is evaluated at the special point  $\mathbf{r}$  under consideration, and does not vary with the position of the particle:

$$\mathbf{c}'_1 - \mathbf{c}_1 = \mathbf{C}'_1 - \mathbf{C}_1 = -\frac{1}{2}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k})\mathbf{k} \quad (4.169)$$

The following relation is thus obtained by the square of (4.50):

$$(\mathbf{C}'_1)^2 - \mathbf{C}_1^2 = \mathbf{C}_1 \cdot \mathbf{k}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k}) + \frac{1}{4}(1+e)^2(\mathbf{g}_{12} \cdot \mathbf{k})^2 \quad (4.170)$$

Upon substitution of (4.170) into the integrals of  $\mathbf{q}_d^{\text{coll},1}$  and  $\mathbf{q}_d^{\text{coll},2}$  in (4.168), integration with respect to  $\mathbf{k}$ ,  $\mathbf{c}_1$  and  $\mathbf{c}_2$  are performed following the same determination procedure as used for the collisional pressure tensor and summarized by Chapman and Cowling [25] Sect. 16.42. The first integral yields:

$$\mathbf{q}_d^{\text{coll},1} = \frac{3}{5} \alpha_d g_o(\alpha_d) (1+e) \rho_d \alpha_d \langle \mathbf{C} C^2 \rangle \quad (4.171)$$

Hence, for the first velocity distribution represented by the Maxwellian distribution, the heat flux vanishes due to the same reasons as for (4.162):

$$\mathbf{q}_d^{\text{coll},1,(0)} = \frac{3}{5} \alpha_d g_o(\alpha_d) (1+e) \rho_d \alpha_d \langle \mathbf{C} C^2 \rangle^{(0)} = 0 \quad (4.172)$$

For the second approximation to the velocity distribution, the dense gas flow analysis by Chapman and Cowling [25] was adapted to particle flows by Gidaspow [49]. The result is:

$$\begin{aligned}
\mathbf{q}_d^{\text{coll},1,(1)} &= \frac{3}{5} \alpha_d g_0(\alpha_d) (1+e) \rho_d \alpha_d \langle \mathbf{C} \mathbf{C}^2 \rangle^{(1)} \\
&\approx \frac{6}{5} \alpha_d g_0(\alpha_d) (1+e) \left[ -\frac{2[1 + \frac{6}{5} \alpha_d g_0(\alpha_d) (1+e)]}{g_0(\alpha_d) (1+e)} \kappa_d^{\text{dilute}} \right] \nabla \theta \\
&\approx -\alpha_d \left\{ \frac{6}{5} g_0(\alpha_d) (1+e) \left[ -\frac{2[1 + \frac{6}{5} \alpha_d g_0(\alpha_d) (1+e)]}{g_0(\alpha_d) (1+e)} \kappa_d^{\text{dilute}} \right] \right\} \nabla \theta \\
&= -\alpha_d \kappa_d^{\text{coll},1} \nabla \theta
\end{aligned} \tag{4.173}$$

for  $e$  near unity.

The second integral in (4.168) can be approximated as:

$$\mathbf{q}_d^{\text{coll},2} = -\alpha_d \left\{ 2\rho_d \alpha_d d_{12} (1+e) g_0(\alpha_d) \sqrt{\frac{\theta}{\pi}} \right\} \nabla \theta = -\alpha_d \kappa_d^{\text{coll},2} \nabla \theta \tag{4.174}$$

#### 4.1.5.6 Total Granular Heat Flux

The total granular heat flux is thus the sum of the kinetic- and collisional fluxes [49]:

$$\begin{aligned}
\mathbf{q}_d &= \mathbf{q}_d^{\text{kin}} + \mathbf{q}_d^{\text{coll},1} + \mathbf{q}_d^{\text{coll},2} \\
&= \frac{1}{2} \alpha_d \rho_d \langle \mathbf{C} \mathbf{C}^2 \rangle^{(1)} + \frac{1}{2} \alpha_d \rho_d \langle \mathbf{C} \mathbf{C}^2 \rangle^{(1)} \left[ \frac{6}{5} \alpha_d g_0(\alpha_d) (1+e) \right] - \alpha_d \kappa_d^{\text{coll},2} \nabla \theta \\
&= -\alpha_d (\kappa_d^{\text{kin}} + \kappa_d^{\text{coll},1} + \kappa_d^{\text{coll},2}) \nabla \theta \\
&= -\alpha_d \kappa_d \nabla \theta
\end{aligned} \tag{4.175}$$

The total granular conductivity for  $e$  near unity is given by:

$$\kappa_d = \frac{2\kappa_d^{\text{dilute}}}{(1+e)g_0\alpha_d} \left[ 1 + \frac{6}{5} (1+e)g_0\alpha_d \right]^2 + 2\alpha_d \rho_d d_{12} g_0 (1+e) \sqrt{\frac{\theta}{\pi}} \tag{4.176}$$

where  $\kappa_d^{\text{dilute}}$  is given by (4.166). As for the viscosity  $\mu_d$ , the first term on the RHS of the conductivity  $\kappa_d$  closure denotes the kinetic contribution and dominates in the dilute regime. The second term on the RHS of the closure equation denotes the collisional contribution and dominates in the dense flow regime.

#### 4.1.5.7 Granular Temperature (Translational Energy) Dissipation Term

The algebraic dissipation term in the equation for granular temperature (4.105) is defined in accordance with (4.28), and approximated by assuming equilibrium flow:

$$\begin{aligned}
\gamma &= -\Omega \left( \frac{1}{2} m c^2 \right) \\
&\approx -\frac{d_{12}^2}{2} g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \Delta \left( \frac{1}{2} m c^2 \right) f_1^{(0)} f_2^{(0)} (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \\
&\quad - \frac{d_{12}^3}{4} g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \Delta \left( \frac{1}{2} m c^2 \right) f_1^{(0)} f_2^{(0)} \mathbf{k} \cdot \nabla \ln \frac{f_2^{(0)}}{f_1^{(0)}} (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2
\end{aligned} \tag{4.177}$$

where  $\Delta(\frac{1}{2} m c^2) = \frac{1}{2} m (c_1'^2 + c_2'^2 - c_1^2 - c_2^2)$ . Moreover,  $f_1^{(0)}$  and  $f_2^{(0)}$  are the Maxwellian velocity distributions at the point  $\mathbf{r}$  for particle 1 and 2, respectively. Using (4.56) to eliminate  $\Delta(\frac{1}{2} m c^2)$ , (4.177) can be expressed as:

$$\begin{aligned}
\gamma &\approx -\frac{d_{12}^2}{2} g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \left\{ \frac{1}{4} m (e^2 - 1) (\mathbf{k} \cdot \mathbf{g}_{12})^2 \right\} (\mathbf{g}_{21} \cdot \mathbf{k}) \\
&\quad \times \left[ f_1^{(0)} f_2^{(0)} + \frac{1}{2} d_{12} f_1^{(0)} f_2^{(0)} \mathbf{k} \cdot \nabla \ln \frac{f_2^{(0)}}{f_1^{(0)}} \right] d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2
\end{aligned} \tag{4.178}$$

The necessary integration theorems are taken from Chapman and Cowling [25] and are listed in App E. The integral in (4.178) was first evaluated by Jenkins and Savage [68], whereas Ding and Gidaspow [30] achieved a reduced relation on the form [49]:

$$\gamma = -\Omega \left( \frac{1}{2} m c^2 \right) = 3(1 - e^2) \alpha_d^2 \rho_d g_0 \theta \left( \frac{4}{d_{12}} \sqrt{\frac{\theta}{\pi}} - \nabla \cdot \mathbf{v}_d \right) \tag{4.179}$$

It is noted that for elastic particle collisions the dissipation term vanishes,  $\gamma = -\Omega(\frac{1}{2} m c^2) = 0$ , because  $e = 1$ .

#### 4.1.6 Initial- and Boundary Conditions for Particle Phase Equations

To solve the equations of granular flows, appropriate boundary conditions for the velocities and for the granular temperature are required. The boundary conditions proposed by Ding and Gidaspow [30] are generally adopted in most granular flow simulations.

At the *impermeable wall*, the no-slip condition is generally not appropriate for granular flows. Nevertheless, the granular phase velocity component normal to the wall is normally set to zero. However, the granular phase is usually allowed to slip along the wall. A velocity slip proportional to the velocity gradient at the wall is

commonly applied:

$$v_{d,z}|_{\text{wall}} = -\lambda_d \frac{\partial v_{d,z}}{\partial n}|_{\text{wall}} \quad (4.180)$$

where the  $n$  denotes the direction normal to the wall.

The slip parameter  $\lambda_d$  takes the value of the mean free path of the molecules.  $\lambda_d$  is normally estimated by:

$$\alpha_d \frac{4}{3} \pi \left( \frac{\lambda_d}{2} \right)^3 = \frac{\pi}{6} d_{12}^3 \quad (4.181)$$

with some simple manipulations we achieve

$$\lambda_d = \frac{d_{12}}{\alpha_d^{1/3}} \quad (4.182)$$

Although there might be a granular temperature flux through the wall, little is known about the magnitude of such a flux. Hence, a simple zero gradient boundary condition is normally used:

$$\left( \frac{\partial \theta}{\partial r} \right)_{\text{wall}} = 0 \quad (4.183)$$

The dispersed phase volume fraction normal gradient is set to zero.

The boundary value for the normal velocity at the *symmetry axis* is zero. The tangential velocity, volume fraction and granular temperature gradients normal to the symmetry axis are all set to zero. The *inlet* conditions for the fluidized bed are given in accordance with the operating conditions specified. In particular, a small but non-zero value is specified for the granular temperature, i.e.,  $\theta \approx 10^{-7} (m^2/s^2)$ . The dispersed phase volume fraction is set to zero at the inlet where solid-free gas enters the system. At the *outlet*, the normal gradients of all granular material quantities are zero as the mass flux is assumed to be continuous. The *initial* condition specifies a fluidized bed operating at the minimum fluidization state. The granular temperature is set equal to the inlet value everywhere inside the calculation domain.

## 4.2 Modeling of Reactive Flows in Fluidized Beds

The multi-fluid models discussed in Chap. 3 have been employed extensively describing the behavior of cold flow and reactive flow systems in multiphase reactors. However, for gas–solid fluidized bed systems, and in particular for dense systems, it has been found that the dispersed phase behavior cannot be captured without an extended description of the pressure tensor closure. The first extensions of the dilute continuum mechanical two-fluid model concept included a very rough approximation of the solid phase collisional pressure in terms of a semi-empirical correlation for the modulus of elasticity and a constant representative particle fluid viscosity. This type

of gas–solid particle two-fluid models is sometimes named the Constant Particle Viscosity (CPV) model. The more recent two-fluid models for granular particle fluid flows are established by describing the continuous gas phase by one set of the governing dilute continuum mechanical two-fluid model equations derived in Chap. 3 and the dispersed phase(s) by the dense granular fluid modeling concepts outlined previously in this chapter. In this section the model extensions required in order to describe reactive flows in different designs of fluidized bed reactors are discussed. Moreover, the suggested modeling extensions required in order to describe cold flow poly-dispersed dispersions and reactive poly-dispersed dispersions in fluidized beds are outlined.

### ***4.2.1 Two-fluid Model Formulation and Closure Limitations***

The main advantage associated with the kinetic theory approach for dense dispersions is the appearance of two extra pressure tensor terms in addition to the interstitial fluid phase pressure tensor, one kinetic pressure tensor accounting for the transport phenomena due to the translational particle movement and one collisional pressure tensor accounting for the transport phenomena due to particle collisions. Nevertheless, for dense dispersions at low shear rates it might be necessary to add a third pressure tensor accounting for the long range particle-particle interactions represented by a semi-empirical frictional pressure tensor closure. However, there are many aspects of rapid granular flows that have barely been studied and require further considerations to provide appropriate closures for reactor flows. One of the more severe two-fluid model limitations is related to the Eulerian model description of the local energy dissipation phenomena during particle-particle and particle-wall interactions. The theoretical studies of rapid granular flows are generally based on the assumption that the energy dissipation in a binary particle collision is determined by a constant coefficient of restitution  $e$ , the ratio of the relative approach to recoil velocities normal to the point of impact on the particle. However, measurements show that the coefficient of restitution is a strong function of the relative impact velocity and the impact parameter [17]. Physically, the energy dissipation relates to the plastic deformation of the particle's surface. Thus, a realistic microscopic model should include the deformation history of the particle's surface. It seems a Lagrangian model might be advantageous for analyzing this type of problems. However, the Lagrangian model simulations of industrial scale reactor units are not feasible due to the computational costs related to computational speed and data storage requirements. Thus, for most pilot and industrial scale reactor simulations researchers resort to the Eulerian multi-fluid modeling concept. In one such investigation, Wang et al. [160] did perform a parameter sensitivity study of the two-fluid model closure parameters determining the main gas–solid particle fluid flow pattern characteristics of a bubbling bed and a circulating fluidized bed. They concluded that the coefficient of restitution had a very strong influence on the flow pattern of the particle phase in the bubbling bed. Moreover, the flow pattern predictions were very sensitive to small changes of the

constant restitution coefficient value chosen in the range 0.95, 0.965, 0.997, 0.9995. With relative small changes in the inlet gas flux, the single value used for the restitution coefficient had to be tuned to known flow patterns and was thus not universal for the same system and geometry. They further proposed that the restitution coefficient value might change locally depending on the local velocity and solid dispersion density. For the circulating fluidized bed flow simulation predictions, the sensitivity to the restitution coefficient value was much less. Further investigations are thus required in order to elucidate these phenomena and to find ways to make mechanistic models for the spatial changes in the collisional granular fluid kinetic energy dissipation rate. Furthermore, most theoretical studies performed so far with the two-fluid model are based on the assumption that the granular material is composed of uniformly sized disk or spheres. However, granular materials in industrial reactor units generally have a wide particle size distribution and the particle shape might be highly angular. Sphericity has been assumed in most studies for many reasons. In theoretical work and computer simulations it is easy to detect a collision of spherical particles, as particles are in contact whenever their centers are a distance of two radii apart. For non-spherical particles, the contact mechanisms become much more complicated, as the orientation of the particle, which changes as the particle rotates, must be taken into account. For this reason the assumption of spherical particles are normally considered a fair approximation for catalyst pellets. The alternative dilute continuum mechanical two-fluid modeling approach derived in Chap. 3 reflects the advantage of allowing the same averaging operators to be applied to both phases. In this way the governing equations for both phases contain consistent interfacial coupling terms. However, the dilute approach does not give rise to any of the two pressure tensors accounting for the transport phenomena caused by the particle movement and collisions. The dense phase two-fluid modeling concept presented previously in this chapter, on the other hand, contain an inherent inconsistency as the dispersed granular material phase is averaged over the velocity space using the Maxwellian averaging approach while the Eulerian microscopic dilute phase equations are time-, volume- or ensemble averaged. The formulation of consistent phase interaction- and co-variance terms is thus a very complex task. In particular, referring to the introduction of the external forces as presented in Sect. 4.1.3 there are still no complete consensus in the literature regarding the treatment of the interfacial coupling terms like the steady drag-, added mass- and lift forces. In one modeling concept introduced by Maxey and Riley [108], and later extensively employed in the fluidization literature [117, 118, 132, 137, 138], it is considered convenient to split the net force exerted by the interstitial fluid on the particle into two different contributions: One virtual force applied by an *undisturbed flow* on a imaginary fluid particle which coincides with the solid particle in volume and shape, and a second contribution that represents the forces due to the perturbations in the flow. These flow disturbances are created by the presence of the particles. The phrase *undisturbed flow* thus refers to the flow that would be observed if the particle was not present. Neglecting the effects of the perturbations in the flow, the net force exerted on a particle (4.65) might be approximated by:

$$\tilde{\mathbf{F}} = \frac{1}{\tau_{cd}}(\tilde{\mathbf{v}}_c - \mathbf{c}) - \frac{1}{\rho_d} \nabla \tilde{p} + \mathbf{g} \quad (4.184)$$

where the quantities  $\tilde{p}_c$  and  $\tilde{\mathbf{v}}_c$  are the imaginary pressure and velocity fields of the undisturbed flow.

For undisturbed turbulent flows the local instantaneous velocity of the continuous phase have been decomposed in various ways, not necessarily in accordance with the familiar Reynolds—and Favre averaging procedures. To explain the basic problem we use the Reynolds decomposition and averaging procedure, as an example. Introducing the peculiar velocity for the dispersed phase (4.184) can be re-arranged as:

$$\tilde{\mathbf{F}} = \frac{1}{\tau_{cd}}((\tilde{\mathbf{v}})_c - \mathbf{v}_d) + \frac{1}{\tau_{cd}}(\tilde{\mathbf{v}}'_c - \mathbf{C}) - \frac{1}{\rho_d} \nabla \tilde{p} + \mathbf{g} \quad (4.185)$$

The interpretations of the velocity variables in the first and second terms on the RHS represent a severe problem due to a general lack of knowledge about the physics they represent. Besides, when the  $\mathbf{F}$  quantity in the Maxwell equation is substituted by this relation and Maxwellian averaged, the resulting covariances consist of velocity quantities which are averaged in an inconsistent manner (Maxwellian- vs. time-, volume-, or ensemble averaging). For this reason other somewhat ad hoc decomposition procedures have been defined intending to achieve more consistent closures for these terms.

The granular flow modeling work of Simonin and co-workers [6, 7, 9, 15, 29, 56, 117, 132–136, 151, 156, 157, 159] is briefly outlined in App D illustrating the complexity of this task. The group referred is recognized for developing two-fluid models for industrial applications based roughly on the modeling ideas of Enskog [38] and the solution strategy of Grad [53]. Most of these model closures can be considered as extensions of, rather than alternatives to, the modeling approach of Gidaspow [49] taking into account the fluid-particle covariance term (i.e., the drift velocity) which is normally neglected employing the Chapman-Enskog approach. The closures of Simonin and co-workers are deduced by use of the statistical turbulence theories of Taylor [146], Hinze [57], Tchen [147], Csanady [28] and Yudine [169]. The work of Tchen [147] represents one of the first attempts to study the dispersion of particles in a steady and homogeneous turbulent flow field by use of the fluid Lagrangian two-point correlation function  $R_{ij}(\tau)$  and the gradient hypothesis. The turbulence dispersion coefficient needed to close the flux model is defined in terms of the correlation function and thus the fluid-particle velocity covariance (correlation tensor). Several additional assumptions were made in his derivation: (1) The particles are spherical and follow Stoke's law of resistance, (2) the particles are small compared to the smallest length scales of the fluid flow, and (3) during the motion of the particles, their neighborhood is formed by the same fluid. A few years later assumption (3) in the Tchen theory was assessed and found questionable. Yudine [169] and Csanady [28] studied the effect of turbulent diffusion of heavy particles in turbulent flows. In particular, the existence of the *crossing trajectory*

*effect*<sup>1</sup> was recognized. Based on these classical analyzes Deutsch and Simonin [29] derived closure models for the particle velocity covariances, the fluid-particle velocity covariances, and the drift velocity intending to avoid assumption (3) in the theory of Tchen. An algebraic formula for the dispersion—or drift velocity computed along the particle trajectories was deduced for homogeneous isotropic turbulence.<sup>2</sup> Nevertheless, in the case of industrial gas–solid flows, most assumptions of these models are still too restrictive and a more general formulation is necessary. The generalized formulation proposed in the subsequent work of Simonin and co-workers consists of separate transport equations for the drift velocity and the fluid-particle velocity correlation tensor. For dilute suspensions the derivation of the second order velocity moment closure follows a similar procedure as used for single phase flows deriving the Reynolds stress turbulence model. For dense suspensions similar transport equations are derived for the drift velocity and fluid-particle velocity correlation tensor based on the kinetic theory of granular flow approach. However, in another view the second order closure might be exaggerated in complexity, computationally expensive and impossible to validate. Besides, there are still no consensus regarding the physical meaning of these covariance terms [78]. The algebraic formulas proposed by Deutsch and Simonin [29] for the drift velocity supposedly valid for homogeneous isotropic turbulence of the interstitial fluid is not generally accepted but considered important by the inventors at least for particular applications. The second order closure of Simonin and co-workers is still only applied in academic research. For these reasons further details of the work of Simonin and co-workers are disregarded in this presentation. A further comparison between the two-phase dilute continuum mechanical formulation and the dense phase two-fluid model with a KTGF closure reveals another striking difference. The continuum mechanics modeling concepts give rise to a set of transport equations on the flux form, while the kinetic theory concepts as expressed in terms of the peculiar velocity give rise to transport equations defined by (4.102) on the advective- or non-flux form. The standard formulation using the local particle velocity  $\mathbf{c}$  defined by (4.59) leads to a set of equations on the flux form. Nevertheless, both forms of the dense phase equations are valid, as the continuity equation can be used to transform the equations in a consistent manner. Moreover, for multi-component reactive flows it is vital to ensure that the interfacial mass transfer fluxes are treated in a consistent manner. Likewise, for non-isothermal flows a consistent sensible heat or rather a thermal molecular temperature equation has to be formulated considering the important phenomena like interfacial heat transfer, heat of reaction, conductive heat flux, radiation heat flux, heat of mixing, etc. Hence it follows that for multi-component reactive mixtures the problem has to be re-considered deriving the governing equations again from scratch, this time in terms of an extended distribution function for particles of a particular

<sup>1</sup> The crossing trajectory effect refers to the impact of the continuous change of the fluid eddy-particle interactions as the heavy particle trajectory might go through numerous eddies reflecting different flow properties. Hence it follows that the velocity history of heavy particles may differ from that of a marked fluid particle.

<sup>2</sup> Similar closure models for the drift velocity and the velocity co-variances have been derived from kinetic theory by Koch and co-workers [81, 82] and Reeks [120, 121].

type. The corresponding multi-component kinetic theory for a dilute gas has been considered by Hirschfelder et al. [58]. Tham and Gubbins [148] extended the Enskog theory of dense, rigid sphere fluids to multi-component systems. The extension of this theory to reactive non-isothermal granular flows is not trivial. Very few theoretical and experimental studies have focused on developing parameterizations for the thermal conductivity of granular materials. The work of Gelperin and Einstein [46] may be mentioned. However, the importance of these terms in fluidized bed simulations might not be crucial since the granular material advection processes generally dominate the heat transport. Moreover, very few parameterizations are reported on the wall- and fluid-granular material convective thermal heat transfer coefficients. For introductory studies, the work of Natarajan and Hunt [110], Gunn [54], Kuibe and Broughton [83], Kuipers et al. [84] and Patil et al. [116] might be consulted. To enable validation and reliable predictions of non-isothermal non-adiabatic reactive granular flows, the thermal conductivity and the convective heat transfer coefficients have to be determined with sufficient accuracy. By definition a catalyst particle is a substance that affects the reaction rate of a reaction but emerges from the chemical process unchanged. It follows that for isothermal catalytic processes it might suffice to extend the classical mono-disperse single component granular flow model equations with a set of transport equations for the species mass in the gas phase. For non-isothermal processes the complexity changes dramatically as the granular fluid phase molecular temperature changes. For gas–solid reaction processes the modeling complexity increases even further as the solid particles reacts with some of the gas species and changes weight and possibly size, porosity, etc. Further work is thus needed in order to validate the performance of the granular flow models applied to different types of chemical reactive systems.

In a series of papers Lathouwers and Bellan [87–91] presented a kinetic theory model for multi-component reactive granular flows of binary particle mixtures. The model considered multiple particle suspensions in order to take into account that the physical properties (e.g., diameter, density) and thermo-chemistry (reactive vs. inert) of the particles might differ. Separate transport equations were constructed for each of the particle types, based on similar principles as used formulating the population balance equations [119]. To describe the behavior of the multi-component reactive granular material Lathouwers and Bellan started out from the work of Simonin [138] defining a single particle distribution function  $f_i^{(1)}(\mathbf{r}, \mathbf{c}, \omega_\xi, T, m, t)$  of particle type  $i$  such that  $f_i^{(1)}$  is the probable number of particles of type  $i$  having their center of mass in the region  $\mathbf{r}, \mathbf{r} + d\mathbf{r}$ , a velocity in the region  $\mathbf{c}, \mathbf{c} + d\mathbf{c}$ , mass fractions in  $\omega_\xi, \omega_\xi + d\omega_\xi$  with  $\xi = 1, \dots, N_\xi$ , temperature in  $T, T + dT$ , and mass in the region  $m, m + dm$ . With moderate mathematical complexity in derivation, they established a set of equations governing reactive multiple granular flows. The multi-component model was applied to dense gas–solid reactive mixtures to investigate the performance and optimal operating conditions of biomass pyrolysis in fluidized bed. The main reason for using such a complex model was to enable incorporation of the phase change phenomena changing the particle mass along its trajectory. However,

the discussion focused mainly on the chemical process and no experimental validation of the particle segregation mechanisms were performed.

Savage [128] made a review on the different mechanisms responsible for particle percolation, dispersion, and segregation. One such segregation effect is common in everyday experience and can be easily recognized. When a poly-disperse mixture is agitated in the presence of gravity the random particle motion is more likely to open a gap large enough for a small particle to fall into than one that can accommodate a large particle. Hence, the small particles migrate to the bottom of the flow, and the large particles migrate to the top. However, there is other phenomena associated with the deposition of sediments that results in the opposite behavior in which the finer particles are found in the top of the flow and the coarse ones are located at the bottom. Many similar phenomena have been identified. In fluidized beds in particular the axial segregation, due to particle diameters and/or density, is generally explained by the fact that smaller particles are more easily fluidized and will follow the gas more effectively than larger ones. Larger particles will not follow the gas effectively and start accumulating, particularly in the wall region where the gas velocity is very low. The radial particle segregation may have a similar origin. All these phenomena are caused by complex interactions between the particle sizes and densities that are not well understood, yet these mechanisms should be represented by the interaction terms of the individual phase equations. The important terms are thus the fluid particle steady drag-, the particle-particle steady drag-, the added mass-, and the transversal lift forces, etc. Jenkins and Mancini [70] used the kinetic theory to derive balance laws and constitutive equations for plane flows of a dense, binary mixture of smooth, nearly elastic, circular disks. The disks may have different radii and masses and the coefficient of restitution, characterizing the energy dissipated in the collisions between like and unlike pairs, may be different. The collisional fluxes and sources of momentum and energy that appear in these equations involve the complete pair distribution function for colliding pairs of like and unlike disks. They assume that these distribution functions can be expressed as the product of the single particle distribution function for each disk and a factor that accounts for the effects of excluded area and collisional shielding. However, rather than determining the single particle distribution function as an appropriate solution to the kinetic equations governing their evolution, they were assumed to be Maxwellian. Equipartition of energy was also assumed, leading to equality of the granular temperatures of both particle phases. While these assumptions were found reasonable for mixtures of molecules experience elastic collisions, several authors [20–23, 50, 62, 63, 99–101, 105, 107] doubted that these assumptions hold for inelastic solid particles. For this reason, Gidaspow and co-workers (i.e., Gidaspow et al. [50], Manger [105]) extended the kinetic theory to binary particle mixtures with unequal granular temperatures for the different particle phases. Manger [105] implemented the binary mixture model with two different granular temperatures into a 2D computer code to simulate segregation in a channel flow and concluded that the model can predict particle segregation induced by simultaneous changes in particle size and weight. In most of the derivations of the multi-fluid models for binary and poly-dispersed particle dispersions [20–23, 50, 62, 63, 99–101, 105, 107], the extended single

distribution function was obtained by solving a generalized Boltzmann equation using the Chapman-Engskog solution method of successive approximations. In a detailed analysis of the previous modeling work, van Sint Annland et al. [149, 150] revealed that in the mentioned models only the first approximation was employed. Moreover, it was found that the first approximation requires that the particle velocities of all particles are distributed the same mean velocity with the same granular temperature. It was thus concluded that all the models mentioned above contain an inherent inconsistency as the first approximation does not give rise to individual particle velocities and granular temperatures for the different particle phases. The mechanisms creating different velocities and granular temperatures for the individual particle fluid phases are deduced from the second approximation of the probability density function. Furthermore, no experimental validation of the model predictions were performed so further work was required on this topic. Hjertager and co-workers (i.e., Mathiesen et al. [106, 107]) thus performed an experimental and computational investigation of the multiphase flow behavior in a circulating fluidized bed. In this work, the binary particle phase flow model developed by Gidaspow and co-workers [50, 105] was generalized to  $N$  granular phases to enable a realistic description of the particle size and density distributions in gas–solid mixtures. Each granular phase is uniquely defined by a diameter, density and a restitution coefficient. A 2D model implemented in Cartesian coordinates with two, sometimes three, dispersed phases was applied to the circulating fluidized bed. The turbulence of the interstitial gas phase was modeled by use of a VLES turbulence closure. The model predictions were compared with literature data and their own measurements. In both experimental investigations Laser Doppler Anemometry and Phase Doppler Anemometry techniques were used to measure mean and fluctuating velocity, diameter and solid concentration, simultaneously. The model predictions were in fair agreement with the experimental data.

About a decade later, Chao et al. [20] presented a multi-fluid Eulerian model derived from the binary kinetic theory of granular flows, the mean free path theory and an empirical friction theory. The effects of the like- and unlike- particle-particle collisions, particle translational motions and particle-particle friction were included. As the effects due to fluid dynamic particle velocity differences and particle-particle friction were considered, some unconventional terms were obtained compared with the previous models. Model validation using the data from Mathiesen et al. [107] for a dilute riser flow did show that the coupling terms might give reasonable approximations of the binary coupling of particles as the effects due to the fluid dynamic velocity differences were considered. The model did also give reasonable predictions of the particle volume fraction, particle velocities and velocity fluctuations. The model analysis did reveal that the basic particle velocity fluctuations constitute 2 terms: the velocity fluctuations of the discrete particles, and the velocity fluctuations of the continuous fluid flow. Furthermore, the simulation results show that the velocity fluctuations of the continuous fluid flow are dominant in a binary riser flow. Moreover, Chao et al. [23] performed simulations of particle density segregation in a dense binary gas fluidized bed using the multi-fluid model derived by Chao et al. [20]. The segregation behavior of two types of particles with approximately

the same particle diameters and different particle densities was studied and validated using the experimental data from Formisani et al. [43]. Detailed information regarding the gas, particle velocity profiles, the distributions of the particle volume fractions and the flotsam-to-total particle volume fraction ratios was presented therein. The simulation results show that the simulated axial average flotsam-to-total particle volume fraction ratio distribution agrees reasonably with the experimental data of Formisani et al. [43]. It was found that the binary particle velocities are closely coupled though segregation exists. The segregation behavior and the particle velocity profiles were believed to be superficial gas velocity dependent. The number and distribution of the particle velocity vortices did change dramatically with superficial gas velocity: at a comparatively low superficial gas velocity, the particles mainly segregate axially, and at a comparatively high superficial gas velocity, the particles segregate both axially and radially. Furthermore, Chao et al. [22] studied the behavior of seven binary particle—particle drag closures from the literature using the binary KTGF model. These particle-particle drag closures employed were derived based on the kinetic theory of granular flow (KTGF) for the application to fluidized beds. Experimental dynamic size segregation data from Goldschmidt et al. [52] was used to validate the simulation results. The validation did show that all of the seven binary particle—particle drags did under-predict the binary particle—particle coupling in the dense fluidized bed. However, satisfactory results could be obtained if an extra semi-empirical frictional binary particle—particle drag was included. The semi-empirical frictional binary particle—particle drag considering the long term particle-particle contact effects is a correction of the short term collisional frictional binary particle—particle drag from Syamlal [145]. Furthermore, a group of comprehensive calculations did show that the same three-fluid model with the semi-empirical frictional binary particle—particle drag did fairly well predict the particle segregation rates and the bed heights of the individual particles with a change of gas fluidization velocity, the initial bed height, and the small particle ratio with the same fixed correction coefficient. Therefore, Chao et al. [22] proposed that the frictional binary particle—particle drag which represents the binary particle—particle momentum exchange due to the long term particle contacts (sliding/rolling) must be included in order to model dense binary fluidized beds. These particle segregation investigations show that the understanding of these complex flows are greatly improved. However, there are still many aspects of particle segregation in granular flows that need further considerations.

### ***4.2.2 Extending the Kinetic Theory of Granular Flow to Reactive Systems***

The success in deriving the Maxwellian type macroscopic transport equations and in obtaining appropriate source and flux closures based on the kinetic theory of granular flow relies heavily on the knowledge about the distribution function involved. In principle, for reactive systems the single particle distribution function should satisfy

an extended Boltzmann type equation which allows for changes in particle mass, particle species composition and thermal temperature. However, without making any restrictions in the structure of the distribution function, the tasks of formulating the Boltzmann type of equation and find solutions to determine the function values become very complex because the phase space includes many variables. In previous work, the structure of the distribution function has been simplified by decoupling the distribution function variables in terms of the respective variables in the phase space [89, 90, 92, 166]. In accordance with these investigations, a simplified single particle distribution function for reactive flows can thus be formulated as:

$$\begin{aligned} f(\mathbf{r}, \mathbf{c}, m, \omega_1, \omega_2, \dots, \omega_{N_\xi}, T, t) \\ = f(\mathbf{r}, \mathbf{c}, t) \delta(m - \bar{m}) \delta(\omega_1 - \langle \omega_1 \rangle_M) \dots \delta(\omega_{N_\xi} - \langle \omega_{N_\xi} \rangle_M) \delta(T - \langle T \rangle_M) \end{aligned} \quad (4.186)$$

where  $\delta$  denotes the Dirac delta function.

By introducing the simplified single distribution function, the fluid dynamic flow problem is decoupled from the thermo-chemistry such that the velocity distribution may be obtained by the techniques used for non-reactive flows. In the basic kinetic theory of granular flow (KTGF), the number of particles as well as the particle mass are constant. The thermal temperature of the particles is also considered constant since the particle collisions are considered nearly elastic so no notable kinetic energy is converted to heat. However, for a reactive system operated in a fluidized bed, the particles may degrade by attrition due to mechanical stresses and/or agglomerate due to particle cohesion so that the total number of particles is changing in the reactor unit. Moreover, heterogeneous catalyst particles may change temperature due to the chemical reactions and gas–solid reactions may cause changes in both particle mass and thermal temperature. In order to develop a model that takes into account the changes in these variables, a population balance modeling strategy similar to the approach of Williams [166] might be employed. Williams [166] developed a statistical model intended to describe the behavior of sprays based on a distribution function that satisfied a Boltzmann type equation which allows for the effects of particle growth and breakage of particles due to attrition. Lathouwers and Bellan [89, 90] adopted a similar modeling strategy for simulations of biomass pyrolysis in fluidized beds. The two- and three-fluid models for reactive systems in fluidized bed reactors developed by Lindborg et al. [97], Wang et al. [160–163] and Chao et al. [19–23] were to a large extent inspired by these investigations. The probable number of particles in the region  $[\mathbf{r}, \mathbf{r} + d\mathbf{r}]$  with velocities in the range  $[\mathbf{c}, \mathbf{c} + d\mathbf{c}]$ , mass in the range  $[m, m + dm]$ , species mass fractions in the ranges  $[\omega_1, \omega_1 + d\omega_1]$ ,  $[\omega_2, \omega_2 + d\omega_2]$ ,  $\dots$ ,  $[\omega_{N_\xi}, \omega_{N_\xi} + d\omega_{N_\xi}]$  and thermal temperature in the range  $[T, T + dT]$  can be expressed as  $f(\mathbf{r}, \mathbf{c}, m, \omega_1, \omega_2, \dots, \omega_{N_\xi}, T, t)$ . The governing Boltzmann type equation becomes:

$$\frac{\partial f}{\partial t} + \mathbf{c}_r \cdot \nabla f + \nabla_c \cdot (\mathbf{F}f) + \frac{\partial(v_m f)}{\partial m} + \frac{\partial(v_T f)}{\partial T} = \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} + J(f) \quad (4.187)$$

where  $v_m = \frac{dm(t)}{dt}$  is the rate of change of particle mass due to chemical reactions or interfacial mass transfer and  $v_T = \frac{dT(t)}{dt}$  is the rate of change of thermal temperature due to chemical reactions, interfacial heat transfer and external heat transfer. The source term,  $J(f)$ , may account for the change in the number of particles due to particle agglomeration and breakage caused by attrition. In the modeling framework of Williams [166] only the particle collision phenomena are included in the source term, whereas the original population balance formulation allows also other phenomena to be considered. However, in most of the current model formulations the source term is disregarded for simplicity even though these phenomena might be significant.

In this framework the mass weighted average of a particle property is defined by:

$$\langle \psi \rangle_M = \frac{1}{\alpha_d \bar{\rho}_d} \int m \psi f d\mathbf{c} d\mathbf{m} d\omega_1 d\omega_2 \cdots d\omega_{N_\xi} dT \quad (4.188)$$

The local bulk density of the dispersed phase is defined as:

$$\alpha_d \bar{\rho}_d = n \bar{m} = \int m f d\mathbf{c} d\mathbf{m} d\omega_1 d\omega_2 \cdots d\omega_{N_\xi} dT \quad (4.189)$$

Following the standard procedure, a Maxwellian type macroscopic transport equation for the granular fluid properties can be obtained by multiplying the Boltzmann type equation (4.187) by  $m\psi$  and integrate over the total phase space performing Maxwellian averaging.

The outcome of this procedure is, in addition to the previously described kinetic theory of granular flow (KTGF) transport equations with the given flux and source closures, characteristic transport equations for species mass and thermal temperature. It is noted that the use of second order velocity moments or higher moments usually requires some kind of manipulation in order to obtain equations in the desired form. The derivation of the thermal temperature equation for reactive systems is certainly not trivial. The application of this theory to reactive systems is extensively discussed in the following two sections.

### 4.3 Bubbling Bed Reactor Simulations Using Two-Fluid Models

In the literature numerous two-fluid models of different complexity have been proposed to predict the fluidized bed reactor cold flow and reactive flow behaviors. Four decades ago emphasis was placed on the modeling of the velocity fluctuation covariance terms in the dispersed particle fluid phase momentum equations. The early one-dimensional models were normally closed by an elasticity modulus parameterization for the particle phase collisional pressure and a constant viscosity parameter for the corresponding shear stresses. Later, with the improved computer memory and speed capacities, multi-dimensional flow models and more advanced model closures were developed based on the kinetic theory of granular flow (KTGF). Moreover, the

development of suitable turbulence models for the gas phase was considered along with the interactions between the granular fluid microscopic particle peculiar velocity and the macroscopic turbulent velocity fluctuations in the continuous phase. In most gas-particle flow situations occurring in fluidized bed reactors, a standard  $k - \epsilon$  turbulence model has been used to describe the turbulence in the continuous phase [33–35, 49, 93, 124, 158].

### 4.3.1 One-Dimensional Reactor Simulations

Two- and three dimensional two-fluid models are yet too computational demanding due to the complexity of the gas–solid flow in the fluidized bed reactors. Moreover, chemical reactions and the handling of large geometries of commercial reactors challenge the presently available computing capacity. In particular, the computations becomes excessively time consuming for the additional consideration of interconnected reactors in a circulating fluidized bed design because the dynamic solid fluxes exchanging between the fluidized bed reactors needs to be incorporated in the numerical solution algorithm. Such simulations are highly relevant and important in the progress of commercial fluidized bed reactors for processes such as the novel SE-SMR technology. A one-dimensional two-fluid model has the advantages of considerable lower computational costs relative to the two- and three dimensional models. Whereas details in the complex gas–solid flow within a fluidized bed reactor; as obtained with the two- and three dimensional models, is lost with a one-dimensional two-fluid model, the cross-sectional averaged two-fluid model presents an improvement over the Kunii-Levenspiel models [85] regarding the important solid fluxes transferred between the reactor units in a interconnected fluidized bed design.

Solsvik and Jakobsen [140] performed a set of one-dimensional two-fluid model simulations in order to elucidate whether such simple models can be suitable for further simulations of two interconnected fluidized bed reactor units with a dynamic solid flux transferred between these reactor units which collectively is denoting a circulating fluidized bed. Dynamic solid circulation between two fluidized bed units that operate at different conditions (e.g., temperatures and feed compositions) is an inherent requirement for the novel SE-SMR technology operated in fluidized bed reactors. A less computational demanding one-dimensional model to study the performance of interconnected reactor units will be an important contribution to the progress of the commercialization of circulating fluidized bed reactors intended for the SE-SMR technology.

#### 4.3.1.1 Chemical Reactions

The kinetic model used for the conventional steam reforming process was taken from Xu and Froment [167]. The reaction takes place on a  $\text{Ni/MgAl}_2\text{O}_4$  catalyst. The kinetics can be described by three equations, where two are independent at

equilibrium:

The rate equations are given by the following equations:

$$R_1^{SMR} = \frac{k_1}{3600 p_{H_2}^{2.5}} \frac{(p_{CH_4} p_{H_2O} - \frac{p_{H_2}^3 p_{CO}}{K_1})}{DEN^2}, \quad \left[ \frac{\text{kmol}}{\text{kg}_{cat} s} \right] \quad (4.193)$$

$$R_2^{SMR} = \frac{k_2}{3600 p_{H_2}} \frac{(p_{CO} p_{H_2O} - \frac{p_{H_2} p_{CO_2}}{K_2})}{DEN^2}, \quad \left[ \frac{\text{kmol}}{\text{kg}_{cat} s} \right] \quad (4.194)$$

$$R_3^{SMR} = \frac{k_3}{3600 p_{H_2}^{3.5}} \frac{(p_{CH_4} p_{H_2O}^2 - \frac{p_{H_2}^4 p_{CO_2}}{K_3})}{DEN^2}, \quad \left[ \frac{\text{kmol}}{\text{kg}_{cat} s} \right] \quad (4.195)$$

where

$$DEN = 1 + K_{CO} p_{CO} + K_{H_2} p_{H_2} + K_{CH_4} p_{CH_4} + K_{H_2O} p_{H_2O} / p_{H_2} \quad (4.196)$$

All equilibrium and kinetic constants are taken from Xu and Froment [167].

In the SE-SMR process, the  $CO_2$  capture reaction by a CaO-based sorbent is presented as:

The rate equation adopted in the simulations for the  $CO_2$  adsorption was taken from [142].

In the study by Solsvik and Jakobsen [140], a one-dimensional two-fluid model describing gas–solid flows with chemical reactions in bubbling bed reactors was derived. The reactor system was modeled in terms of mass, species mass, heat and momentum balances for each of the phases in the Eulerian reference frame. The governing equations describing the reactive flow are presented in the sequent.

Continuity equation for phase  $k$  ( $= g, s$ ):

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \frac{\partial}{\partial z}(\alpha_k \rho_k v_k) = \Gamma_k \quad (4.198)$$

Momentum equation for the continuous gas phase:

**Table 4.2** Constitutive equations for stresses

Viscous stress:

$$\sigma_k = \alpha_k \mu_k \frac{\partial v_k}{\partial z} \quad (4.204)$$

Wall friction stress:

$$\sigma_{k,\text{wall}} = \frac{f_k^f \rho_k v_k v_k}{2} \quad (4.205)$$

$$\frac{\partial}{\partial t}(\alpha_c \rho_c v_c) + \frac{\partial}{\partial z}(\alpha_c \rho_c v_c v_c) = -\alpha_c \frac{\partial p_c}{\partial z} - \frac{4\alpha_c \sigma_{c,\text{wall}}}{d_t} + \frac{\partial \sigma_c}{\partial z} + \alpha_c \rho_c g_z + M_c \quad (4.199)$$

Momentum equation for the dispersed solid phase:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_d \rho_d v_d) + \frac{\partial}{\partial z}(\alpha_d \rho_d v_d v_d) = & -\alpha_d \frac{\partial p_c}{\partial z} - \frac{4\alpha_d \sigma_{d,\text{wall}}}{d_t} \\ & + \frac{\partial \sigma_d}{\partial z} + \alpha_d \rho_d g_z - \frac{\partial}{\partial z}(\alpha_d p_{d,\text{coll}}) + M_d \end{aligned} \quad (4.200)$$

Species mass balances for phase  $k$  ( $= g, s$ ):

$$\frac{\partial}{\partial t}(\alpha_k \rho_k \omega_{k,s}) + \frac{\partial}{\partial z}(\alpha_k \rho_k v_k \omega_{k,s}) = \frac{\partial}{\partial z} \left( \alpha_k \rho_k D_{k,s}^{\text{eff}} \frac{\partial \omega_{k,s}}{\partial z} \right) + M_s R_{k,s} \quad (4.201)$$

Temperature equation for the gas phase:

$$\alpha_c \rho_c C_{p_c} \frac{\partial T_c}{\partial t} + \alpha_c \rho_c C_{p_c} v_c \frac{\partial T_c}{\partial z} = \frac{\partial}{\partial z} \left( \alpha_c k_c^{\text{eff}} \frac{\partial T_c}{\partial z} \right) + \sum_r^{q=3} (-\Delta H_{R_s}^{\text{SMR}}) R_s^{\text{SMR}} + Q_{cd}^s \quad (4.202)$$

Temperature equation for the solid phase:

$$\alpha_d \rho_d C_{p_d} \frac{\partial T_d}{\partial t} + \alpha_d \rho_d C_{p_d} v_d \frac{\partial T_d}{\partial z} = \frac{\partial}{\partial z} \left( \alpha_d k_d^{\text{eff}} \frac{\partial T_d}{\partial z} \right) + (-\Delta H_{R_{CO_2}}^{\text{ads}}) R_{CO_2}^{\text{ads}} - Q_{cd}^s \quad (4.203)$$

In order to close the two-fluid model, constitutive equations are required for: (i) stresses (Table 4.2), (ii) internal heat transfer (Table 4.3), (iii) internal mass transfer (Table 4.4), (iv) interfacial heat transfer (Table 4.5), (v) interfacial momentum transfer (Table 4.6), and (vi) solid phase collision pressure (Table 4.7). To solve the mathematical model, the finite volume discretization technique was employed.

The model has been adopted to simulate the SMR process and the novel SE-SMR technology operated in bubbling fluidized bed reactors. The reactor operation conditions and numerical parameters used in the simulations are presented in Table 4.8. Initially, approximate minimum fluidization conditions is specified for the bubbling fluidized bed reactor. The gas phase velocity at the reactor entrance is gradually

**Table 4.3** Constitutive equations for internal heat transfer

Effective conductivity:

$$k_k^{\text{eff}} = \left[ k_k^m + \frac{\mu_k^t}{\rho_k \text{Pr}^t} \right] C_k \quad (4.206)$$

Thermal conductivity [13, 61]:

$$k_c^m = \frac{k_c^{\text{stat}}}{\alpha_c} (1 - \sqrt{\alpha_d}) \quad (4.207)$$

$$k_d^m = \frac{k_c^{\text{stat}}}{\sqrt{\alpha_d}} (\phi A + (1 - \phi) \Lambda) \quad (4.208)$$

$$\Lambda = \frac{2}{1-B/A} \left[ \frac{A-1}{(1-B/A)^2} \frac{B}{A} \ln \frac{A}{B} - \frac{B-1}{1-B/A} - \frac{1}{2} (B+1) \right] \quad (4.209)$$

$$A = \frac{k_d^{\text{stat}}}{k_c^{\text{stat}}} \quad (4.210)$$

$$k_c^{\text{stat}} = \sum_j y_j (\mathcal{A}_j + \mathcal{B}_j T + \mathcal{C}_j T^2 + \mathcal{D}_j T^3) \quad (4.211)$$

$$B = 1.25 \left( \frac{\alpha_d}{\alpha_c} \right)^{10/9} \quad (4.212)$$

$$\phi = 7.26 \cdot 10^{-3} \quad (4.213)$$

**Table 4.4** Constitutive equations for internal mass transfer

Effective gas phase diffusivity:

$$D_{g,s}^{\text{eff}} = \left[ D_{g,s}^m + \frac{\mu_g^t}{\rho_g \text{Sc}^t} \right] C_{\text{Diff}} \quad (4.214)$$

Molecular diffusion coefficient [165]:

$$D_{g,s}^m = \frac{1 - \omega_{g,d}}{M_{\omega_g}} \frac{1}{\sum_{\substack{r=1 \\ r \neq s}}^n \frac{\omega_{g,r}}{M_{\omega_r} D_{sr}}} \quad (4.215)$$

Binary diffusion coefficient [44]:

$$D_{sr} = \frac{0.00266 \cdot 101325 T_g^{3/2}}{0.01^2 p \Omega_{sr} \Sigma_{sr}^2 M_{\omega_{sr}}^{1/2}} \quad (4.216)$$

**Table 4.5** Constitutive equations for interfacial heat transfer

Interfacial heat transfer:

$$Q_{cd}^i = \frac{6\alpha_d}{d_p} h_{cd} (T_d - T_c) \quad (4.217)$$

Interfacial heat transfer coefficient (spherical particles):

$$h_{cd} = \frac{k_c}{d_p} \left[ (7 - 10\alpha_c + 5\alpha_c^2)(1 + 0.7\text{Re}_p^{0.2}\text{Pr}^{1/3}) + (1.33 - 2.4\alpha_c + 1.2\alpha_c^2)\text{Re}_p^{0.7}\text{Pr}^{1/3} \right] \quad (4.218)$$

Particle Reynolds number:

$$\text{Re}_p = \frac{\alpha_c \rho_c |v_d - v_c| d_p}{\mu_c} \quad (4.219)$$

Prandtl number:

$$\text{Pr} = \frac{\mu_c C_{p_c}}{k_c} \quad (4.220)$$

**Table 4.6** Constitutive equations for interfacial momentum transfer

Interfacial drag force:

$$M_c = -M_d = \beta(v_d - v_c) \quad (4.221)$$

The following constitutive equation for the inter-phase drag coefficient,  $\beta$ , was taken from [49]:

$$\beta = (1 - w) \left( a \frac{\alpha_d^2 \mu_c^m}{\alpha_c d_p} + b \frac{\rho_c |v_c - v_d| \alpha_d}{d_p} \right) + w \left( \frac{3}{4} \frac{C_D |v_c - v_d| \rho_c \alpha_d \alpha_c^{-2.65}}{d_p} \right) \quad (4.222)$$

with  $a = 150$  and  $b = 1.75$ .

The values of the parameters in the underlying correlations were approximated by:

$$Re_p = \frac{(1 - \alpha_s) \rho_g |u_g - u_s| d_p}{\mu_g^m} \quad (4.223)$$

$$w = \frac{\text{atan}(150(\alpha_g - 1))}{\pi} + 0.5 \quad (4.224)$$

$$C_D = \begin{cases} \frac{24(1+0.15Re_p^{0.687})}{Re_p} & Re_p < 1000 \\ 0.44 & Re_p \geq 1000 \end{cases} \quad (4.224)$$

The weight  $w$  defined by (4.224) denotes an interpolation between the Ergun equation and the Wen and Yu [164] drag closure.

**Table 4.7** Constitutive equations for solid phase collisional pressure

Solid phase collisional pressure in terms of the modulus of elasticity:

$$\frac{\partial}{\partial z} (\alpha_d p_d^{\text{coll}}) = G(\alpha_c) \frac{\partial \alpha_d}{\partial z} \quad (4.226)$$

with  $G(\alpha_c)$  given as:

$$G(\alpha_c) = 10^{-10.46\alpha_c + 6.557} [Pa] \quad (4.227)$$

increased to the final operating velocity. Due to initial violent dynamics, the velocity increase is controlled. Chemical reactions are introduced when the bed is fluidized at the operating conditions. The mass fraction of  $CH_4$  in the reactor feed is gradually increased in order to avoid numerical problems due to rapidly introduced large gradients caused by the change in the chemical composition and reaction heat. The phasic velocities, area phase fractions, temperatures and species mass fractions were specified at the reactor entrance. Moreover, gradients at the reactor outlet were assumed equal to zero. The gas phase pressure was given at the reactor outlet. Table 4.8 holds the boundary condition values applied.

The suggested dynamic one-dimensional Eulerian–Eulerian two-fluid model was applied to investigate the reactive gas–solid flows of the SMR and SE-SMR processes; and moreover, the simulation results were compared with the results of the more complex two-dimensional model with a solid stress closure based on kinetic theory of granular flow. The one-dimensional model predictions of the chemical process performance are in good agreement with the corresponding profiles predicted with the two-dimensional model. The deviations are larger comparing the internal flow details but these do not owe significant impact on the chemical process which to a large extent is determined by the imposed temperature in the reactor. Adopting the reactor operating conditions, bed size and numerical parameters as specified by Table 4.8,

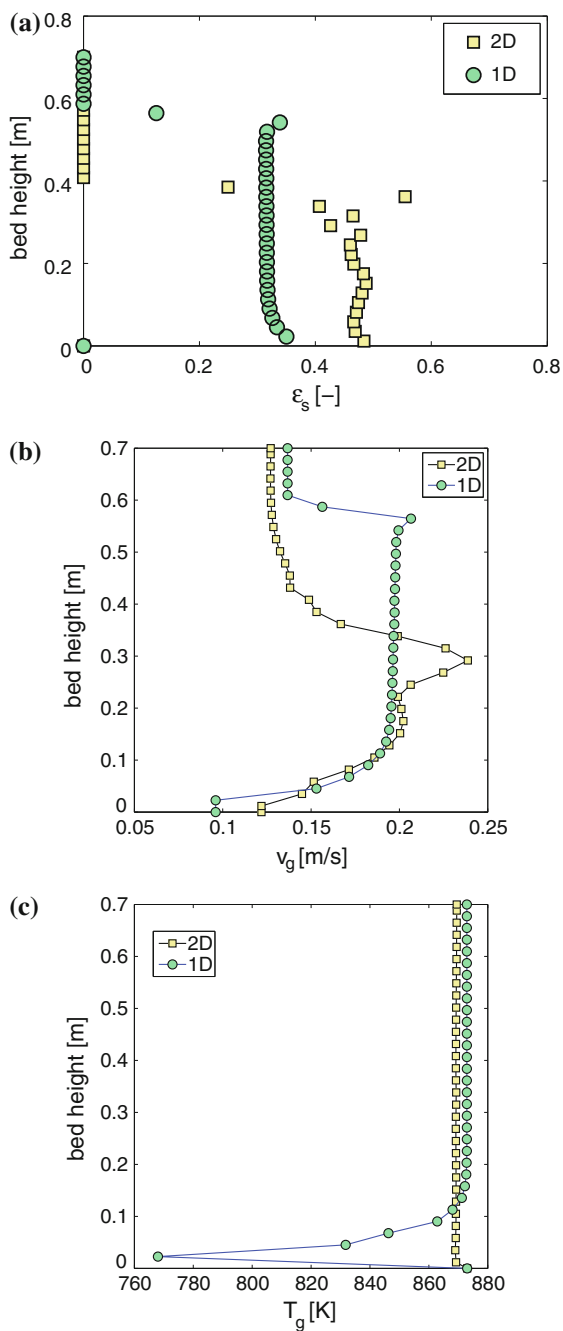

Figs. 4.2, 4.3, 4.4, 4.5 present the comparison between the one- and two-dimensional model simulation results after 40 s of simulation. Considering the SMR process, the one-dimensional model predicts a larger bed expansion than obtained with the two-dimensional model; Fig. 4.2a. In Fig. 4.2b, the gas phase velocity compared fairly well comparing the results of the two model approaches in the lower part of the reactor bed, but differences were observed in the upper part due to the relatively larger bed expansion of the one-dimensional model. Further, a significant temperature drop at the reactor entrance was obtained with the one-dimensional model, whereas the simulation results of the two-dimensional model gives a uniform temperature; Fig. 4.2c. On the other hand, Fig. 4.3 showed that the species composition compared well between the two model solutions. Adopting the one-dimensional model for simulation of the SE-SMR process, only small differences were observed in the phase fraction and gas phase velocity predictions relative to that obtained in the simulation of the SMR process, i.e., Figs. 4.4a and 4.4b versus Fig. 4.2a and 4.2b, respectively. On the other hand, relatively large differences were obtained for the  $\alpha_d$  and  $v_c$  profiles simulating the SMR and SE-SMR processes with the two-dimensional model. Adopting the one-dimensional model, a smaller temperature drop is observed in the temperature prediction within the SE-SMR reactor bed; Fig. 4.4c, relative to

that of the temperature prediction of the SMR process; Fig. 4.2c. This observation is due to the heat generated in the reaction between  $\text{CO}_2$  and the solid sorbent. In contradiction to the two-dimensional model result, the temperature drop obtained with the one-dimensional model was concentrated at the reactor entrance and thus relatively larger.

The relative differences in the flow, i.e.,  $\alpha_d$  and  $v_c$  variables in Figs. 4.2a, b for the SMR process and 4.4 a, b for the SE-SMR process, were related to the  $\text{CO}_2$  capture, that is, mass of  $\text{CO}_2$  was removed from the gas phase into the solid phase where  $\text{CO}_2$  was chemical bounded to the sorbent in accordance to reaction (4.197). However, due to the effect of mixing the reformer catalyst with the sorbent, had a larger effect on the simulation results of the two-dimensional model than on the results obtained with the one-dimensional model. The two-dimensional representations in Figs. 4.6 and 4.7 reveal the significant differences in the flow, i.e.,  $\alpha_d$  and  $v_c$ , between the SMR and SE-SMR process. The relatively larger two-dimensional mixing effect observed in the reactor bed for the SMR process compared to the SE-SMR process, reveal the reason for the temperature variations in the SE-SMR process; Fig. 4.4c, relative to the homogeneous temperature profile obtained in the SMR process; Fig. 4.2c. Moreover, the one-dimensional model did obtain relatively larger temperature drops in the reactor bed compared to the two-dimensional model; Figs. 4.2c and 4.4c, due to the lack of the radial convective flow pattern as captured by the two-dimensional model; Figs. 4.6 and 4.7.

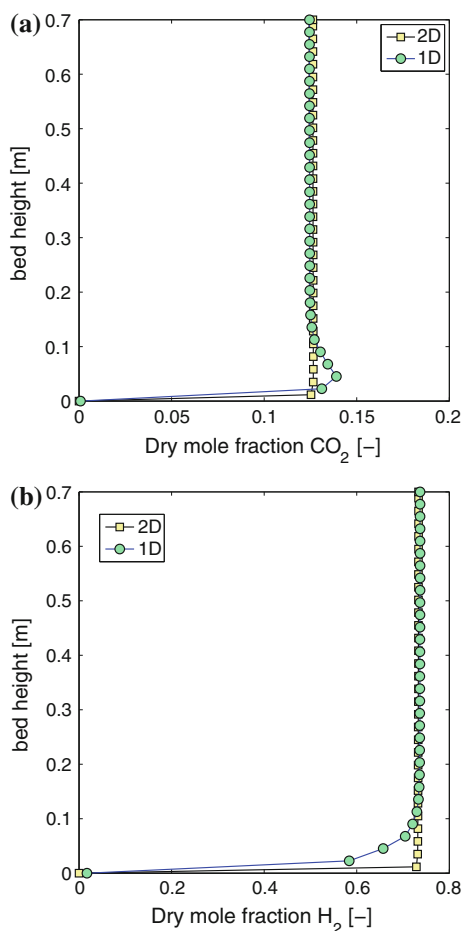

The 40 s of simulations of the SMR and SE-SMR processes by the two-dimensional two-fluid model implemented in FORTRAN, took 3–4 days on a super-computer, whereas the corresponding one-dimensional simulation results were completed within 5–6 h on a standard personal computer using the programming language MATLAB. The programming language MATLAB was used for the simulation of the one-dimensional model due to the convenient debugging and graphical properties. Translating the MATLAB language into, e.g., FORTRAN may further reduce the computational time which is of particular interests when the model is extended from a stand alone fluidized bed to a part of a circulating fluidized bed design with interconnected solid fluxes transferred between the reformer and re-generator units.

The simulation results of the one-dimensional model were found to be in fair agreement with the two-dimensional model considering the chemical conversion of the reactor, as is also utilized by the Kunii-Levenspiel type of models [85]. Moreover, with extended conductive fluxes, fair temperature profiles can be predicted with the one-dimensional model. On the other hand, the flow pattern, i.e., the phasic fractions and gas phase velocity, were associated with the largest uncertainty in the current model. However, the internal flow details did not have significant influence on the chemical process performance. Thus, the current one-dimensional model was considered to have good potentials for further CFB model developments in order to study interconnected fluidized bed reactors with a dynamic solid flux transferred between the reactor units.

### 4.3.2 Two-Dimensional Two-fluid model for Cold Flow Analysis

The bubbling bed cold flow analysis performed by Lindborg [97] and Lindborg et al. [96] is assessed in this section. Cold flow analysis basically consist in performing a set of simulations to study the non-reactive and isothermal flow phenomena in a reactor vessel designed for operation of reactive non-isothermal processes. To carry out cold flow analysis of a dense bubbling bed reactor unit, the governing equations used by Lindborg et al. [96, 97] resemble the dilute continuum mechanical model derived in Sect. 3.4.3. However, the solid phase momentum equation did contain several additional terms derived from kinetic theory and a frictional stress closure for slow quasi-static flow conditions based on concepts developed in soil mechanics.

Moreover, to close the kinetic theory model the granular temperature was calculated from a separate transport equation. Furthermore, the gas phase turbulence was described by use of a  $k-\varepsilon$  turbulence model. This model version is often referred to as a *two-fluid model with a KTGF closure* as discussed earlier in this chapter. However, since the KTGF closure equations are computationally demanding, Lindborg [97] did evaluate the performance of an early and mathematically simpler two-fluid model closure that was developed to account for roughly the same effective solid pressure and viscous stresses that are inherently considered in the KTGF closure. On the other hand, the early two-fluid models were closed by a semi-empirical elasticity modulus parameterization for the particle phase collisional pressure and a constant representative viscosity parameter for the corresponding shear stresses. To avoid misconception, the set of model equations used are given below (in which the averaging symbols are disregarded for convenience).

#### 4.3.2.1 Two-Fluid Model with KTGF Closure and Gas Turbulence Model

The *continuity equation* for phase  $k$  ( $= c, d$ ) was given as:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k) = 0 \quad (4.228)$$

The *momentum equation for the gas phase* was expressed as:

$$\frac{\partial}{\partial t}(\alpha_c \rho_c \mathbf{v}_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c \mathbf{v}_c) = -\alpha_c \nabla p_c - \nabla \cdot (\alpha_c \boldsymbol{\sigma}_c) + \alpha_c \rho_c \mathbf{g} + \mathbf{M}_c \quad (4.229)$$

The single phase viscous stress tensor (1.77), in which the bulk viscosity of the continuous gas was set to zero, is used:

$$\boldsymbol{\sigma}_c = -2\mu_c \mathbf{S}_c = -\mu_c \left( \nabla \mathbf{v}_c + (\nabla \mathbf{v}_c)^T - \frac{2}{3}(\nabla \cdot \mathbf{v}_c) \mathbf{e} \right) \quad (4.230)$$

The interfacial momentum transfer term is approximated by the steady drag:

$$\mathbf{M}_c = -\mathbf{M}_d = -\mathbf{F}_{D,d} = \beta(\mathbf{v}_d - \mathbf{v}_c) \quad (4.231)$$

in which the drag force coefficient used was taken from Gibilaro et al. [47].

From (D.17) and (D.18) a derived coefficient was defined by:

$$\beta = \left( \frac{17.3}{Re_p} + 0.336 \right) \frac{\rho_c |\mathbf{v}_d - \mathbf{v}_c|}{d_p} \alpha_d \alpha_c^{-1.8} \quad (4.232)$$

The  $k_c$ - $\varepsilon_c$  turbulence model for the gas phase was expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c k_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c k_c) = & \nabla \cdot \left( \alpha_c \frac{\mu_c^t}{\sigma_{k_c}} \nabla k_c \right) \\ & + \alpha_c \left( \boldsymbol{\sigma}_c^{\text{Re}} : \nabla \mathbf{v}_c + S_{k_c} \right) - \alpha_c \rho_c \varepsilon_c \end{aligned} \quad (4.233)$$

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c \varepsilon_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c \varepsilon_c) = & \nabla \cdot \left( \alpha_c \frac{\mu_c^t}{\sigma_{\varepsilon_c}} \nabla \varepsilon_c \right) \\ & + \alpha_c C_1 \frac{\varepsilon_c}{k_c} \left( \boldsymbol{\sigma}_c^{\text{Re}} : \nabla \mathbf{v}_c + S_{k_c} \right) - \alpha_c \rho_c C_2 \frac{\varepsilon_c^2}{k_c} \end{aligned} \quad (4.234)$$

The turbulent viscosity is defined as:

$$\mu_c^t = \rho_c C_\mu \frac{k_c^2}{\varepsilon_c} \quad (4.235)$$

The turbulent kinetic energy production due to the movement of the dispersed particles, is approximated as:

$$S_{k_c} = C_p \beta (\mathbf{v}_d - \mathbf{v}_c)^2 \quad (4.236)$$

The Reynolds average covariance term denoting a turbulent stress tensor was modeled using the gradient- and Boussinesq hypotheses:

**Table 4.9** Conventional values of the empirical parameters in the  $k_c$ - $\varepsilon_c$  model

| $C_\mu$ | $\sigma_{k_c}$ | $\sigma_{\varepsilon_c}$ | $C_1$ | $C_2$ | $C_p$ |
|---------|----------------|--------------------------|-------|-------|-------|
| 0.09    | 1.00           | 1.30                     | 1.44  | 1.92  | 0.25  |

$$\sigma_c^{\text{Re}} = -\frac{2}{3}\rho_c k_c \mathbf{e} + 2\mu_c^t \left( \frac{1}{2} \left[ \nabla \mathbf{v}_c + (\nabla \mathbf{v}_c)^T \right] - \frac{1}{3} \nabla \cdot \mathbf{v}_c \mathbf{e} \right) \quad (4.237)$$

The values used for the empirical parameters in the  $k_c$ - $\varepsilon_c$  turbulence model used for the continuous gas phase flow are given in Table 4.9.

The *momentum equation for the solid phase* was written as:

$$\frac{\partial}{\partial t}(\alpha_d \rho_d \mathbf{v}_d) + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \mathbf{v}_d) = -\alpha_d \nabla p_c - \nabla \cdot \mathbf{p}_d + \alpha_d \rho_d \mathbf{g} + \mathbf{M}_d \quad (4.238)$$

The total pressure tensor is expressed in terms of Newton's viscosity law (1.77):

$$\mathbf{p}_d = - \left( -p_d + \alpha_d \mu_{B,d} \nabla \cdot \mathbf{v}_d \right) \mathbf{e} - 2\alpha_d \mu_d \mathbf{S}_d \quad (4.239)$$

The strain tensor was defined in accordance with (4.159):

$$\mathbf{S}_d = \frac{1}{2} \left( \nabla \mathbf{v}_d + (\nabla \mathbf{v}_d)^T - \frac{2}{3} (\nabla \cdot \mathbf{v}_d) \mathbf{e} \right) \quad (4.159)$$

For dense flows at low shear rates the total solid phase kinetic and collisional pressure tensor closure derived from kinetic theory was extended by an semi-empirical frictional pressure tensor in order to consider the impact of the long term particle-particle interactions such as sliding or rolling contacts. The dispersed phase pressure was thus calculated from (4.151), closed with (4.158) and (4.155):

$$\begin{aligned} p_d &= p_d^{\text{kin}} + p_d^{\text{coll}} + p_d^{\text{fric}} \\ &= \alpha_d \rho_d \Theta_d [1 + 2(1 - e)\alpha_d g_0] + p_d^{\text{fric}} \end{aligned} \quad (4.240)$$

The corresponding viscous stresses were computed with the total viscosity computed from (4.152):

$$\begin{aligned} \mu_d &= \mu_d^{\text{kin}} + \mu_d^{\text{coll}} + \mu_d^{\text{fric}} \\ &= \frac{2\mu_d^{\text{dilute}}}{\alpha_d g_0 (1 + e)} \left[ 1 + \frac{4}{5} \alpha_d g_0 (1 + e) \right]^2 + \frac{4}{5} \alpha_d \rho_d g_0 (1 + e) \sqrt{\frac{\Theta_d}{\pi}} + \mu_d^{\text{fric}} \end{aligned} \quad (4.152)$$

The solids frictional pressure (4.155) and viscosity (4.156) were approximated as:

$$p_d^{\text{fric}} \approx \begin{cases} \zeta \frac{(\alpha_d - \alpha_d^{\min})^r}{(\alpha_d^{\max} - \alpha_d)^s} & \text{if } \alpha_d > \alpha_d^{\min} \\ 0 & \text{if } \alpha_d \leq \alpha_d^{\min} \end{cases} \quad (4.241)$$

$$\mu_d^{\text{fric}} \approx \frac{p_d^{\text{fric}} \sqrt{2} \sin \phi}{2\alpha_d \sqrt{\mathbf{S}_d : \mathbf{S}_d + \Theta_d/d_p^2}} \quad (4.242)$$

The parameters adopted in the work of Lindborg et al. [96] were taken from Ocone et al. [112]. The parameter values used are given in Table 4.1.

The solid phase bulk viscosity was calculated from:

$$\mu_{B,d} = \frac{4}{3} \alpha_d \rho_d d_p g_0 (1 + e) \sqrt{\frac{\Theta_d}{\pi}} \quad (4.146)$$

The dilute particle viscosity was calculated from:

$$\mu_d^{\text{dilute}} = \frac{5}{96} \rho_d d_p \sqrt{\pi \Theta_d} \quad (4.113)$$

The radial distribution function was approximated from an empirical relation given by [104]:

$$g_0 = \frac{1 + 2.5\alpha_d + 4.5904\alpha_d^2 + 4.515439\alpha_d^3}{\left[1 - \left(\frac{\alpha_d}{\alpha_d^{\max}}\right)^3\right]^{0.67802}} \quad (4.243)$$

The *granular temperature equation for the particle phase* was written as:

$$\begin{aligned} \frac{3}{2} \frac{\partial}{\partial t} (\alpha_d \rho_d \Theta_d) + \frac{3}{2} \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \Theta_d) = & - (\mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}} + \mathbf{p}_d^{\text{fric}}) : \nabla \mathbf{v}_d \\ & - \nabla \cdot (-\alpha_d \kappa_d \nabla \theta_d) - 3\beta \Theta_d + \beta \langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle \\ & - \gamma_d \end{aligned} \quad (4.244)$$

The total heat flux was modeled in accordance with (4.175). Hence, the conductivity of the granular temperature was calculated from [49]:

$$\begin{aligned} \alpha_d \kappa_d = & \alpha_d (\kappa_d^{\text{kin}} + \kappa_d^{\text{coll}}) \\ = & \frac{15}{2} \frac{\mu_d^{\text{dilute}}}{(1 + e) g_0} \left[ 1 + \frac{6}{5} \alpha_d g_0 (1 + e) \right]^2 + 2\alpha_d^2 \rho_d d_p g_0 (1 + e) \sqrt{\frac{\Theta_d}{\pi}} \end{aligned} \quad (4.176)$$

The collisional energy dissipation term, as derived by [68], was given by;

$$\gamma_d = 3(1 - e^2) \alpha_d^2 \rho_d g_0 \Theta_d \left[ \frac{4}{d_p} \sqrt{\frac{\Theta_d}{\pi}} - \nabla \cdot \mathbf{v}_d \right] \quad (4.179)$$

The term  $\beta \langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle$  in the granular temperature equation is normally neglected due to a general lack of understanding of the physics represented by this term [30, 49]. Nevertheless, a few attempts to model this term have been proposed in the literature. Lindborg et al. [96] performed numerous simulations to study the influence of these phenomena as represented by the closure proposed by [82]. Koch [81] proposed a closure for these gas-particle interactions for dilute suspensions. In this modeling approach, the gas-particle velocity covariance term was considered a production term in the granular temperature equation. Moreover, the covariance term was interpreted as a mechanism that breaks a homogeneous fluidized bed flow regime with no shearing motion into a non-homogeneous shear flow. Koch and Sagani [82] extended the closure of Koch [81] accounting for the dense suspensions effects.

The given closure was expressed in terms of the particle relaxation time for Stokes flow,  $\tau_{cd} = \rho_d d_p^2 / 18 \mu_c$ , as:

$$\beta \langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle = \frac{\alpha_d \rho_d d_p |\mathbf{v}_d - \mathbf{v}_c|^2 R_s \zeta^2}{4 \tau_{cd}^2 \sqrt{\pi \theta_d}} \quad (4.245)$$

where  $R_s$  represents the energy source due to a specified mean force acting on the particles. An expression for  $R_s$  was obtained by a fit of the parameters in following function to lattice-Boltzmann simulation data:

$$R_s = \frac{1}{g_0 (1 + 3.5 \sqrt{\alpha_d} + 5.9 \alpha_d)} \quad (4.246)$$

Lindborg et al. [96] manipulated the  $\beta \langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle$  closure proposed by Koch and Sagani [82]. By use of the  $\zeta$  definition of Benyahia et al. [11] that relates  $\zeta$  and  $\beta$ , the  $\beta \langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle$  closure was expressed as a function of the drag or friction coefficient,  $\beta$ , instead of the dimensionless drag coefficient  $\zeta$  [96]:

$$\beta \langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle = \frac{\beta^2 d_p |\mathbf{v}_d - \mathbf{v}_c|^2 R_s}{4 \alpha_c^4 \alpha_d \rho_d \sqrt{\pi \theta_d}} \quad (4.247)$$

The *species mass balance* for the continuous phase tracer was written as:

$$\frac{\partial}{\partial t} (\alpha_c \rho_c \omega_{c,s}) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c \omega_{c,s}) = \nabla \cdot \left( \alpha_c \rho_c D_{c,s}^{\text{eff}} \nabla \omega_{c,s} \right) \quad (4.248)$$

in which  $D_{c,s}^{\text{eff}}$  represents the effective mass diffusion coefficient of species  $s$  in phase  $c$ . This parameter is usually approximated by:  $D_{c,s}^{\text{eff}} = D_{c,s}^m + D_c^t$ , where the molecular diffusivity,  $D_{c,s}^m$ , is determined from a semi-empirical relation and the turbulent diffusivity  $D_{c,s}^t$  from a turbulence model invoking a Reynolds analogy.

### 4.3.2.2 Initial and Boundary Conditions

Initially, there was no gas flow through the reactor, and the true volume fraction of solids in the bed was about that of maximum packing. However, Lindborg et al. [96] adopted the customary approach of specifying the initial conditions in accordance with the state of a bubbling bed operating at minimum fluidization conditions. The bed height at minimum fluidization conditions was thus set to an estimated value  $L_{mf}$ , and the gas volume fraction was set to  $\alpha^{mf}$  at the bed levels below  $L_{mf}$  and unity in the freeboard. The pressure profile in the bed was initialized using the Ergun [39] equation, whereas the pressure in the freeboard was set to the operational pressure at the outlet. The horizontal velocity components of both phases and the vertical particle velocity component were set to zero. The vertical interstitial gas velocity in the bed was initiated as  $U_{in}^s/\alpha^{mf}$ , and  $U_{mf}^s$  in the freeboard.

The gas density was either initiated by a fixed value or calculated by use of the ideal gas law requiring that the gas pressure, species composition and temperature are known. When turbulence is considered,  $k_c^{eff}$ ,  $k_d^{eff}$  and  $\epsilon_c$  are frequently set to small but non-zero values. Typical levels of the turbulent kinetic energy and the dissipation rate were about  $10^{-5} \text{ (m}^2 \text{ s}^{-2}\text{)}$  and  $10^{-5} \text{ (m}^2 \text{ s}^{-3}\text{)}$ , respectively. The granular temperature was set at about  $10^{-5} \text{ (m}^2 \text{ s}^{-2}\text{)}$ . To obtain an asymmetrical flow, as observed for real cases, particular flow perturbations were generally introduced for a short time period as the flow develops in time from the start. Heterogeneity was introduced by tilting the gravity vector by 1 % the first second if axi-symmetry was not assumed. The governing equations are elliptic so boundary conditions are required at all boundaries. The normal velocity components for both phases were set to zero at the vertical boundaries. The wall boundary conditions for the vertical velocity component,  $k_c$  and  $\epsilon_c$  were specified in accordance with the standard wall function approach. The particle phase was allowed to slip along the wall following the boundary condition given by (4.180). Uniform flow was assumed at inlet. The gas pressure was set at outlet. The particles were not allowed to leave the reactor. For the scalar variables, except pressure, Dirichlet boundary conditions were used at inlet, whereas Neumann conditions were employed at the other boundaries [96]. During start up the system was very unstable. To simplify the conditions in the reactor, reactants were gradually introduced after 5 s of cold flow simulation to avoid large variations of density in the gas phase.

### 4.3.2.3 Two-Dimensional Cold Flow Simulations with Elasticity Modulus

In a bubbling bed cold flow assessment performed by Lindborg [97], the two-fluid model employed was closed by a semi-empirical elasticity modulus parameterization for the particle phase collisional pressure and a constant representative viscosity

for the corresponding shear stresses.<sup>3</sup> The continuous phase was closed by a  $k_c$ - $\varepsilon_c$  turbulence model.

Starting out from the governing two-fluid model equations with the KTGF closure, as defined earlier by (4.228)–(4.248), several model simplifications were imposed. First, the particle phase collisional pressure gradient was approximated by a semi-empirical elasticity modulus parameterization on the form:

$$\nabla p_d \approx \nabla p_d^{\text{coll}} \approx -G(\alpha_c) \nabla \alpha_c \quad (4.249)$$

The elasticity modulus parameterization by Ettehadieh et al. [40] was employed:

$$G(\alpha_c) = -10^{-10.46\alpha_c + 6.577} \quad (\text{Nm}^{-2}) \quad (4.250)$$

This particle pressure gradient closure invokes a second approximation:

$$p_d \approx p_d^{\text{coll}} \quad (4.240)$$

Third, the total viscosity relation (4.152) is approximated by a representative constant value:

$$\mu_d \approx 1.0 \text{ kg/ms} \quad (4.251)$$

This parameter value is used in the strain tensor (4.159). Fourth, the total pressure tensor (4.239) was further simplified as the bulk viscosity (4.146) was set to zero. Fifth, it follows that with this pressure tensor closure the granular temperature variable was not used, thus (4.244) was not solved.

The resulting two-fluid model was used to simulate the bed behavior in the cylindrical vessel investigated experimentally by Lin et al. [95]. A particular set of cold flow simulations were run with the physical properties and model parameters presented in Table 4.10. It was concluded that the two-fluid model closed with the elasticity modulus and a constant viscosity parameter was not able to reproduce the experimentally determined flow pattern, as is easily recognized by comparing Figs. 4.8 and 10.8. The flow patterns predicted were in many ways opposite to the measured ones. The simulations may give an upward flow in the center region of the tube and downwards close to the wall, whereas the measured data for the same case shows that the flow should be downwards in the center and upwards close to the wall and visa versa. Nevertheless, by increasing the particle phase viscosity artificially by a factor of about 5 the simulated flow patterns coincide much better with the observed ones. The deviation between the simulated and measured flow patterns may thus be explained by the two-fluid model limitations caused by the rough elasticity modulus and in particular the viscous stress closures. However, the influence of the

---

<sup>3</sup> This two-fluid model closure consisting of an elasticity modulus and a constant granular fluid viscosity, as used by Lindborg et al. [96, 97], corresponds to the CPV model concept defined in App D.

**Table 4.10** Physical properties and model parameters [96] (case 1)

|                         |                                                     | Cold flow simulations |
|-------------------------|-----------------------------------------------------|-----------------------|
| $p_c^{\text{out}}$      | Outlet pressure (bar)                               | 1.0                   |
| $\rho_c$                | Gas density (kg/m <sup>3</sup> )                    | 1.21                  |
| $\mu_c$                 | Gas viscosity (kg/ms <sup>3</sup> )                 | $1.8 \times 10^{-5}$  |
| $\rho_d$                | Particle density (kg/m <sup>3</sup> )               | 2500                  |
| $d_p$                   | Particle diameter ( $\mu\text{m}$ )                 | 500                   |
| $e$                     | Restitution coefficient                             | 0.997                 |
| $\alpha_d^{\text{max}}$ | Maximum particle packing                            | 0.62                  |
| $\alpha_d^{\text{mf}}$  | Particle volume fraction<br>at minimum fluidization | 0.58                  |
| $v_c^{\text{mf}}$       | Minimum fluidization velocity (m/s)                 | 0.19                  |
| $H^{\text{mf}}$         | Bed height at minimum fluidization (m)              | 0.113                 |
| $H$                     | height of reactor (m)                               | 0.3164                |
| $D$                     | Reactor diameter (m)                                | 0.1380                |
| $\Delta r$              | Lateral resolution (mm)                             | 3.450                 |
| $\Delta z$              | Axial resolution (mm)                               | 2.825                 |

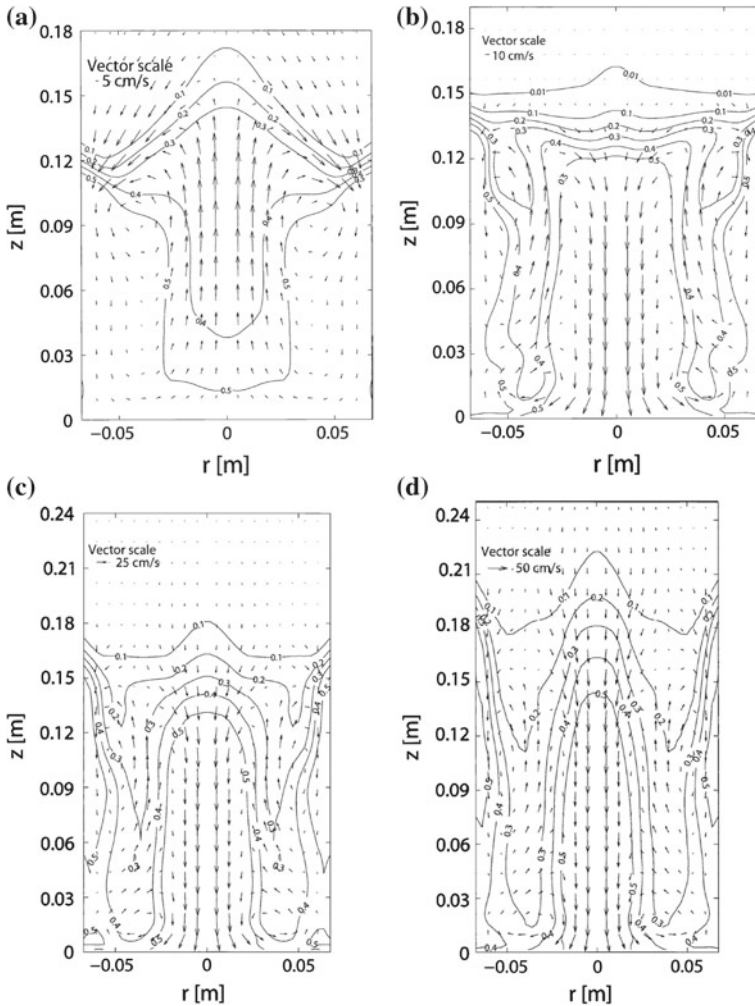

axi-symmetry boundary condition applied in the two-dimensional flow simulations was strictly not verified.

**4.3.2.4 Two-Dimensional Cold Flow Simulations with KTGF Closure**

In a bubbling bed cold flow assessment performed by Lindborg et al. [96] and Lindborg [97], the two-fluid model employed was closed by a KTGF closure for the particle phase sources and fluxes and a  $k_c\text{-}\varepsilon_c$  turbulence model for the continuous phase turbulent Reynolds stresses. Moreover, the turbulent fluxes in the continuous phase heat- and species mass balances were closed invoking a Reynolds analogy for turbulent flows. The resulting governing two-fluid model equations used were defined earlier by (4.228)–(4.248).

By comparing experimental tracer data with the model predictions of the tracer gas mixing, Lindborg et al. [96] did conclude that the gas phase turbulence, as described by the  $k_c\text{-}\varepsilon_c$  turbulence model, is important considering the species mixing within the gas phase. Numerous simulations were also conducted to investigate the effect of gas turbulence on the bubbling bed behavior. The implementation of the turbulence model had no significant effect on neither the particle motion nor the bed expansion. Moreover, using the (4.247) closure, the simulations performed by Lindborg et al. [96] confirmed that the  $\beta\langle \mathbf{v}'_c \cdot \mathbf{C}_d \rangle$  term in the granular temperature equation has no significant effect on the solution and can be neglected. Simulating the Lin et al. [95] data sets by use of the two-fluid model with the KTGF closure, Lindborg [97] and Lindborg et al. [96] obtained good predictions of the flow as shown comparing the measured flow patterns Fig. 10.8 and the predicted ones Fig.4.9. The gas bubbles

**Fig. 4.8** Particle circulation patterns at various fluidizing velocities for a gas fluidized bed consisting of 0.42–0.6 (mm) diameter glass beads [95]. Simulated flow patterns obtained with the CPV model of Lindborg [97]. **a**  $U_{in}^s = 32$  (cm/s) and  $U_{in}^s/U_{mf}^s = 1.65$ , **b**  $U_{in}^s = 45.8$  (cm/s) and  $U_{in}^s/U_{mf}^s = 2.36$ , **c**  $U_{in}^s = 64.1$  (cm/s) and  $U_{in}^s/U_{mf}^s = 3.31$ , **d**  $U_{in}^s = 89.2$  (cm/s) and  $U_{in}^s/U_{mf}^s = 4.6$

generally form close to the gas distributor near the wall, and migrate towards the center as they rise. On their way up through the bed they withdraw particles into the wake and thereby create a gulf streaming circulation where the bubbles create a net up-flow of solids in the low density regions and a down-flow of solids in the dense regions. On average, at the lowest gas flow rate, descending particles are observed at the center of the vessel while ascending closer to the wall (case (a)). With increasing gas flow rate the center-directed bubble migration is more pronounced, hence the

solids circulation pattern gradually turns so that particles eventually ascend at the center and descend near the wall (cases (b)–(d)). Although the transition between the two main circulation patterns are not perfectly predicted, the particle motion dependence on the superficial gas velocity is captured very well since both the particle velocity magnitudes and circulation patterns coincide with the experimental data. In addition to the gas and solid motion in the bubbling bed, the bed expansion estimated from the same data corresponds quite well with the simulations. Moreover, the simulated mean bubble size and bubble rise velocity were in fair agreement with the frequently employed correlations given in the literature. Based on the above simulation results, Lindborg et al. [96] and Lindborg [97] concluded that, with the choice between the elasticity modulus closure together with a constant viscosity and the KTGF closure, the two-fluid model with a KTGF closure for the particle phase and a  $k_c\text{-}\varepsilon_c$  turbulence model for the continuous phase was recommended for the purpose of simulating reactive flows in bubbling bed reactors.

### 4.3.3 Two-Dimensional Simulation of a SE-SMR Process

For reactive flows the governing equations used by Lindborg [97] and Lindborg et al. [98] resemble those used for the cold flow analysis, as defined by (4.228)—(4.248), in Sect. 4.3.2.3. However, to implement the reactive process, the two fluid model for cold flow analysis was extended by including species mass- and thermal heat balances for both phases. In these equations, the chemical reaction model, the heat of reaction, and the interfacial heat- and mass transfer terms were included. Moreover, the interfacial mass transfer fluxes also give rise to additional terms in all the balance equations. Nevertheless, the other model closures, the initial and boundary conditions used coincide with those used for the cold flow equations. Therefore, to avoid misconception the model equations used are given below.

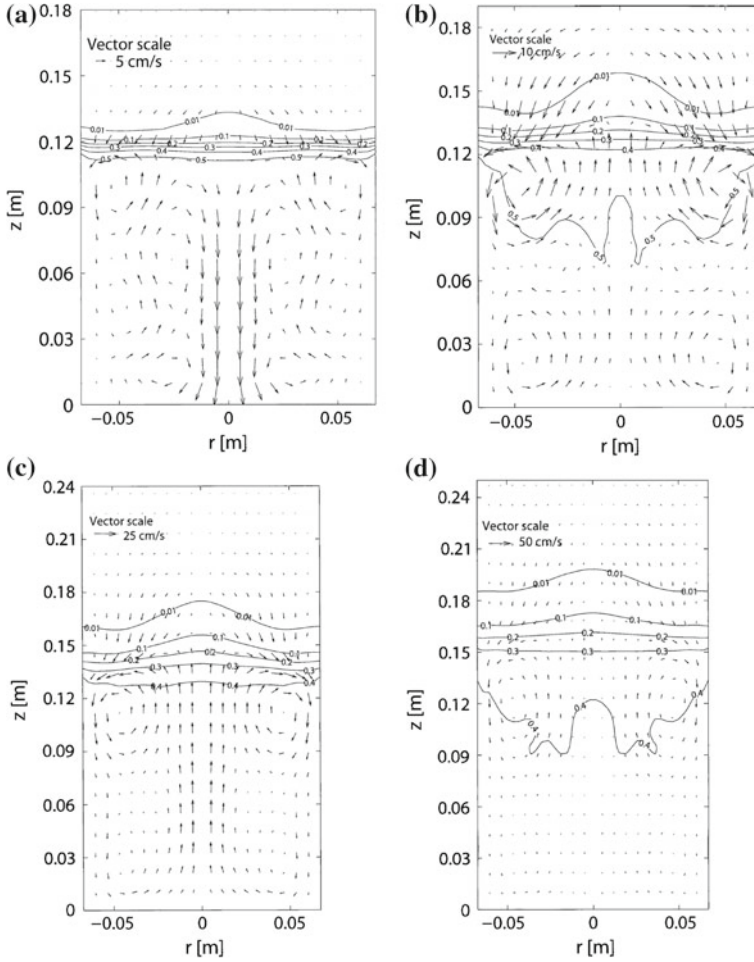

#### 4.3.3.1 Governing Equations for Reactive Flows in Fluidized Beds

The *continuity equation* for phase  $k$  ( $= c, d$ ) was expressed as:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k) = \Gamma_k \quad (4.252)$$

The *momentum equation for the gas phase* was expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c \mathbf{v}_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c \mathbf{v}_c) = & -\alpha_c \nabla p_c - \nabla \cdot (\alpha_c \boldsymbol{\sigma}_c) + \alpha_c \rho_c \mathbf{g} \\ & + \mathbf{M}_c + \Gamma_c \mathbf{v}_c^i \end{aligned} \quad (4.253)$$

**Fig. 4.9** Particle circulation patterns at various fluidizing velocities for a gas fluidized bed consisting of 0.42–0.6 (mm) diameter glass beads [95]. Simulated flow patterns obtained with the PGT model of Lindborg [97]. (a)  $U_{in}^s = 32$  (cm/s) and  $U_{in}^s/U_{mf}^s = 1.65$ , (b)  $U_{in}^s = 45.8$  (cm/s) and  $U_{in}^s/U_{mf}^s = 2.36$ , (c)  $U_{in}^s = 64.1$  (cm/s) and  $U_{in}^s/U_{mf}^s = 3.31$ , (d)  $U_{in}^s = 89.2$  (cm/s) and  $U_{in}^s/U_{mf}^s = 4.6$

The  $k_c$ - $\varepsilon$  turbulence model for the gas phase was expressed as:

$$\frac{\partial}{\partial t}(\alpha_c \rho_c k_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c k_c) = \nabla \cdot \left( \alpha_c \frac{\mu_c^t}{\sigma_{k_c}} \nabla k_c \right) + \alpha_c \left( \boldsymbol{\sigma}_c^{\text{Re}} : \nabla \mathbf{v}_c + S_{k_c} \right) - \alpha_c \rho_c \varepsilon_c \quad (4.254)$$

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_c \rho_c \varepsilon_c) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c \varepsilon_c) = \nabla \cdot \left( \alpha_c \frac{\mu_c^t}{\sigma_{\varepsilon_c}} \nabla \varepsilon_c \right) \\ + \alpha_c C_1 \frac{\varepsilon_c}{k_c} \left( \boldsymbol{\sigma}_c^{\text{Re}} : \nabla \mathbf{v}_c + S_{k_c} \right) - \alpha_c \rho_c C_2 \frac{\varepsilon_c^2}{k_c} \end{aligned} \quad (4.255)$$

The *momentum equation for the solid phase* is written as:

$$\frac{\partial}{\partial t}(\alpha_d \rho_d \mathbf{v}_d) + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \mathbf{v}_d) = -\alpha_d \nabla p_c - \nabla \cdot \mathbf{p}_d + \alpha_d \rho_d \mathbf{g} + \mathbf{M}_d + \Gamma_d \mathbf{v}_d^i \quad (4.256)$$

The *granular temperature equation for the particle phase* is written:

$$\begin{aligned} \frac{3}{2} \frac{\partial}{\partial t}(\alpha_d \rho_d \Theta_d) + \frac{3}{2} \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \Theta_d) = -(\mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}} + \mathbf{p}_d^{\text{fric}}) : \nabla \mathbf{v}_d \\ - \nabla \cdot (-\alpha_d \kappa_d \nabla \Theta_d) - 3\beta \Theta_d + \beta \langle \mathbf{v}_c' \cdot \mathbf{C}_d \rangle \\ - \gamma_d + \frac{3}{2} \Gamma_d \Theta_d \end{aligned} \quad (4.257)$$

The *molecular temperature equation for the continuous phase* is defined by:

$$\begin{aligned} \sum_s \alpha_c \rho_c \omega_{c,s} C p_{c,s} \left( \frac{\partial T_c}{\partial t} + \mathbf{v}_c \cdot \nabla T_c \right) = \nabla \cdot (\alpha_c k_c^{\text{eff}} \nabla T_c) \\ + \sum_r (-\Delta H_{R_{c,r}}^{\text{homo}}) R_{c,r}^{\text{homo}} + \sum_r (-\Delta H_{R_{c,r}}^{\text{het,cat}}) R_{c,r}^{\text{het,cat}} + Q_c^i + \Gamma_c (h_d^s - h_c) \end{aligned} \quad (4.258)$$

in which both homogeneous and heterogeneous catalytic reactions—and heat transfer due to interfacial mass transfer have been considered.

The *molecular temperature equation for the dispersed phase* is defined by:

$$\begin{aligned} \sum_s \alpha_d \rho_d \omega_{d,s} C p_{d,s} \left( \frac{\partial T_d}{\partial t} + \mathbf{v}_d \cdot \nabla T_d \right) = \nabla \cdot (\alpha_d k_d^{\text{eff}} \nabla T_d) \\ + (-\Delta H_{R_{d,r}}^{\text{het,non-cat}}) R_{d,r}^{\text{het,non-cat}} + Q_d^i - \Gamma_c (h_d^s - h_c) \end{aligned} \quad (4.259)$$

in which heterogeneous gas–solid non-catalytic reactions—and heat transfer due to interfacial mass transfer have been considered. The particles are considered non-porous rigid and spherical, thus the reactions are assumed to occur on the surface. For spherical particles the volumetric heat transfer coefficient is given as the product of the specific surface area and the interfacial heat transfer coefficient (4.268). The volumetric interfacial heat transfer coefficient is modeled by (4.269).

The *species mass balance* for the continuous phase was written as:

$$\frac{\partial}{\partial t}(\alpha_c \rho_c \omega_{c,s}) + \nabla \cdot (\alpha_c \rho_c \mathbf{v}_c \omega_{c,s}) = \nabla \cdot \left( \alpha_c \rho_c D_{c,s}^{\text{eff}} \nabla \omega_{c,s} \right) + M_{w_s} R_{c,s}^{\text{homo}} \quad (4.260)$$

$$+ \alpha_d \rho_d M_{w_s} R_{c,s}^{\text{het,cat}} + \Gamma_{c,s}$$

in which  $D_{c,s}^{\text{eff}}$  represents the effective mass diffusion coefficient of species  $s$  in phase  $c$ . This parameter is usually approximated by:  $D_{c,s}^{\text{eff}} = D_{c,s}^{\text{m}} + D_{c,s}^{\text{t}}$ , where the molecular diffusivity,  $D_{c,s}^{\text{m}}$ , is determined from a semi-empirical relation and the turbulent diffusivity  $D_{c,s}^{\text{t}}$  from a turbulence model invoking a Reynolds analogy.

The *species mass balance* for the dispersed phase was written as:

$$\frac{\partial}{\partial t}(\alpha_d \rho_d \omega_{d,s}) + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \omega_{d,s}) = \nabla \cdot \left( \alpha_d \rho_d D_{d,s}^{\text{eff}} \nabla \omega_{d,s} \right) \quad (4.261)$$

$$+ \alpha_d \rho_d M_{w_s} R_{d,s}^{\text{het, non-cat}}$$

in which  $D_{d,s}^{\text{eff}}$  represents the effective mass diffusion coefficient of species  $s$  in phase  $d$ . This parameter is difficult to determine. Different approximations deduced from kinetic theory and the mean free path concept have been proposed in the literature [21, 61, 89, 97].

### Chemical Processes

As for the one-dimensional model simulations, the kinetic model used for the conventional steam methane reforming (SMR) process was taken from Xu and Froment [167]. The reaction takes place on a Ni/MgAl<sub>2</sub>O<sub>4</sub> catalyst. The kinetics can be described by three reaction equations:

The rate equations are given by the following equations:

$$R_1^{\text{SMR}} = \frac{k_1}{3600 p_{\text{H}_2}^{2.5}} \frac{(p_{\text{CH}_4} p_{\text{H}_2\text{O}} - \frac{p_{\text{H}_2}^3 p_{\text{CO}}}{K_1})}{D E N^2}, \quad \left[ \frac{\text{kmol}}{\text{kg}_{\text{cat}} \text{ s}} \right] \quad (4.193)$$

$$R_2^{\text{SMR}} = \frac{k_2}{3600 p_{\text{H}_2}} \frac{(p_{\text{CO}} p_{\text{H}_2\text{O}} - \frac{p_{\text{H}_2} p_{\text{CO}_2}}{K_2})}{D E N^2}, \quad \left[ \frac{\text{kmol}}{\text{kg}_{\text{cat}} \text{ s}} \right] \quad (4.194)$$

$$R_3^{\text{SMR}} = \frac{k_3}{3600 p_{\text{H}_2}^{3.5}} \frac{(p_{\text{CH}_4} p_{\text{H}_2\text{O}}^2 - \frac{p_{\text{H}_2}^4 p_{\text{CO}_2}}{K_3})}{D E N^2}, \quad \left[ \frac{\text{kmol}}{\text{kg}_{\text{cat}} \text{ s}} \right] \quad (4.195)$$

where

$$DEN = 1 + K_{CO}p_{CO} + K_{H_2}p_{H_2} + K_{CH_4}p_{CH_4} + K_{H_2O}p_{H_2O}/p_{H_2} \quad (4.262)$$

All equilibrium and kinetic constants are taken from Xu and Froment [167].

The sorption enhanced-steam methane reforming (SE-SMR) process has the potential to reduce the costs of hydrogen production by steam methane reforming, in addition to removing CO<sub>2</sub> from the product stream. In this process, a CO<sub>2</sub> acceptor was installed together with the catalyst for removal of CO<sub>2</sub> from the gas phase, and hence changing the equilibrium conversion towards higher H<sub>2</sub> yield. The steam reforming process was thus run at lower temperatures than conventional steam reforming (723–903 K), possibly reducing the investment and operational costs significantly [111].

The gas–solid Lithium Silicate sorbent—CO<sub>2</sub> equilibrium reaction was defined as:

The mathematical model for the sorption reactions is given by [125]:

$$\frac{dX}{dt} = k_1(P_{CO_2} - P_{CO_2,eq})^{n_1}(1 - X)^{n_2} \quad (4.264)$$

where  $X$  is the fractional conversion of the reaction, defined as  $X = q/q^{\max}$ .  $q$  is defined as the mass of CO<sub>2</sub> adsorbed divided by the adsorbent mass.  $q^{\max}$  refers to the maximum amount of CO<sub>2</sub> that can be adsorbed.

The temperature dependence of  $k_1$  is given by:

$$k_1 = k_{10}e^{-\frac{E_a}{R}(\frac{1}{T} - \frac{1}{T_0})} \quad (4.265)$$

The reaction rate for the adsorption process was then given by:

$$R_{CO_2}^{ads} = \frac{q^{\max}}{M_{wCO_2}} \frac{dX}{dt}, \quad \left[ \frac{\text{kmol CO}_2}{\text{kg}_{ads} \text{ s}} \right] \quad (4.266)$$

The adsorption source/sink terms were expressed as:

$$\Gamma_{k,CO_2} = \alpha_d \rho_d M_{wCO_2} R_{k,CO_2}^{ads} \quad (4.267)$$

in which  $R_{k,CO_2}^{ads}$  denotes the sorption particle adsorption reaction which is positive for the dispersed phase,  $k = d$ , and negative for the continuous phase,  $k = c$ , as CO<sub>2</sub> is captured by the sorbent in the SE-SMR process.

The parameters in the  $Li_4SiO_4$  sorption kinetics are given in Table 4.11.

*Interfacial Heat Transfer Model Coefficient Parameterizations*

A review of the heat transfer characteristics of fluidized beds has been given by Yates [168]. It is generally accepted that the heat transfer between gas and particles is very efficient in fluidized beds as a result of the high surface area of the particle phase. The heat transfer fluxes between an immersed surface and the gas-fluidized bed material are more important from a practical design point of view. Due to the efficient particle mixing in fluidized bed vessels, these beds are frequently assumed to be operated in a non-adiabatic uniform bed temperature mode. However, for particular processes, the effective conductivity of the bed material is required to predict possible temperature gradients within the bed.

The gas-particle interfacial heat transfer terms in the temperature equations were modeled as summarized in Table 4.5:

$$Q_c^i = -Q_d^i = -\frac{6\alpha_d k_c^{\text{eff}}}{d_p^2} Nu_d (T_d - T_c) \quad (4.268)$$

A large number of empirical correlations is available for estimating the Nusselt number in both packed- and fluidized beds. A Nusselt number correlation proposed by Gunn [54] was used. The Nusselt number parameterization represents a functional fit to experimental data for Reynolds number up to  $10^5$  in the porosity range 0.35–1:

$$Nu_d = (7 - 10\alpha_c + 5\alpha_c^2)(1 + 0.7 Re_p^{0.2} Pr^{0.3}) + (1.33 - 2.4\alpha_c + 1.2\alpha_c^2) Re_p^{0.7} Pr^{0.3} \quad (4.269)$$

where

$$Nu_d = \frac{h_{cd} d_p}{k_c^{\text{eff}}}, \quad Re_p = \frac{\alpha_c \rho_c |\mathbf{v}_c - \mathbf{v}_d|}{\mu_c} \quad \text{and} \quad Pr = \frac{\mu_c C_{p,c}}{k_c^{\text{eff}}} \quad (4.270)$$

#### Thermal Heat Conductivity Parameterizations

According to Natarajan and Hunt [110] the effective thermal conductivity of the solids phase  $k_d^{\text{eff}}$  can be expressed as a linear sum of the kinetic- and thermal conductivities:

$$k_d^{\text{eff}} \approx k_d^{\text{kin}} + k_d^{\text{m}} \quad (4.271)$$

The kinetic conductivity for a two-dimensional system was calculated from a relation given by Hunt [61]:

$$k_d^{\text{kin}} \approx \alpha_d \rho_d C p_d D_{dd} \approx \rho_d C p_d d_p \sqrt{\theta_d} \frac{\pi^{3/2}}{32 \alpha_d g_0} \quad (4.272)$$

For gas-particle systems the molecular conductivities of the different phases are frequently calculated employing two semi-empirical relations deduced from the model of Zehner and Schlünder [170]. The original model of Zehner and Schlünder was originally derived to describe the effective radial conductivity in fixed beds. By using a cell concept the heat is assumed to be transferred by molecular conduction both in a pure gas phase with surface fraction  $1 - \sqrt{\alpha_p}$ , and through a gas-solid bulk phase with the complementing portion of the surface fraction,  $\sqrt{\alpha_p}$ . Deviations from sphericity and inter-particle point-contacts were taken into account by further dividing the gas-solid bulk phase into a surface fraction,  $\phi$ , where heat is transferred through inter-particle contact and  $1 - \phi$  for heat transfer through the remaining surface [8]. However, in the two-fluid model framework it is necessary to separate the overall bulk thermal conductivity into individual conductivities for the gas and solid phases. Such a division has been proposed by Syamlal and Gidaspow [144]. This two-fluid model correlation has later been adopted for calculating the effective thermal conductivity of dense phase fluidized beds [14, 84, 116].

The phase k thermal heat conductivity parameterizations used in the temperature equations were modeled as summarized in Table 4.3:

The dispersed phase thermal conductivity was thus determined by:

$$k_d^m = \frac{k_c}{\sqrt{\alpha_d}} (\phi A + (1 - \phi) \Lambda) \quad (4.273)$$

which corresponds to (3.16a) in the thesis by Lindborg [97].

The effective thermal conductivity of the continuous gas phase was given by:

$$k_c^{\text{eff}} = k_c^m + k_c^t = \frac{k_c^{\text{stat}}}{\alpha_c} (1 - \sqrt{\alpha_d}) + \frac{\mu_c^t}{\rho_c P r^t} \quad (4.274)$$

where

$$\Lambda = \frac{2}{(1 - B/A)} \left( \frac{(A - 1)}{(1 - B/A)^2} \frac{B}{A} \ln \left( \frac{A}{B} \right) - \frac{B - 1}{1 - B/A} - \frac{1}{2}(B + 1) \right) \quad (4.275)$$

#### Wall Heat Transfer Coefficient Parameterizations

Closure equations for heat exchangers at the reactor wall [98]:

$$\mathbf{q}_w = h_w (T_{\text{out tube}, w} - T_{c, w}) \quad (4.276)$$

Overall heat transfer coefficient:

$$h_w = \left( \frac{d_{\text{in tube}}}{2k_{\text{tube}}} \ln \frac{d_{\text{out tube}}}{d_{\text{in tube}}} + \frac{u_b}{u_{br}} \left( \frac{1}{h_s} + \frac{1}{h_f} \right) \right)^{-1} \quad (4.277)$$

The film heat transfer coefficient is defined as:

$$h_f = \frac{mk_c^{\text{stat}}}{d_p} \quad (4.278)$$

in which  $m = 6$  may be adopted for design purposes.

Heat transfer coefficient for a known packet residence time:

$$h_s = 2\sqrt{\frac{k_{mf}^{\text{eff}} \alpha_d^{\text{mf}} \rho_d C_{p,d} (u_0 - u^{\text{mf}})}{0.5\pi d_p}} \quad (4.279)$$

by:

$$k_{mf}^{\text{eff}} = k_{e,r}^{\text{stat}} + 0.14k_c^{\text{stat}} \text{Re}_p Pr \quad (4.280)$$

#### *Turbulent Viscosity Model*

The turbulent viscosity model employed characterizing the continuous phase flow, as required due to the use of the Reynolds averaging procedure as well as in the Reynolds analogy relations, was determined by the  $k_c - \varepsilon_c$  model thus  $\mu_c^t = C_\mu k_c^2 / \varepsilon_c$ .

#### *Species Effective Diffusivity Parameterizations*

The gas phase effective diffusivity parameterizations used are the same as those used for the one-dimensional simulations summarized in Table 4.4.

The effective diffusivity of the gas phase is determined from:

$$D_{c,s}^{\text{eff}} = D_{c,s}^m + D_c^t = D_{c,s}^m + \frac{\mu_c^t}{\rho_c \text{Sc}^t} \quad (4.281)$$

For the gas phase, the turbulent diffusivity  $D_c^t$  was deduced from the  $\mu_c^t$  computed from the  $k_c - \varepsilon_c$  model adopting a Reynolds analogy:

$$D_c^t = \frac{\mu_c^t}{\rho_c \text{Sc}^t} \quad (4.282)$$

**Table 4.12** Circular axi-symmetric reactor configuration used by [79]

| Reactor configuration                            |          |
|--------------------------------------------------|----------|
| Column height (m)                                | 1.5      |
| Reactor diameter (m)                             | 0.25     |
| Bed height at minimum fluidization (m)           | 0.5      |
| Particle volume fraction at minimum fluidization | 0.61     |
| Outlet pressure (bar)                            | 5        |
| Inlet gas velocity (m/s)                         | 0.1      |
| Density dispersed phase (kg/m <sup>3</sup> )     | 1500     |
| Numerical resolution (m)                         | 0.0125   |
| Grid resolution                                  | 122 × 12 |
| Particle diameter (μm)                           | 500      |

**Table 4.13** Feed gas composition

| Component                      | Weight fraction | Mole fraction |
|--------------------------------|-----------------|---------------|
| <i>CH</i> <sub>4</sub>         | 0.129           | 0.143         |
| <i>H</i> <sub>2</sub> <i>O</i> | 0.871           | 0.857         |

The approximate multi-component molecular diffusion coefficients were computed by use of the Wilke equation [165]:

$$D_{c,s}^m = \frac{1 - \omega_s}{M_\omega \sum_{s \neq r} \frac{\omega_s}{M_s D_{sr}}} \quad (4.283)$$

The binary molecular diffusion coefficient values were computed from the Fuller et al. [44] relation:

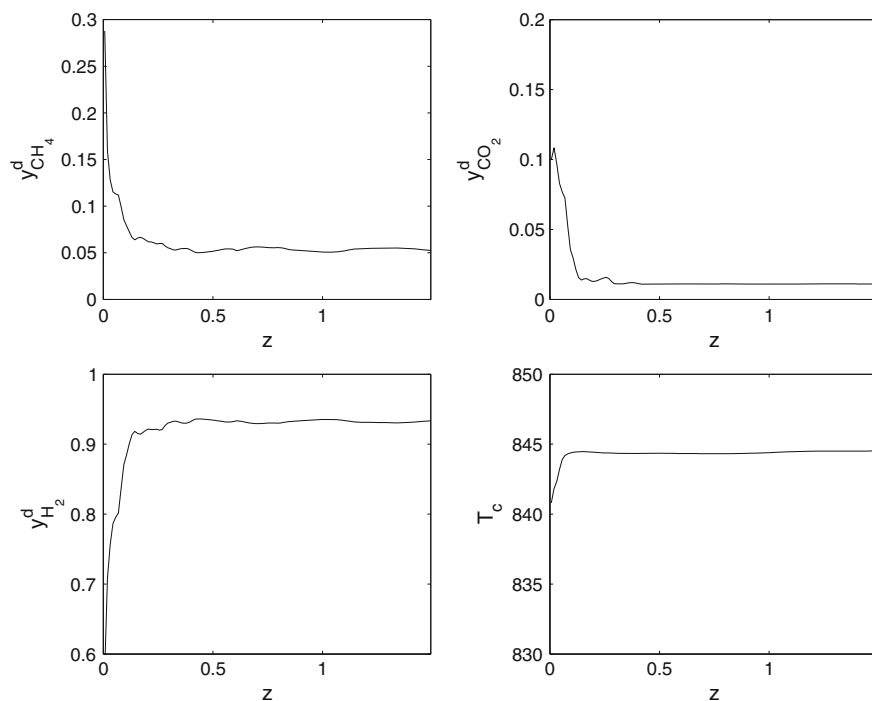

$$D_{sr} = \frac{T_c^{1.75} \sqrt{1/M_{\omega_s} + 1/M_{\omega_r}}}{101.325 p ((\sum V)_s^{1/3} + (\sum V)_r^{1/3})^2} \quad (4.284)$$

The expression for particle self-diffusion deduced from kinetic theory for rigid elastic spheres of diameter  $d_p$  was adopted [25, 116]:

$$D_d^t = \frac{d_p}{16\alpha_d} \sqrt{\pi \Theta}. \quad (4.285)$$

### 4.3.3.2 SE-SMR Process Simulations

Jørgensen [79] simulated the sorption enhanced steam reforming (SE-SMR) process employing a two-fluid model derived and implemented in an in-house code by Lindborg [97] and Lindborg et al. [96]. The reactor configuration used operating the novel chemical process is defined in Table 4.12.

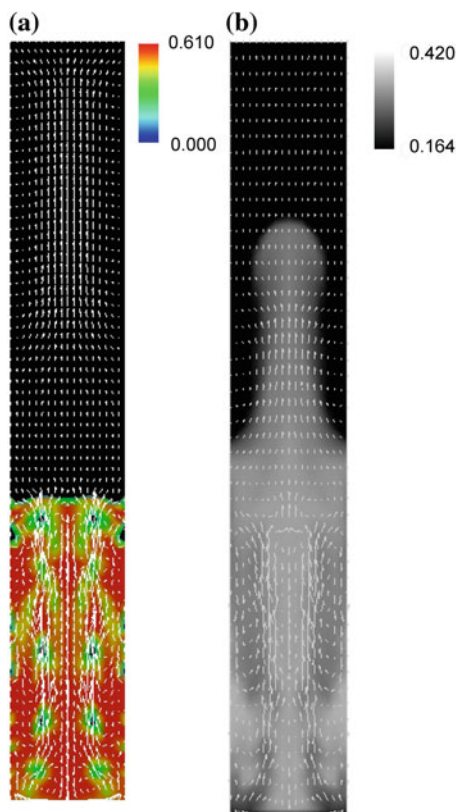

**Fig. 4.10** Simulation of a chemical reactive mixture. Cross sectional average dry mole fraction profiles of  $\text{CH}_4$ ,  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{CO}$ ,  $\text{H}_2$  and temperate profile after 100 s. The results are averaged over the 2 last seconds to smooth the profiles

The simulations were run with the feed gas composition presented in Table 4.13. This composition represents a steam to carbon-ratio of 6. The feed gas enters the column with a temperature of 848 K.

Figure 4.10 shows the composition field (mole fractions under dry conditions) in the reactor after 100 s. A rapid decrease in the methane and  $\text{CO}_2$  mole fractions, and a steep increase in the  $\text{H}_2$  mole fraction are observed. The endothermic steam methane reforming process reactions are fast, so most of the conversion is taking place immediately after the gas reactants enter the reactor. The  $\text{CO}_2$ -sorption process is slower and takes place in the entire bed, removing  $\text{CO}_2$  from the gas and thus shifting the chemical equilibrium limit for the SE-SMR toward a higher  $\text{H}_2$  yield compared to the conventional steam methane reforming (SMR) process. The exothermic sorption reaction also reduces the temperature drop compared to the conventional steam methane reforming process. The temperature of the gas entering the vessel is 848 K.

In Fig. 4.11a instantaneous fields of the solids volume fraction and velocity vectors after 50 s simulation time are shown. The black areas indicate locations where the solid fraction is below 0.2. It is seen that the solids in the bottom of the vessel have a tendency to move toward the center of the tube and rise at a radial position halfway

**Fig. 4.11** Simulation of a chemical reactive mixture.  
**a** Instantaneous fields of the solids volume fraction and the particle velocity vectors after 50 s. **b** Contour plot of an instantaneous dry  $H_2$  mole fraction field during start up of the process, 5 s after the reactants enter the column and 10 s after the start up of the flow. The consistent gas velocity vector field is given in the same plot

between the wall and the center. The particles are moving down again away from the up-flowing area both closer the wall and the center of the vessel.

In Fig. 4.11b instantaneous fields of the dry  $H_2$  mole fraction and the gas velocity vectors after 10 s simulation time are shown. That is, the reactions were turned on 5 s after the flow was initiated. The hydrogen production is fast in the inlet zone and the hydrogen produced are transported toward the exit. It is also seen that the gas bubbles created in the bottom of the vessel have a tendency to move toward the center of the tube and rise at a radial position halfway between the wall and the center. These bubbles carry some of the solids in their wakes producing the solids circulation pattern seen in (a). There are no experimental data available for this process yet, so no firm validation has been performed. Nevertheless, the flow pattern is deemed to be reasonable and the chemical conversion is in fair agreement with those obtained in fixed bed simulations [125].

#### 4.3.4 Three-Dimensional Simulations of a SE-SMR Process

Wang et al. [161–163] developed a three-dimensional non-axisymmetric two-fluid model for gas–solid flow, representing an extension of the two-dimensional model used by Lindborg [97] as given in Sect. 4.3.3, to study the sorption enhanced steam methane reforming (SE-SMR) and the sorbent regeneration processes with CaO based sorbent in fluidized bed reactors. These models were implemented in in-house codes and solved with the finite volume algorithm described by Lindborg et al. [96–98]. Moreover, Wang et al. [161–163] did apply the drag model presented by Benyahia et al. [11] to account for the gas solid interactions whereas Lindborg et al. [96–98] did employ the drag coefficient proposed by Gibilaro et al. [47]. Wang et al. [160] did show that the drag model presented by Benyahia et al. [11] was better suited for simulation of the experimental conditions used by Lin et al. [95].

For the SMR reactor, there are the three chemical reactions (4.190)–(4.192). The kinetic expressions for SMR reactions from Xu and Froment [167] were used in these simulations. The kinetics expressions are given in (4.193), (4.194) and (4.195). For the SE-SMR reactor, there is one more reaction, the  $CO_2$  adsorption reaction:

The rate equations for  $CO_2$  adsorption by the CaO sorbent were taken from Sun et al. [142]:

$$R_{CO_2}^{SE} = \frac{\partial X}{\partial t} = 56k_s w(1 - X)(p_{CO_2} - p_{CO_2,eq})^n S \quad (4.287)$$

The equilibrium pressure of  $CO_2$  is calculated from the equilibrium concentration of  $CO_2$  presented by Abanades et al. [2]:

$$p_{CO_2,eq} = \frac{1.462 \times 10^{11}}{T} \exp\left(-\frac{19130}{T}\right) \quad (4.288)$$

Okunev et al. [115] proposed an approximate analytical expression for the rate of  $CO_2$  desorption as a function of sorbent texture, temperature,  $CO_2$  pressure, particle size, and Sherwood number. The reaction was defined as:

$$R_{CO_2}^{\text{Desorption}} = \frac{2.46 \times 10^4 S_{sp} e^{-20474/T}}{2.27 \times 10^3 \left[ \frac{d_p^2 S_{sp}}{Sh} \right]^{2/3} + \exp^{7.8(p_{CO_2}/p_{CO_2}^*)}} \times \left( 1 - \frac{p_{CO_2}}{p_{CO_2}^*} \right) \quad (4.290)$$

with units  $[kg_{CO_2}/kg_{CaO} s]$ .

**Table 4.14** Physical properties of simulations performed by Wang et al. [162]

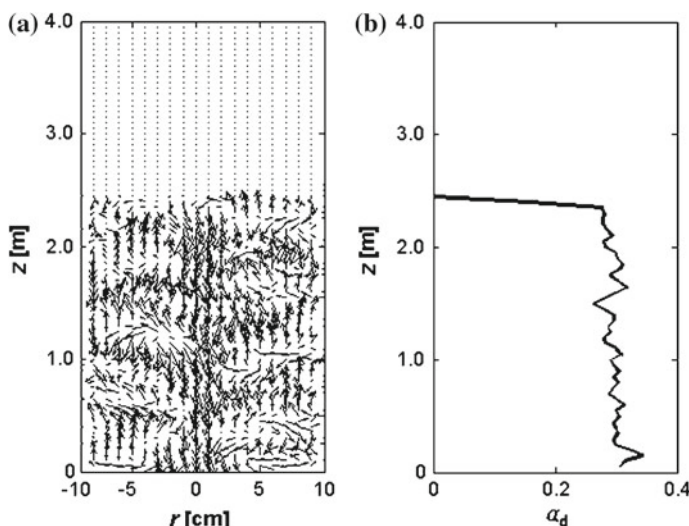

|                                                                                             |                                                                            |
|---------------------------------------------------------------------------------------------|----------------------------------------------------------------------------|
| Particle diameter                                                                           | 500 $\mu\text{m}$                                                          |
| Particle density                                                                            | 1500 $\text{kg/m}^3$                                                       |

| Steam-to-carbon ratio (i.e., $\frac{m_{\text{H}_2\text{O}}}{m_{\text{CH}_4}}$ in inlet gas) | 5:1                                                                        |
| $v_c^s$ , Superficial gas velocity                                                          | 0.3 m/s                                                                    |
| BFB operation temperature                                                                   | 848 K                                                                      |
| Outlet pressure                                                                             | 1 bar                                                                      |
| Reactor size                                                                                | $R = 0.1 \text{ m}$ , $H = 4 \text{ m}$                                    |
| Initial bed height                                                                          | 2 m                                                                        |
| Grid cell number                                                                            | $12 \times 12 \times 80$                                                   |
| Time step                                                                                   | $1 \times 10^{-4} \text{ s}$                                               |
| Convergence criterion                                                                       | $\ \mathbf{r}_m\  < \varepsilon \ \mathbf{b}\ $ , $\varepsilon = 10^{-10}$ |

#### 4.3.4.1 Three-Dimensional Simulation of $\text{H}_2$ Production by the SE-SMR Process Operated in a BFB Reactor

Wang et al. [162] did perform a numerical study of hydrogen production by the SE-SMR process with in-situ  $\text{CO}_2$  capture. The SMR- and adsorption of  $\text{CO}_2$  processes were carried out simultaneously in a bubbling fluidized bed reactor. Enhanced production of hydrogen was achieved in the SE-SMR process compared with the conventional SMR process. The hydrogen molar fraction in the gas phase was near the equilibrium composition. The effects of inlet gas superficial velocity and steam-to-carbon ratio (or mass ratio of steam to methane in the inlet gas) on the process performance were examined. The reactor system design parameters used in the numerical simulation are listed in Table 4.14.

The velocity profiles and the axial distribution of volume fraction of solid particles are shown in Fig 4.12. The solid velocity pattern did show a non-axial symmetric behavior. The axial distribution of the solid phase was close to uniform. Figure 4.13 displays the outlet fractions of hydrogen, methane, and  $\text{CO}_2$  in the gas phase as achieved for the SMR and SE-SMR processes operated in a BFB reactor. In the SMR results, the outlet molar fraction of  $\text{H}_2$  is only 75 %, thus a considerable amount of  $\text{CO}_2$  and  $\text{CH}_4$  are emitted out of the reactor. In the SE-SMR process results, both the conversion of methane and the adsorption of  $\text{CO}_2$  are larger than 99 %. The simulation results show that the integration of  $\text{CO}_2$  sorption in the SMR process can enhance the methane conversion to hydrogen to near the equilibrium composition in the BFB reactor.

The adsorption kinetics was sufficiently fast so that the sorbent did adsorb the  $\text{CO}_2$  produced in the SE-SMR process for  $u_g^s < 0.89 \text{ m/s}$  until sorbent breakthrough. The adsorption rate of  $\text{CO}_2$  was higher at higher gas superficial velocity and higher pressure. The best value of steam-to-carbon ratio was about 4 considering the balance between higher hydrogen production and lower steam consumption. The simu-

**Fig. 4.12** Velocity flow pattern and volume fraction of solid particles in a bubbling fluidized bed reactor. The operational conditions are specified in Table 4.14. Reprinted from Wang et al. [162] with permission from Springer

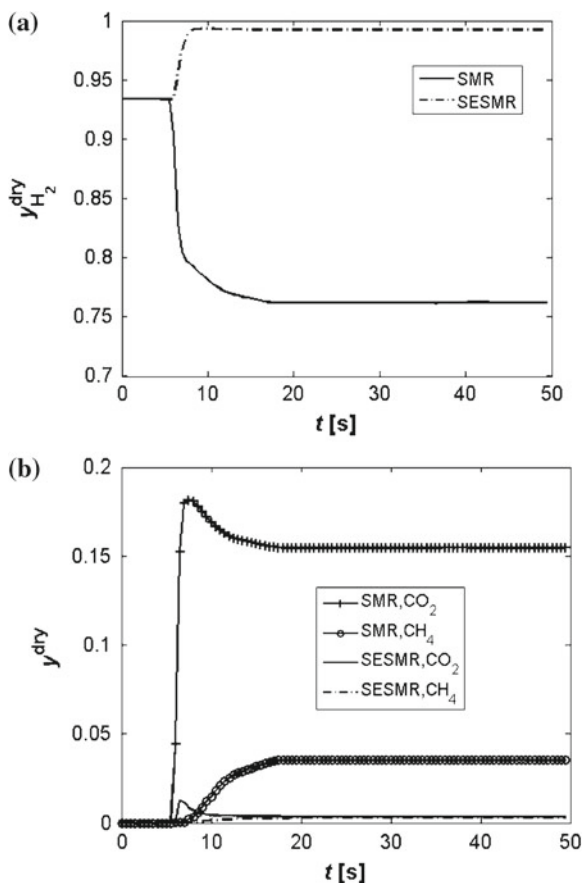

lated results were in agreement with the experimental data reported in the literature [55, 72].

For the required desorption of  $\text{CO}_2$  from the carbonated sorbent, an additional process unit is necessary for optimal overall SE-SMR process plant performance. The main purpose with the SE-SMR process development which was to reduce the emission of  $\text{CO}_2$  to the atmosphere, was achieved. However, the desorption apparatus increase the total costs and the energy consumption of the process plant. On the other hand, the heat released by the adsorption of  $\text{CO}_2$  may compensate for some of the energy consumed in the desorption process.

#### 4.3.4.2 Off-Line Three-Dimensional Simulation of the SE-SMR-and the Desorption Processes to Mimic a Complete CFB Reactor Simulation

Wang et al. [161] investigated the SE-SMR-and desorption processes with  $\text{CaO}$  based sorbents by running separate simulations of the  $\text{CO}_2$  adsorption—and desorption processes due to the complexity of the three-dimensional system. The operating conditions are specified in Table 4.15. The SE-SMR process (i.e., SMR and adsorption of  $\text{CO}_2$ ) was carried out in a bubbling fluidized bed. The effects of pressure and steam-to-carbon ratio on the reactions are studied. High pressure and low steam-to-carbon ratio did decrease the conversion of methane. However, the high pressure makes the adsorption of  $\text{CO}_2$  faster. The methane conversion and heat utility were enhanced by  $\text{CO}_2$  adsorption. The produced  $\text{CO}_2$  in SMR process was almost com-

pletely adsorbed during the relative long residence time in the bubbling fluidized bed. It means that the adsorption rate of CO<sub>2</sub> was sufficiently fast compared with the SMR rate. The process of sorbent regeneration was carried out in a riser. In this reactor an unfeasible residence time was required in order to complete the regeneration process. Higher temperature makes the release of CO<sub>2</sub> faster, but the rate is severely restrained by the increased CO<sub>2</sub> concentration in the gas phase. The temperature distribution was uniform over the whole reactor. Regeneration rate and capacity of sorbents are important factors in selecting the type of reactors for the SE-SMR process.

The heterogeneous catalytic reforming reactions are supposed to take place on the gas–solid interface. In heterogeneous catalysis no species enter into the solid phase, hence for this process the species mass balance are solved only in the gas phase. For the adsorption process the reaction actually takes place within the solid adsorbent material. However, in the modeling approach employed by Wang et al. [161] a pseudo-homogeneous reaction model was adopted so that the CO<sub>2</sub> capture reaction was approximated by a particle surface reaction thus the overall diffusion

limitations (i.e., the external film- and internal particle pore mass transfer resistances) were neglected. Likewise, for the catalytic SMR process the heat of reaction terms are normally included in the gas phase temperature equation whereas the adsorption process takes place within the solid particles and should be included in the dispersed phase temperature equation. However, a heterogeneous heat of reaction model was adopted thus the heat of reaction terms were placed in the solid phase temperature equation. The solids were thus primarily heated by the adsorption process and thereafter the gas was heated by heat transfer from the solids. The secondary exchange of momentum, granular energy and heat due to interfacial mass transfer, were neglected. When increasing the pressure from 1 to 10 bar, the outlet methane concentration was increased from 0.3 to 2.5 % after 49 s simulation time. However, the  $\text{CO}_2$  adsorption rate was faster at higher pressure than at lower pressure. The higher pressure is thus favorable for adsorption of  $\text{CO}_2$ , but unfavorable for the SMR process reactions. The steam-to-carbon ratio is important for the conversion of methane in the reactor. Sufficient steam concentration in the feed is a necessary condition for complete conversion of methane. When the steam-to-carbon ratio was decreased from 5 to 3 at  $p=1$  bar, the outlet methane concentration was increased from 0.3 to 3 %. The temperature in both the BFB and riser was close to uniform. In the BFB there was a minor temperature drop at the inlet. The reason for this is that the net endothermic SMR- and the exothermic adsorption reactions are close to be in balance, and that the solids in the BFB was well mixed. The temperature in the BFB reactor decreased gradually as the reactions proceed. The simulation results show that the integration of  $\text{CO}_2$  sorption to the SMR process can increase the methane conversion to approximately the equilibrium composition and thus make more effective energy utility. However, the desorption of  $\text{CO}_2$  in the riser was not very successful. The reaction rate of the desorption was too slow and the sorbent capacity was too large to complete the release of  $\text{CO}_2$  under the continuous operating conditions of a riser with relatively short residence time. Hence, the present sorbent properties are seemingly best utilized in bubbling bed reactors both for the adsorption and desorption processes under continuous operation, or alternatively a fixed bed reactor may be used due to

the low desorption rate and high capacity of the sorbent. When such a sorbent is used in a CFB reactor, only a small fraction of its capacity can be utilized.

#### 4.3.4.3 Interactions of the SE-SMR Process and the Gas–Solid Fluid Dynamics in a BFB Reactor

Wang et al. [163] developed a three-dimensional two-fluid model with a KTGF closure for simulation of the SE-SMR process carried out in a BFB reactor. The effects of the superficial gas velocity and restitution coefficient on the solid flow pattern and chemical process performance were investigated. The restitution coefficient and the superficial gas velocity significantly influence the solid flow patterns in a BFB [160]. The fluid dynamic properties of the reactive flow showed different behaviors compared to the cold flow. The superficial gas velocity and restitution coefficient influence the bed expansion and bed uniformity in different ways. The gas flow rate mainly affects the bed expansion of the BFB. Higher gas flow rates make the bed expansion higher. The restitution coefficient mainly affects the uniformity of the bed. A large restitution coefficient corresponds to a more uniform state of the bed. The physical properties of the reactor and particles as well as simulation parameters are listed in Table 4.16. These conditions are close to those used by Lin et al. [95] characterizing the flow in these vessels. The reactions of the SE-SMR process were affected mainly by the superficial gas velocity, while the restitution coefficient has less influence on the chemical process performance. Under the simulated conditions, the  $\text{CO}_2$  adsorption was completed, thus the SMR reactions were kept away from equilibrium. When the reaction is not in equilibrium, a higher gas flow rate decrease the degree of completeness of the reaction. However, a larger restitution coefficient did increase the progress of the reaction. A uniform state of the solid bed is in

favor of the reactions, and the resulting effects on the slower reactions were stronger than that on the fast reactions. In the reactive flow, the temperature and pressure were different than under the cold flow conditions, thus the resulting gas density and viscosity variations did change the solid flow patterns considerably. A main trend was observed, for the SE-SMR process operated under the specified operating conditions in BFB reactors, within the simulated solid phase velocity field there was no clear dominant vortex as distinct from the cold flow behavior.

## 4.4 Three-Fluid Model with Kinetic Theory of Granular Flow Closure

Chao [21] and Chao et al. [20, 22, 23] made a three-fluid model for a binary particle system with an interstitial gas to simulate particle segregation due to size and weight differences between the two particle types. The first part of the work considered a cold flow study of a binary particle mixture. Later, Chao [21] and Chao et al. [24] made a three-fluid model for a reactive binary particle system with a multi-component interstitial gas. The process investigated was sorption-enhanced steam methane reforming (SE-SMR) which is steam methane reforming (SMR) and a gas–solid adsorption reaction CO<sub>2</sub> capture process.

In order to simulate the flow behaviors in fluidized bed reactors, the Eulerian–Eulerian models were used in which the gas and particles were treated as interpenetrating continuous fluids. The governing transport equations for the solid phase were closed using the kinetic theory of granular flow (KTGF) which is a theory based on an analogy to the classical kinetic theory of dense gas. In the KTGF modeling approach, the basic billiard ball collision theory and some additional statistical methods (i.e., statistical collision frequency and statistical moment) are applied to obtain the necessary governing balance equations (i.e., the continuity equations, Navier–Stokes-like momentum equations and other transport equations) describing the fluid dynamics of the solids in fluidized beds. For mono-particle systems, Lun et al. [102] and Gidaspow [49] derived the KTGF closure models which are still widely used. Jenkins and Mancini [70] extended the mono-particle KTGF model to binary particle systems. In their binary particle model, it was assumed that both particle types share the same local granular temperature. However, for binary systems with apparent particle property differences (e.g., in density, size or shape), some degree of particle segregation might be imposed between the binary group of particles, thus the two group of particles tend to flow as two separate fluids. In order to take into account the random velocity fluctuations for each type of particles, Gidaspow et al. [50], Manger [105], Mathiesen et al. [107], Lu et al. [99–101] and Iddir et al. [62, 63] derived and applied similar binary KTGF closure models containing unequal individual granular temperatures for each type of particles. Lathouwers and Bellan [87, 89] also derived a binary KTGF model with unequal individual granular temperatures, but the constitutive equations are different from those of Gidaspow et al. [50], Manger [105], Mathiesen et al. [107], Lu et al. [99–101] and Iddir et al. [62, 63].

To derive the necessary constitutive equations for the governing equations for the binary mixture granular fluids, a statistical single density function  $f_i(\mathbf{r}_i, \mathbf{c}_i, t)$  is required. This single density function might be obtained by solving a generalized Boltzmann equation using the Chapman-Enskog successive approximations solution method [25]. The first Maxwellian approximation,  $f_i \approx f_i^{(0)}$ , corresponds to a system in equilibrium with frequent particle-particle interactions that is non-dissipative because there are no gradients in the properties. However, by introducing the perturbation function  $\phi_i^{(0)}$ , the second approximation  $f_i \approx f_i^{(0)} + f_i^{(1)} \approx f_i^{(0)}(1 + \phi_i^{(0)})$  includes the effects of spatial gradients thus giving rise to energy dissipation [149, 150]. In the aforementioned models for mono-particle systems, Gidaspow [49] used a combination of the first and second approximations of the single density function in his model derivation. For binary and multiple particle systems, most modeling attempts applied the first approximation of the single density function only (e.g., Gidaspow et al. [50], Manger [105], Lu et al. [99–101] and Iddir et al. [62, 63], and Lathouwers and Bellan [87, 89]). Compared with these binary particle models, Mathiesen et al. [107] applied some additional kinetic terms (i.e., Eqs. (21) (28) in Mathiesen et al. [107]) which are related to the segregation/mixing effects. A careful comparison with the mono-particle equations (i.e., 9.232, 9.233, 9.250 and 9.272) from Gidaspow [49] shows that these segregation/mixing effect terms occur due to the application of the second approximation of the single density function. Hence, it might be considered that Mathiesen et al. [107] partly applied the second approximation of the single density function. A detailed analysis by van Sint Annland et al. [149, 150] did show that the first approximation requires that the particle velocities of all particles species are distributed around the same mean velocity with the same granular temperature. Therefore, all the above mentioned models based on the first approximation with individual granular temperatures for the two types of particles [50, 62, 63, 87, 89, 99–101, 105] are containing an inconsistency associated with the assumption of using different particle velocities and granular temperatures for different particle species and the first order single density function approximation. To avoid this inconsistency, van Sint Annland et al. [149, 150] developed a more advanced KTGF model for multiple particle gas–solid flow on the basis of the average velocity and a single granular temperature of the particle mixture. The differences in the granular temperatures for the different particle species and the particle segregation are higher order approximation effects arising from the perturbation function,  $\phi_i^{(0)}$ .

In all these KTGF closure models, there are many integral terms related to  $\mathbf{c}_{ij}$ . From the kinetic theory, we know that the random particle velocity  $\mathbf{c}_i$  is defined as the sum of the peculiar velocity  $\mathbf{C}_i$  and fluid dynamic velocity  $\mathbf{v}_i$ , i.e.,  $\mathbf{c}_i = \mathbf{C}_i + \mathbf{v}_i$ , hence the correct definition for  $\mathbf{c}_{ij}$  should be  $\mathbf{c}_{ij} = \mathbf{C}_{ij} + \mathbf{v}_{ij}$ . In all previous models,  $\mathbf{c}_{ij}$  is approximated by the peculiar particle-particle velocity differences  $\mathbf{C}_{ij}$  only, thus the fluid dynamic particle-particle velocity differences  $\mathbf{v}_{ij}$  are neglected. This simplification may lead to an under-prediction of the particle-particle momentum coupling. Moreover, the main momentum coupling between the binary particle fluids are through the particle-particle drag. Therefore, when deriving the particle-particle

drag model, it is of outmost importance to start out from the exact definition for the discrete particle velocity difference  $\mathbf{c}_{ij} = \mathbf{C}_{ij} + \mathbf{v}_{ij}$ , thus two particle-particle drags, denoted the peculiar drag,  $\mathbf{F}_{ij}^{pec}$ , and the fluid dynamic drag,  $\mathbf{F}_{ij}^{flu}$ , can be derived from  $\mathbf{C}_{ij}$  and  $\mathbf{v}_{ij}$  respectively. In accordance with the theoretical basis of the kinetic theory of dilute gases, these properties are transported by short-term collisional contacts. For this reason, the KTGF models including the total particle-particle drag model,  $\mathbf{F}_{ij} = \mathbf{F}_{ij}^{pec} + \mathbf{F}_{ij}^{flu}$  represent the solid flow dynamics for dilute binary fluidized beds. However, for dense beds, additional frictional effects need to be considered. An extra frictional particle-particle drag term,  $\mathbf{F}_{ij}^{fric}$  must be taken into account. The novel total particle-particle drag is thus represented by  $\mathbf{F}_{ij} = \mathbf{F}_{ij}^{pec} + \mathbf{F}_{ij}^{flu} + \mathbf{F}_{ij}^{fric}$ . Gera et al [51] found that the conventional binary KTGF models give rise to particle segregation even for low fluidization velocities, but such a segregation phenomenon has not been confirmed by experiments. Accordingly, they concluded that in the conventional binary KTGF closure models, the conventional particle-particle drag was under-estimated for dense systems, hence a correction term was added in the particle-particle drag model to make this term sufficiently large in order to obtain physically reasonable results. In a similar manner, Fan and Fox [41] also included an extra particle-particle drag term in their closure to make the total particle-particle drag sufficiently large. Gera et al. [51] introduced the terminology *hindrance effect* in order to explain the term. In the conventional binary KTGF formulations, a granular medium consisting of two types of particles is described as two distinct phases. The two types of particles can pass each other without any hindrance since the major contacts for them are the particle collisions. When the particles are closely packed and the diameter ratio is such that the fines cannot percolate through the interstices of the packed bed, the binary particles may hinder each other. In particular, the binary particles experience the long-term enduring frictional sliding/rolling contacts. Compared with the short-term particle-particle collisions in comparatively fast flow/dilute beds, the long term friction contact is interpreted as a flow situation in which the binary particles are moving together somewhat as one phase problem. This means, the binary particles are closely coupled by the frictional particle-particle drag,  $\mathbf{F}_{ij}^{fric}$ , in such a dense state. Fan and Fox [41] did assume that the extra particle-particle drag term occurring in dense systems is proportional to the granular pressure. It is hard to verify this model assumption, as no rigorous derivation of the frictional binary particle-particle drag has been given. Nevertheless, Syamlal [144] has derived a collisional frictional binary particle-particle drag closure which considers the particle sliding motions at the short term collisions. In this work, it is assumed that the long-term binary particle-particle drag follows similar rules as the short-term collisional sliding frictional drag, but has a much longer contact time, thus a semi-empirical particle-particle frictional drag term,  $\mathbf{F}_{ij}^{fric}$ , is introduced in the model. For most of the models based on the kinetic theory of granular flow described above, the particle mass and molecular temperatures are usually uniform. However, for chemical reactors, the particle mass may change due to chemical reactions or mass transfer, and the particle molecular temperature may also change due to chemical reactions and the heat transfer from the surrounding particles or gas. In order to include these

effects due to the mass and molecular temperature changes in the KTGF model, Lathouwers and Bellan [89] derived a group of governing equations starting from an extended Boltzmann equation. Lindborg [97] also adopted a similar method to derive his general KTGF reactive flow model. The method used by Lathouwers and Bellan [89] and Lindborg [97] is inherited in this study as well. The gas phase equations for turbulent flow, are closed using the conventional  $k - \varepsilon$  turbulence model [65, 97]. In this section, the reactive KTGF model is derived for the SE-SMR fluidized bed reactors with a reasonable binary particle-particle coupling.

#### 4.4.1 Binary Particle Maxwell-Enskog Transport Equation and Balance Laws

In order to calculate the statistical average properties of the discrete single particles in the kinetic theory of granular flow, a probability density function  $f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t)$  is used, in which  $\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{\xi,i}$  are the coordinates, velocities, thermal temperatures and masses of the discrete single particles. The  $\omega_{\xi,i}$  is the single particle mass fraction of species  $\xi, i$ .  $N_{\xi,i}$  is the number of species within the single particles of type  $i$ . In reactor engineering different catalyst and sorbent particle models might be required (in kinetic controlled vs. diffusion controlled reaction regions) and combined with consistent particle representations in the fluid dynamic part of the multi-fluid model. For simplicity, the fluidized particles are normally assumed to be sufficiently small such that the reactions are kinetically controlled, and for a single particle the internal molecular temperature equilibrates rapidly and the species composition is about uniform. Thus, the single particle temperature, mass and species composition completely describe the state of the single particles. For each particle type  $i$ , the single particle distribution density function is defined such that  $f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t) d\mathbf{c}_i dm_i dT_i d\omega_{1,i} d\omega_{2,i} \dots d\omega_{N_{\xi,i}} d\mathbf{r}_i$  denotes the probable number of particles in the volume element  $d\mathbf{r}_i$  located at  $\mathbf{r}_i$ , whose velocities lie in the range  $d\mathbf{c}_i$  about  $\mathbf{c}_i$ , temperatures in the range  $dT_i$  about  $T_i$ , masses in the range  $dm_i$  about  $m_i$ , species composition in the range  $d\omega_{\xi,i}$  about  $\omega_{\xi,i}$  at time  $t$ .

Based on this density function, the number of particles per unit volume,  $n_i(\mathbf{r}, t)$ , can be calculated by [25, 89, 97]:

$$n_i(\mathbf{r}, t) = \int f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t) d\mathbf{c}_i dm_i dT_i d\omega_{1,i} d\omega_{2,i} \dots d\omega_{N_{\xi,i}} d\mathbf{r}_i \quad (4.291)$$

The particle number average of a generalized single particle property  $\psi_i(t)$  is defined as [89]:

$$\bar{\psi}_i(\mathbf{r}, t) = \frac{1}{n_i(\mathbf{r}, t)} \int \psi_i(t) f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t) d\mathbf{V} \quad (4.292)$$

where  $d\mathbf{V} = d\mathbf{c}_i dm_i dT_i d\omega_{1,i} d\omega_{2,i} \dots d\omega_{N_{\xi,i}}$  denotes the set of integration variables.

The mass-weighted average of the generalized property  $\psi_i(t)$  is introduced as [89, 97]:

$$\langle \psi_i \rangle(\mathbf{r}, t) = \frac{1}{\rho_i^B(\mathbf{r}, t)} \int m_i \psi_i f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t) d\mathbf{V} \quad (4.293)$$

The bulk density  $\rho_i^B$  is defined as:

$$\begin{aligned} \rho_i^B(\mathbf{r}, t) &= \alpha_i(\mathbf{r}, t) \bar{\rho}_i(\mathbf{r}, t) = n_i(\mathbf{r}, t) \bar{m}_i(\mathbf{r}, t) \\ &= \int m_i f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t) d\mathbf{V} \end{aligned} \quad (4.294)$$

The averages defined in (4.292) and (4.293) may be employed to transform the microscopic properties of the discrete single particles  $\psi_i(t)$  into the macroscopic variables  $\bar{\psi}_i$  and  $\langle \psi_i \rangle$  characterizing the continuous granular fluids.

By substitution of  $\psi_i = \mathbf{c}_i$ , the mass-weighted average particle velocity (i.e.,  $\mathbf{v}_i = \langle \mathbf{c}_i \rangle$ ) is given as:

$$\mathbf{v}_i(\mathbf{r}, t) = \frac{1}{\alpha_i(\mathbf{r}, t) \bar{\rho}_i(\mathbf{r}, t)} \int m_i \mathbf{c}_i f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, t) d\mathbf{V} \quad (4.295)$$

The peculiar particle velocity  $\mathbf{C}_i$ , representing the velocity difference between a discrete single particle of type  $i$  and the fluid dynamic velocity of the corresponding granular fluid phase  $i$ , is defined by:

$$\mathbf{C}_i = \mathbf{c}_i - \mathbf{v}_i \quad (2.65)$$

The granular temperature for granular fluid  $i$  is preferably defined by (4.70) as for mono-particle systems. However, it is noticed that in several of the pioneering investigations extending the fundamental granular theory to multiple particle mixtures, the granular temperature for granular fluids in multiple particle mixtures was defined somewhat differently. In particular, it might be noted that Jenkins and Mancini [70], Gidaspow [49] and Manger [105], among others, found it convenient to define the granular temperature for multiple particle mixtures as follows:

$$\Theta_i = \frac{1}{3} m_i \langle C_i^2 \rangle \quad (4.296)$$

Lathouwers and Bellan [87–91] and Chao [21], on the other hand, proposed that the granular temperature of granular fluids in multiple particle mixtures might rather be consistently defined in accordance with the mono-particle system definition (4.70). This means that the fluid dynamic velocity,  $\mathbf{v}_i$ , represents a statistical average measure of the velocities of the discrete single particles, and the granular temperature,  $\Theta_i$ , is a

statistical average measure or mean of the specific kinetic energy of the discrete single particle velocity relative to the fluid dynamic velocity. The granular temperature might thus be interpreted as a specific solids fluctuating energy.

A Boltzmann equation for particles of type  $i$ , in a multiple particle mixture, can be expressed as [89, 105]:

$$\begin{aligned} \frac{\partial f_i}{\partial t} + \mathbf{c}_i \cdot \frac{\partial f_i}{\partial \mathbf{r}_i} + \frac{\partial (\mathbf{F}_i f_i)}{\partial \mathbf{c}_i} + \frac{\partial (\frac{dm_i(t)}{dt} f_i)}{\partial m_i} + \frac{\partial (\frac{dT_i(t)}{dt} f_i)}{\partial T_i} + \sum_{\xi=1}^{N_\xi} \frac{\partial (\frac{d\omega_{\xi,i}(t)}{dt} f_i)}{\partial \omega_{\xi,i}} = \\ \sum_{j=1}^N \int (f_{ij}^{(2)}(\mathbf{r}'_i, \mathbf{c}'_i, T'_i, m'_i, \omega'_{1,i}, \omega'_{2,i}, \dots, \omega'_{N_\xi,i}, \mathbf{r}'_j, \mathbf{c}'_j, T'_j, m'_j, \omega'_{1,j}, \omega'_{2,j}, \dots, \omega'_{N_\xi,j}, t) \\ - f_{ij}^{(2)}(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_\xi,i}, \mathbf{r}_j, \mathbf{c}_j, T_j, m_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_\xi,j}, t)) \\ (\mathbf{c}_{ij} \cdot \mathbf{k}) d^2_{ij} d\mathbf{c}_j d\mathbf{k} dm_j dT_j d\omega_{1,j} d\omega_{2,j} \dots d\omega_{N_\xi,j} \end{aligned} \quad (4.297)$$

where  $\mathbf{F}_i$  denotes the external force exerted on a particle of type  $i$  per unit mass of the particle.

The RHS terms represent the effects of the collisions between particles of type  $i$  and all particles of type  $j$ . The pair density function is defined such that  $f_{ij}^{(2)}(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_\xi,i}, \mathbf{r}_j, \mathbf{c}_j, T_j, m_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_\xi,j}, t) d\mathbf{r}_i d\mathbf{r}_j \times d\mathbf{c}_i d\mathbf{c}_j dT_i dT_j dm_i dm_j d\omega_{1,i} d\omega_{1,j} d\omega_{2,i} d\omega_{2,j} \dots d\omega_{N_\xi,i} d\omega_{N_\xi,j}$  is the probability of finding a pair of particles in the volume elements  $d\mathbf{r}_i$  and  $d\mathbf{r}_j$  surrounding the points  $\mathbf{r}_i$  and  $\mathbf{r}_j$  of particle types  $i$  and  $j$  with respective velocities in the range  $\mathbf{c}_i + d\mathbf{c}_i$  and  $\mathbf{c}_j + d\mathbf{c}_j$ , masses in the range  $m_i + dm_i$  and  $m_j + dm_j$ , temperatures in the range  $T_i + dT_i$  and  $T_j + dT_j$ , particle species in the ranges  $\omega_{1,i} + d\omega_{1,i}$ ,  $\omega_{1,j} + d\omega_{1,j}$ ,  $\omega_{2,i} + d\omega_{2,i}$ ,  $\omega_{2,j} + d\omega_{2,j}$ ,  $\dots$ ,  $\omega_{N_\xi,i} + d\omega_{N_\xi,i}$  and  $\omega_{N_\xi,j} + d\omega_{N_\xi,j}$ . The unit vector directed from the center of particle  $i$  to that of particle  $j$  upon contact, is denoted by  $\mathbf{k}$ . The arguments of the pair density function represented with and without primes denote the variables after and before collisions, respectively.  $N$  denotes the number of particle types, thus the system is binary when  $N$  equals 2.

The relative velocity between particles  $i$  and  $j$  is defined as :

$$\mathbf{g}_{ij} = \mathbf{c}_i - \mathbf{c}_j \quad (4.298)$$

A macroscopic transport equation for a generalized macroscopic property  $\langle \psi_i \rangle$  was derived by multiplying the Boltzmann type of equation (4.297) by a specific single particle general property  $m_i(t)\psi_i(t)$ , and the resulting equation was mass-weighted averaged and manipulated in a similar fashion as performed with the corresponding mono-particle system equation [49, 97]. The macroscopic or mass weighted averaged form of (4.297) can be expressed as [89]:

$$\begin{aligned}
\frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \langle \psi_i \rangle) + \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{c}_i \psi_i \rangle) &= \sum_{j=1}^N \Omega_{g_{ij}}(\psi_i) - \sum_{j=1}^N \nabla \cdot \Phi_{g_{ij}}(\psi_i) \\
&+ \alpha_i \bar{\rho}_i \langle \mathbf{F}_i \frac{\partial \psi_i}{\partial \mathbf{c}_i} \rangle + \sum_{\xi=1}^{N_\xi} \alpha_i \bar{\rho}_i \langle \frac{d\omega_{\xi,i}}{dt} \frac{\partial \psi_i}{\partial \omega_{\xi,i}} \rangle + \alpha_i \bar{\rho}_i \langle \frac{dT_i}{dt} \frac{\partial \psi_i}{\partial T_i} \rangle \\
&+ \alpha_i \bar{\rho}_i \langle \frac{dm_i}{dt} (\frac{\partial \psi_i}{\partial m_i} + \frac{\psi_i}{m_i}) \rangle
\end{aligned} \tag{4.299}$$

where  $i = 1, 2, \dots, N$ .

This equation is a *Maxwell-Enskog type of equation* for multiple particle mixtures with an interstitial gas. The first term on the RHS,  $\Omega_{g_{ij}}(\psi_i)$ , denotes a collisional source. The second term,  $\Phi_{g_{ij}}(\psi_i)$ , denotes a collisional flux. In these two terms, the notation  $j$  denotes any particle type, so the two terms have both contributions from inner-collisions among particles of type  $i$  and inter-collisions between particles of type  $i$  and any other particles of type  $j$ . Detailed expressions for the two terms were derived by Gidaspow [49] for mono-particle systems, and by Manger [105] and Jenkins and Mancini [70] for binary particle systems.

Based on the work of Jenkins and Mancini [70], the collisional source term for a binary system could be expressed as:

$$\Omega_{g_{ij}}(\psi_i) = d_{ij}^2 \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} m_i(\psi'_i - \psi_i) f^{(2)}(\mathbf{g}_{ij} \cdot \mathbf{k}) d\mathbf{V} \tag{4.300}$$

where the integration variables is collectively denoted by the generalized integral volume;  $d\mathbf{V} = d\mathbf{k} d\mathbf{c}_i d\mathbf{c}_j dm_i dm_j dT_i dT_j d\omega_{1,i} d\omega_{1,j} d\omega_{2,i} d\omega_{2,j} \dots d\omega_{N_\xi,i} d\omega_{N_\xi,j}$ .

The corresponding collisional flux is expressed as:

$$\Phi_{g_{ij}}(\psi_i) = -0.5 d_{ij}^3 \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} m_i(\psi'_i - \psi_i) f^{(2)} \mathbf{k}(\mathbf{g}_{ij} \cdot \mathbf{k}) d\mathbf{V} \tag{4.301}$$

in which  $f^{(2)} = f^{(2)}(\mathbf{r} - 0.5d_{ij}\mathbf{k}, \mathbf{c}_i, m_i, h_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_\xi,i}, \mathbf{r} + 0.5d_{ij}\mathbf{k}, \mathbf{c}_j, m_j, T_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_\xi,j}, t)$ .

It is noted that the collisional source and flux terms given by (28) and (30) in Jenkins and Mancini [70] are somewhat different from the corresponding terms (9.192) and (9.193) given by Gidaspow [49] and both of these formulations are different from (2.9) and (2.10) given by Chao [21]. To a first order approximation the collisional flux terms in these reports are almost identical. The only difference is the power of the equivalent particle diameter. The reason for this difference is that Jenkins and Mancini [70] were considering circular disks whereas Gidaspow [49] on the other hand considered spherical particles. A disk (sometimes spelled disc) is the projection of a sphere on a plane perpendicular to the sphere-radiant point line. For the spheres a three-dimensional description of the collisions is achieved

through the use of the solid angle concept defined in terms of an element of surface area and the equivalent particle diameter squared. For the disks a two-dimensional description of the collisions is expressed through a reduced solid angle in terms of the arc length and the equivalent particle diameter. The collisional source terms also differ in the power of the equivalent particle diameter for the same reason as explained for the collisional flux terms. In addition, Gidaspow [49] reformulated the collisional source terms assuming that the particle property  $\psi$  is conserved in a collision  $\psi'_i + \psi'_k = \psi_i + \psi_k$  as also mentioned by Jenkins and Mancini [70]. This approach results in a prefactor  $1/2$ . Moreover, Gidaspow [49] did apply a Taylor series expansion for  $f_{ik}^{(2)}$  at  $\mathbf{r} - d_{12}\mathbf{k}$  and  $\mathbf{r}$ , whereas Jenkins and Mancini [70] did apply a Taylor series expansion for  $f_{ik}^{(2)}$  at  $\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}$  and at  $\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}$ . Nevertheless, in later applications of the collisional source as expressed through (9.212) Gidaspow [49] used the same Taylor series expansion approximation as proposed by Jenkins and Mancini [70]. Chao [21] did apply a Taylor series expansion for  $f_{ik}^{(2)}$  at  $\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}$  and at  $\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}$  giving an approximation very similar to the result of Jenkins and Mancini [70].

#### 4.4.1.1 Balance Laws

Substituting the single particle general property  $\psi_i(t)$  by the variables:  $1$ ,  $\mathbf{c}_i(t)$ ,  $\frac{1}{2}c_i^2(t)$ ,  $h_i(t)$  and  $\omega_i(t)$  respectively, and after introducing (2.65), (4.296), (4.300) and (4.301) into (4.299), the continuum transport equations for the solid phase fluid mass, momentum, granular temperature, molecular enthalpy and the species mass can be obtained with some further manipulations.

*Continuity:*

Substituting the general property value  $\psi_i = 1$  into (4.299), the first and second terms on the LHS becomes:

$$\frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i) + \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{c}_i \rangle) = \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i) \quad (4.302)$$

The first five terms on the RHS of (4.299) vanish since the specific property  $\psi_i$  equals a constant. The first part of the last term on the RHS of (4.299), vanishes too. Therefore, the complete continuity equations reduce to the form:

$$\frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i) = \alpha_i \bar{\rho}_i \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle \quad (4.303)$$

The mass transfer rate  $\Gamma_i$  is defined as:

$$\Gamma_i = \alpha_i \bar{\rho}_i \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle \quad (4.304)$$

For a sorbent particle there are gas–solid reactions taking place and thus mass transfer between the continuous and sorbent phases. If particle phase 2 is the sorbent phase, the mass transfer balance is:

$$\Gamma_0 = -\Gamma_2 \quad (4.305)$$

For the catalyst particle phase, no net mass transfer occurs, thus for particle phase 1 the source term is zero:

$$\Gamma_1 = 0 \quad (4.306)$$

*Momentum:*

Substituting the general property  $\psi_i = \mathbf{c}_i(t)$  into (4.299), the first term on the LHS of (4.299) becomes:

$$\frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \langle \mathbf{c}_i \rangle) = \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \mathbf{v}_i) \quad (4.307)$$

The second term on the LHS of (4.299) becomes:

$$\begin{aligned} \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{c}_i \mathbf{c}_i \rangle) &= \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{v}_i \mathbf{v}_i + \mathbf{C}_i \mathbf{C}_i + \mathbf{v}_i \mathbf{C}_i + \mathbf{C}_i \mathbf{v}_i \rangle) \\ &= \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i \mathbf{v}_i) + \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i \mathbf{C}_i \rangle) \end{aligned} \quad (4.308)$$

The first term on the RHS of (4.299),  $\Omega_{gij}(\psi_i)$ , is a source term which is determined using (4.300).

The second term on the RHS of (4.299) is a flux term,  $\Phi_{gij}(\psi_i)$ , that is determined by (4.301). This flux equals the collisional pressure tensor, i.e.,  $\mathbf{p}_i^{coll} = \Phi_{gij}(\mathbf{c}_i)$ .

The third term on the RHS of (4.299) becomes:

$$\alpha_i \bar{\rho}_i \langle \mathbf{F}_i \cdot \frac{\partial \mathbf{c}_i}{\partial \mathbf{c}_i} \rangle = \alpha_i \bar{\rho}_i \langle \mathbf{F}_i \rangle \quad (4.309)$$

The fourth and fifth terms on the RHS of (4.299) vanish because the particle velocity,  $\mathbf{c}_i(t)$ , is independent of the single particle species,  $\omega_{\xi,i}$ , and the single particle molecular temperature,  $T_i$ , by definition. Likewise, the first part of the last term vanishes as the single particle velocity  $\mathbf{c}_i(t)$  is independent of the single particle mass. It follows that the solid phase fluid momentum equation is reduced to the form:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \mathbf{v}_i) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i \mathbf{v}_i) &= -\nabla \cdot \mathbf{p}_i + \sum_{j=1}^N \Omega_{gij}(\mathbf{c}_i) + \alpha_i \bar{\rho}_i \langle \mathbf{F}_i \rangle \\ &\quad + \alpha_i \bar{\rho}_i \left\langle \frac{\mathbf{c}_i}{m} \frac{dm_i}{dt} \right\rangle \end{aligned} \quad (4.310)$$

in which the total particle pressure tensor is defined as a linear sum of the kinetic and collisional contributions in the same way as for the mono-particle system (4.157):

$\mathbf{p}_i = \mathbf{p}_i^{kin} + \mathbf{p}_i^{coll}$ . The kinetic pressure tensor,  $\mathbf{p}_i^{kin} = \alpha_i \bar{\rho}_i \langle \mathbf{C}_i \mathbf{C}_i \rangle$ , is due to the translational motion of the particles as can be seen from (4.308).

The second term on the RHS of (4.299) denotes the collisional pressure tensor,  $\mathbf{p}_i^{coll} = \Phi_{gij}(\mathbf{c}_i)$ , which is due to the collisions of the particles.

The last term in (4.299) denotes the mass transfer induced momentum transfer and was approximated by neglecting the gas dynamic velocity fluctuations [97]:

$$\alpha_i \bar{\rho}_i \left\langle \frac{\mathbf{c}_i}{m} \frac{dm_i}{dt} \right\rangle \approx \alpha_i \bar{\rho}_i \left\langle \frac{1}{m} \frac{dm_i}{dt} \right\rangle \langle \mathbf{c}_i \rangle \approx \Gamma_i \mathbf{v}_i \quad (4.311)$$

The first part of this term vanishes as the particle properties are independent properties.

*Granular temperature:*

Substituting the general property  $\psi_i = \frac{1}{2} c_i^2$  into (4.299), the first term on the LHS becomes:

$$\begin{aligned} \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i \frac{1}{2} \langle c_i^2 \rangle) &= \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i \frac{1}{2} \langle \mathbf{c}_i \cdot \mathbf{c}_i \rangle) = \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i \frac{1}{2} \langle (\mathbf{C}_i + \mathbf{v}_i) \cdot (\mathbf{C}_i + \mathbf{v}_i) \rangle) \\ &= \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i \frac{1}{2} \langle \mathbf{v}_i \cdot \mathbf{v}_i + \mathbf{C}_i \cdot \mathbf{C}_i + \mathbf{C}_i \cdot \mathbf{v}_i + \mathbf{v}_i \cdot \mathbf{C}_i \rangle) \\ &= \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i \frac{1}{2} \langle v_i^2 + C_i^2 \rangle) = \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i (\frac{1}{2} v_i^2 + \frac{3}{2} \Theta_i)) \end{aligned} \quad (4.312)$$

The second term on the LHS of (4.299) becomes:

$$\begin{aligned} \nabla \cdot (\alpha_i \bar{\rho}_i \langle \frac{1}{2} \mathbf{c}_i c_i^2 \rangle) &= \nabla \cdot (\alpha_i \bar{\rho}_i \langle \frac{1}{2} \mathbf{c}_i (\mathbf{c}_i \cdot \mathbf{c}_i) \rangle) \\ &= \nabla \cdot (\alpha_i \bar{\rho}_i \langle \frac{1}{2} \mathbf{c}_i (\mathbf{v}_i + \mathbf{C}_i) \cdot (\mathbf{v}_i + \mathbf{C}_i) \rangle) \\ &= \nabla \cdot (\alpha_i \bar{\rho}_i \frac{1}{2} \langle (\mathbf{v}_i + \mathbf{C}_i) (\mathbf{v}_i \cdot \mathbf{v}_i + \mathbf{C}_i \cdot \mathbf{C}_i + 2\mathbf{v}_i \cdot \mathbf{C}_i) \rangle) \\ &= \nabla \cdot (\alpha_i \bar{\rho}_i (\frac{1}{2} \langle \mathbf{C}_i C_i^2 \rangle + \mathbf{v}_i \cdot \langle \mathbf{C}_i \mathbf{C}_i \rangle + \frac{1}{2} \mathbf{v}_i \langle C_i^2 \rangle + \frac{1}{2} \mathbf{v}_i v_i^2)) \\ &= \nabla \cdot (\alpha_i \bar{\rho}_i (\frac{1}{2} \langle \mathbf{C}_i C_i^2 \rangle + \frac{3}{2} \mathbf{v}_i \Theta_i + \frac{1}{2} \mathbf{v}_i v_i^2) + \mathbf{p}_i^{kin} \cdot \mathbf{v}_i) \end{aligned} \quad (4.313)$$

The first term on the RHS of (4.299) is a source term which is determined using (4.300).

The second term on the RHS of (4.299) is normally decomposed as:

$$\begin{aligned}
\nabla \cdot \Phi_{gij} \left( \frac{1}{2} c_i^2 \right) &= \nabla \cdot \Phi_{gij} \left( \frac{1}{2} (\mathbf{C}_i + \mathbf{v}_i) \cdot (\mathbf{C}_i + \mathbf{v}_i) \right) \\
&= \nabla \cdot \Phi_{gij} \left( \frac{1}{2} C_i^2 + \mathbf{v}_i \cdot \mathbf{C}_i + \frac{1}{2} v_i^2 \right) = \nabla \cdot \Phi_{gij} \left( \frac{1}{2} C_i^2 + \mathbf{v}_i \cdot \mathbf{c}_i \right) \\
&= \nabla \cdot \Phi_{gij} \left( \frac{1}{2} C_i^2 \right) + \mathbf{v}_i \cdot \mathbf{p}_i^{coll}
\end{aligned} \tag{4.314}$$

To calculate  $\Phi_{gij}(v_i^2)$  from (4.301) it is noted that the statistical average velocity  $\mathbf{v}_i$  does not change before and after a collision, i.e.  $\mathbf{v}_i = \mathbf{v}_i'$ . For this reason,  $\Phi_{gij}(v_i^2) = 0$ .

The third term on the RHS of (4.299) could be manipulated as:

$$\alpha_i \bar{\rho}_i \langle \mathbf{F}_i \frac{\partial(\frac{1}{2} c_i^2)}{\partial \mathbf{c}_i} \rangle = \alpha_i \bar{\rho}_i \langle \mathbf{F}_i \frac{\partial(\frac{1}{2} \mathbf{c}_i \cdot \mathbf{c}_i)}{\partial \mathbf{c}_i} \rangle = \alpha_i \bar{\rho}_i \langle \mathbf{F}_i \cdot \mathbf{c}_i \rangle \tag{4.315}$$

The fourth and fifth terms vanish because the kinetic energy  $\frac{1}{2} c_i^2$  is independent of the particle species  $\omega_{\xi,i}$  and the molecular temperature  $T_i$ , by definition. Similarly, the first part of the last term vanishes because  $\frac{1}{2} c_i^2$  is independent of the single particle mass.

Taking the scalar vector product of  $\mathbf{v}_i$  and the macroscopic momentum equation (4.310), and subtracting the resulting equation from the combined macroscopic granular energy—and kinetic energy equation derived from (4.299) with the given closures, the granular temperature equations can be obtained on the form:

$$\begin{aligned}
\frac{3}{2} \frac{\partial}{\partial t} (\alpha_i \bar{\rho}_i \Theta_i) + \frac{3}{2} \nabla \cdot \alpha_i \bar{\rho}_i \mathbf{v}_i \Theta_i &= -\mathbf{p}_i : \nabla \mathbf{v}_i - \nabla \cdot (\mathbf{q}_i^{kin} + \mathbf{q}_i^{coll}) \\
&+ \alpha_i \bar{\rho}_i \langle \mathbf{F}_i \cdot \mathbf{C}_i \rangle + \sum_{j=1}^N \Omega_{gij} \left( \frac{1}{2} \mathbf{c}_i^2 \right) + \alpha_i \bar{\rho}_i \left\langle \frac{C_i^2}{2m_i} \frac{dm_i}{dt} \right\rangle
\end{aligned} \tag{4.316}$$

where  $\mathbf{q}_i^{kin} = \alpha_i \bar{\rho}_i \langle \frac{1}{2} C_i^2 \mathbf{C}_i \rangle$  represents the kinetic heat flux and  $\mathbf{q}_i^{coll} = \Phi_{gij}(\frac{1}{2} C_i^2)$  denotes the collisional heat flux, respectively.

The last term in (4.316) denotes the mass transfer induced granular energy transfer and was approximated by assuming the average of products equal the products of average [97]:

$$\alpha_i \bar{\rho}_i \left\langle \frac{C_i^2}{2m_i} \frac{dm_i}{dt} \right\rangle \approx \alpha_i \bar{\rho}_i \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle \left\langle \frac{1}{2} C_i^2 \right\rangle \approx \frac{3}{2} \Gamma_i \Theta_i \tag{4.317}$$

*Molecular enthalpy:*

Substituting  $\psi_i = h_i(t)$ , in which  $h_i(t)$  is the specific enthalpy of a single particle, into (4.299), the continuum fluid enthalpy transport equations can be obtained:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \langle h_i \rangle) + \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{c}_i h_i \rangle) &= \sum_{j=1}^N \Omega_{g_{ij}}(h_i) - \sum_{j=1}^N \nabla \cdot \Phi_{g_{ij}}(h_i) \\ &+ \sum_{\xi=1}^{N_\xi} \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \rangle + \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial T_i} \frac{dT_i}{dt} \rangle + \alpha_i \bar{\rho}_i \langle \frac{h_i}{m_i} \frac{dm_i}{dt} \rangle \end{aligned} \quad (4.318)$$

Applying (2.65) and decomposing the enthalpy quantity into an average and a fluctuating part,  $h_i = \langle h_i \rangle + h'_i$ , the convective term can be written as:

$$\nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{c}_i h_i \rangle) = \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i \langle h_i \rangle) + \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i h'_i \rangle) \quad (4.319)$$

It follows that (4.318) can be expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \langle h_i \rangle) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i \langle h_i \rangle) &= \sum_{j=1}^N \Omega_{g_{ij}}(h_i) - \sum_{j=1}^N \nabla \cdot \Phi_{g_{ij}}(h_i) \\ &- \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i h'_i \rangle) + \sum_{\xi=1}^{N_\xi} \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \rangle \\ &+ \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial T_i} \frac{dT_i}{dt} \rangle + \alpha_i \bar{\rho}_i \langle \frac{dm_i}{dt} \frac{h_i}{m_i} \rangle \end{aligned} \quad (4.320)$$

Further manipulation of the LHS of (4.320) into the non-conservative form by use of the continuity equation (4.303), gives:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \langle h_i \rangle) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i \langle h_i \rangle) \\ &= \alpha_i \bar{\rho}_i \left( \frac{\partial \langle h_i \rangle}{\partial t} + \mathbf{v}_i \cdot \nabla \langle h_i \rangle \right) + \langle h_i \rangle \left( \frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i) \right) \\ &= \alpha_i \bar{\rho}_i \left( \frac{\partial \langle h_i \rangle}{\partial t} + \mathbf{v}_i \cdot \nabla \langle h_i \rangle \right) + \alpha_i \bar{\rho}_i \left( \langle h_i \rangle \langle \frac{1}{m_i} \frac{dm_i}{dt} \rangle \right) \end{aligned} \quad (4.321)$$

The first two terms on the RHS corresponds to the substantial derivative operator:

$$\frac{D \langle h_i \rangle}{Dt} = \frac{\partial \langle h_i \rangle}{\partial t} + \mathbf{v}_i \cdot \nabla \langle h_i \rangle \quad (4.322)$$

Inserting (4.321) into (4.320), yields:

$$\begin{aligned} \alpha_i \bar{\rho}_i \frac{D \langle h_i \rangle}{Dt} &= \sum_{j=1}^N \Omega_{g_{ij}}(h_i) - \sum_{j=1}^N \nabla \cdot \Phi_{g_{ij}}(h_i) \\ &- \nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i h'_i \rangle) + \sum_{\xi=1}^{N_\xi} \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \rangle \\ &+ \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial T_i} \frac{dT_i}{dt} \rangle + \alpha_i \bar{\rho}_i \langle \frac{h_i}{m_i} \frac{dm_i}{dt} \rangle - \alpha_i \bar{\rho}_i \langle h_i \rangle \langle \frac{1}{m_i} \frac{dm_i}{dt} \rangle \end{aligned} \quad (4.323)$$

The first and second terms on the RHS of (4.299) and (4.323) are two collisional terms. Due to the limited understanding of the physics represented by these terms, the two terms are neglected as suggested by Lathouwers and Bellan [89] and Lindborg [97]. Further work might be required on the modeling of these terms as one of the distinctive characteristics of dense flows is that momentum and energy are primarily exchanged through collisions between particles rather than through the gaseous phase.

Assuming,  $\langle \frac{dm_i}{dt} \frac{h_i}{m_i} \rangle \approx \langle h_i \rangle \langle \frac{1}{m_i} \frac{dm_i}{dt} \rangle$ , the last two terms cancel out, and (4.323) becomes:

$$\alpha_i \bar{\rho}_i \frac{D\langle h_i \rangle}{Dt} = -\nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i h_i' \rangle) + \sum_{\xi=1}^{N_\xi} \alpha_i \bar{\rho}_i \left\langle \frac{\partial h_i}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \right\rangle + \alpha_i \bar{\rho}_i \left\langle \frac{\partial h_i}{\partial T_i} \frac{dT_i}{dt} \right\rangle \quad (4.324)$$

By use of the local instantaneous equilibrium assumption in the non-equilibrium thermodynamics framework, we assume that the result of the total differential of the enthalpy property (1.151) might be adopted for the particle phase fluid:

$$\begin{aligned} \frac{D\langle h_i \rangle}{Dt} = & \langle C_{p,i} \rangle \frac{D\langle T_i \rangle}{Dt} + \left( \frac{1}{\bar{\rho}_i} + \frac{\langle T_i \rangle}{\bar{\rho}_i} \left\langle \frac{\partial \rho_i}{\partial T_i} \right\rangle_{p,\omega} \right) \frac{D\langle p_i \rangle}{Dt} \\ & + \sum_{r=1}^q \langle R_{r,cref} \rangle \langle (-\Delta H_{R,cref}) \rangle \frac{1}{M_{\omega_{cref}}} \end{aligned} \quad (4.325)$$

Since the granular phase is considered incompressible (i.e., constant density) and the solid phase enthalpy is independent of the solid phase pressure  $p_i$ , the second term on the RHS in (4.325) has no physical meaning and is thus erased. The third term on the RHS of (4.325) considers homogeneous reactions in the granular phase. Such reactions are not taking place in catalyst and sorbent particles, thus this term is erased too. Thus, in chemical reactors the particle phase enthalpy is related to the temperature solely:

$$\frac{D\langle h_i \rangle}{Dt} = \langle C_{p,i} \rangle \frac{D\langle T_i \rangle}{Dt} \quad (4.326)$$

Likewise, for a single particle the change in particle enthalpy is related to changes in particle temperature as:

$$dh_i = C_{p,i} dT_i, \quad (4.327)$$

Thus, the following approximation might be performed:

$$\frac{\partial h_i}{\partial T_i} = C_{p,i} \quad (4.328)$$

Hence, with these two thermodynamic relations (4.324) can be expressed as:

$$\alpha_i \bar{\rho}_i \langle C_{p,i} \rangle \frac{D\langle T_i \rangle}{Dt} = -\nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i \mathbf{h}_i' \rangle) + \sum_{\xi=1}^{N_\xi} \alpha_i \bar{\rho}_i \langle \frac{\partial h_i}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \rangle + \alpha_i \bar{\rho}_i \langle C_{p,i} \frac{dT_i}{dt} \rangle \quad (4.329)$$

The second term on the RHS of (4.329) is related to the heat released by changes in the single particle chemical composition due to interfacial mass transfer and surface reactions.

*The single particle dynamics for catalyst and sorbent particles:*

The collisional terms on the RHS were neglected based on the postulate that there is no direct sorbent-sorbent, catalyst-catalyst or sorbent-catalyst inter-particle heat exchange. Based on this approximation, we assume the changes in enthalpy for a single *catalyst* particle is solely determined by the gas—solid heat exchange resulting from convection and conduction:

$$m_i \frac{dh_i}{dt} = -Q_i^c \quad (4.330)$$

The heats of reaction for catalytic reactions are placed in the continuous phase heat balance for modeling consistency (the catalytic reactions are placed in the continuous phase species mass balances). This approach is an approximations of the physical process as for most catalytic processes both the gas reactants/products and the catalyst molecules will be heated.

No net mass transfer between the gas and the catalyst particles takes place, but the reactive gas species and the gas products diffuse to and away from the catalyst particle surface where the reactants/products are adsorbed/desorbed on the active sites. In the current pseudo-homogeneous modeling approach such effects might be considered by use of an external efficiency factor. However, as a first approach this mass transfer effect is neglected.

Changes in enthalpy of a single *sorbent* particle are caused by the gas—solid heat exchange resulting from convection and conduction, and the heat transferred by the mass exchange:

$$m_i \frac{dh_i}{dt} = -Q_i^c + \frac{dm_i}{dt} (h_0 - h_i) \quad (4.331)$$

Equation (4.331) can be considered a general expression valid both for the sorbent and catalyst pellets. The relation can be reduced to Eq. (4.330) by neglecting the last term.

Employing (4.327), the local instantaneous equilibrium assumption might be invoked:

$$\frac{dh_i}{dt} = C_{p,i} \frac{dT_i}{dt} \quad (4.332)$$

Inserting equations (4.326) and (4.332) into (4.329), the transport equation of the catalyst particle phase thermal temperature is obtained:

$$C_{p,1}\alpha_1\bar{\rho}_1\frac{D\langle T_1\rangle}{Dt} = -\nabla \cdot (\alpha_1\bar{\rho}_1\langle \mathbf{C}_1 h'_1 \rangle) - \alpha_1\bar{\rho}_1\langle \frac{Q_1^c}{m_1} \rangle \quad (4.333)$$

The corresponding transport equation for the sorbent particle phase thermal temperature can be expressed as:

$$C_{p,2}\alpha_2\bar{\rho}_2\frac{D\langle T_2\rangle}{Dt} = -\nabla \cdot (\alpha_2\bar{\rho}_2\langle \mathbf{C}_2 h'_2 \rangle) - \alpha_2\bar{\rho}_2\langle \frac{Q_2^c}{m_2} \rangle + \alpha_2\bar{\rho}_2\langle \frac{dm_2}{dt} \frac{(h_0 - h_2)}{m_2} \rangle \quad (4.334)$$

*Species Mass Balance:*

Substituting  $\psi_i = \omega_i$ , where  $\omega_i$  is the mass fraction of species  $\xi$  in a particle of granular fluid  $i$ , into (4.299), a transport equation for the species mass fraction  $\omega_i$  is obtained:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_i\bar{\rho}_i\langle \omega_i \rangle) + \nabla \cdot (\alpha_i\bar{\rho}_i\langle \mathbf{c}_i \omega_i \rangle) &= \sum_{j=1}^N \Omega_{gij}(\omega_i) - \sum_{j=1}^N \nabla \cdot \Phi_{gij}(\omega_i) \\ &+ \sum_{\xi=1}^{N_\xi} \alpha_i\bar{\rho}_i\langle \frac{\partial \omega_i}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \rangle + \alpha_i\bar{\rho}_i\langle \frac{dT_i}{dt} \frac{\partial \omega_i}{\partial T_i} \rangle + \alpha_i\bar{\rho}_i\langle \frac{dm_i}{dt} (\frac{\partial \omega_i}{\partial m_i} + \frac{\omega_i}{m_i}) \rangle \end{aligned} \quad (4.335)$$

Neglecting the first and second terms on the RHS of (4.335) representing two collisional effects, introducing the peculiar velocity in some of the remaining terms by use of (2.65), and decomposing the species mass fraction property into an average and a fluctuating part, i.e.,  $\omega_i = \langle \omega_i \rangle + \omega'_i$ , the transport equation can be manipulated as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_i\bar{\rho}_i\langle \omega_{\xi,i} \rangle) + \nabla \cdot (\alpha_i\bar{\rho}_i\mathbf{v}_i\langle \omega_{\xi,i} \rangle) &= -\nabla \cdot (\alpha_i\bar{\rho}_i\langle \mathbf{C}_i \omega'_i \rangle) \\ &+ \sum_{\xi=1}^{N_\xi} \alpha_i\bar{\rho}_i\langle \frac{\partial \omega_{\xi,i}}{\partial \omega_{\xi,i}} \frac{d\omega_{\xi,i}}{dt} \rangle + \alpha_i\bar{\rho}_i\langle \frac{dT_i}{dt} \frac{\partial \omega_{\xi,i}}{\partial T_i} \rangle + \alpha_i\bar{\rho}_i\langle \frac{dm_i}{dt} (\frac{\partial \omega_{\xi,i}}{\partial m_i} + \frac{\omega_{\xi,i}}{m_i}) \rangle \end{aligned} \quad (4.336)$$

The first term on the RHS of (4.336) may lead to a diffusive term that can be modelled by use of the gradient and Boussinesq hypotheses:

$$\mathbf{j}_{i,\xi} = \bar{\rho}_i\langle \mathbf{C}_i \omega'_i \rangle \approx -\bar{\rho}_i D_{\xi,\xi,i} \nabla \langle \omega_i \rangle \quad (4.337)$$

The second term on the RHS of (4.336) vanishes since  $\partial \omega_{\xi,i} / \partial \omega_{\xi,i} = 1$  and  $\sum_{\xi} \omega_{\xi,i} = 1$ . The third term on the RHS of (4.336) vanishes because  $\omega_{\xi,i}$  is considered independent of  $T_i$  by definition of the particle properties in the KTGF framework. Likewise, the first part in the last term on the RHS of (4.336) vanishes because  $\omega_{\xi,i}$  is considered independent of  $m_i$  by definition.

The reduced species mass balance equation can thus be expressed as:

$$\frac{\partial}{\partial t}(\alpha_i\bar{\rho}_i\langle \omega_{\xi,i} \rangle) + \nabla \cdot (\alpha_i\bar{\rho}_i\mathbf{v}_i\langle \omega_{\xi,i} \rangle) = \nabla \cdot (\alpha_i\bar{\rho}_i D_{\xi,\xi,i} \nabla \langle \omega_i \rangle) + \alpha_i\bar{\rho}_i\langle \frac{dm_i}{dt} (\frac{\omega_{\xi,i}}{m_i}) \rangle \quad (4.338)$$

The last term on the RHS might be approximated as:

$$\left\langle \frac{dm_i}{dt} \frac{\omega_{\xi,i}}{m_i} \right\rangle \approx \left\langle \frac{dm_i}{dt} \frac{1}{m_i} \right\rangle \langle \omega_{\xi,i} \rangle = \Gamma_1 \langle \omega_{\xi,i} \rangle \quad (4.339)$$

The final form of the last term is determined by the single particle dynamics. For a single *catalyst* particle the species mass balance becomes:

$$\sum_{\xi} \frac{d(m_i \omega_{\xi,i})}{dt} = m_i \sum_{\xi} \frac{d\omega_{\xi,i}}{dt} + \sum_{\xi} \omega_{\xi,i} \frac{dm_i}{dt} = \frac{dm_i}{dt} = 0 \quad (4.340)$$

For a single *sorbent* particle the species mass balance becomes:

$$\sum_{\xi} \frac{d(m_i \omega_{\xi,i})}{dt} = m_i \sum_{\xi} \frac{d\omega_{\xi,i}}{dt} + \sum_{\xi} \omega_{\xi,i} \frac{dm_i}{dt} = \frac{dm_i}{dt} = m_i \sum_{\xi} R_{\xi,i} \quad (4.341)$$

Hence, for gas–solid reactions:

$$\Gamma_2 = \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle = \sum_{\xi} \langle R_{\xi,i} \rangle \neq 0. \quad (4.342)$$

## 4.4.2 Constitutive Relations for the Particle Phase Closure

In this section the constitutive equations for the collisional sources and fluxes are derived.

### 4.4.2.1 The Pair Distribution Function

In order to calculate the collisional sources and collisional fluxes, a pair density function  $f_{ij}^{(2)}(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi},i}, \mathbf{r}_j, \mathbf{c}_j, T_j, m_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_{\xi},j}, t)$  is required. With the assumption of particulate chaos, i.e., the velocities of two particles are about to collide are uncorrelated, and the information on the particle velocity of a certain particle is lost after only a few collisions [149, 150, 154], the function is related to the single density distribution function,  $f_i(r_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi},i}, t)$ , which is defined as [87, 105]:

$$\begin{aligned} f_{ij}^{(2)}(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi},i}, \mathbf{r}_j, \mathbf{c}_j, T_j, m_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_{\xi},j}, t) \\ \approx g_{0,ij}(\alpha_i, \alpha_j) \times f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi},i}, t) \\ \times f_j(\mathbf{r}_j, \mathbf{c}_j, T_j, m_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_{\xi},j}, t) \end{aligned} \quad (4.343)$$

where  $g_{0,ij}(\alpha_i, \alpha_j)$  is the radial distribution function which considers the effects of the volume correction due to finite particle size in dense systems.

By the assumption of particulate chaos, the collisional pair distribution function was expanded in Taylor series following a similar approach as for mono-particle mixtures (4.25):

$$\begin{aligned} f_{ik}^{(2)} \left( \mathbf{r} - \frac{1}{2} d_{p,ik} \mathbf{k}, \mathbf{c}_{1,i}, \dots; \mathbf{r} + \frac{1}{2} d_{p,ik} \mathbf{k}, \mathbf{c}_{2,k}, \dots \right) \\ = g_{0,ik}(\alpha_i, \alpha_k) f_{ik}^{(1)} \left( \mathbf{r} - \frac{1}{2} d_{p,ik} \mathbf{k}, \mathbf{c}_{1,i}, \dots \right) f_{ik}^{(1)} \left( \mathbf{r} + \frac{1}{2} d_{p,ik} \mathbf{k}, \mathbf{c}_{2,k}, \dots \right) \\ = g_{0,ik}(\alpha_i, \alpha_k) \left[ f_i f_k + \frac{1}{2} d_{p,ik} \mathbf{k} f_i f_k \nabla \frac{f_k}{f_i} \right] \end{aligned} \quad (4.344)$$

In most investigations, a Maxwellian single distribution function is used [49, 87, 97]:

$$\begin{aligned} f_i(\mathbf{r}_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_\xi,i}, t) = n_i \left( \frac{1}{2\pi\Theta_i} \right)^{\frac{3}{2}} \exp \left[ -\frac{1}{2\Theta_i} (\mathbf{c}_i - \mathbf{v}_i)^2 \right] \times \\ \delta(m_i - \bar{m}_i) \delta(T_i - \langle T_i \rangle) \delta(\omega_{1,i} - \langle \omega_{1,i} \rangle) \delta(\omega_{2,i} - \langle \omega_{2,i} \rangle) \dots \delta(\omega_{N_\xi,i} - \langle \omega_{N_\xi,i} \rangle) \end{aligned} \quad (4.345)$$

where  $\delta$  denotes the Dirac delta function,  $\delta(m_i - \bar{m}_i)$  thus means that this term is 1 when  $m_i \rightarrow \bar{m}_i$ , and so forth for the other properties.

#### 4.4.2.2 The Collisional Pressure Tensor

Inserting  $\psi_i = \mathbf{c}_i$  into (4.301), and using the collisional dynamics relationships the collisional pressure tensor can be determined. The particular collisional dynamics relation needed can be deduced from the relationships discussed in Sect. 2.4.2.

In (2.111) the relative velocity is define as  $\mathbf{g}_{12} = \mathbf{c}_1 - \mathbf{c}_2$ . Moreover, in (2.110) the  $\mathbf{g}_{12}$  before and after a collision is related as  $(\mathbf{g}'_{12} \cdot \mathbf{k}) = -e_{ik}(\mathbf{g}_{12} \cdot \mathbf{k})$ , where  $e_{ik}$  is the restitution coefficient. Further, the sum of the binary particle system masses is denoted by:

$$m_{c,ik} = m_i + m_k \quad (4.346)$$

The center of mass velocity,  $\mathbf{G}$ , is constant during a collision as can be seen from (2.538). From these relations the velocity relationship can be derived in a similar manner as for dilute gas (2.133) and mono-particle systems (4.52). For binary particle mixtures the velocity relation becomes (Manger [105], p. 86; Lathouwers and Bellan ([87], p. 8):

$$\mathbf{c}'_{1,i} - \mathbf{c}_{1,i} = \frac{m_j}{m_{c,ij}} (\mathbf{g}'_{12,ij} - \mathbf{g}_{12,ij}) = -\frac{m_j}{m_{c,ij}} (1 + e_{ij}) (\mathbf{k} \cdot \mathbf{g}_{12,ij}) \mathbf{k}, \quad (4.347)$$

$$\mathbf{c}'_{2,j} - \mathbf{c}_{2,j} = \frac{m_i}{m_{c,ij}} (\mathbf{g}'_{12,ij} - \mathbf{g}_{12,ij}) = -\frac{m_i}{m_{c,ij}} (1 + e_{ij}) (\mathbf{k} \cdot \mathbf{g}_{12,ij}) \mathbf{k} \quad (4.348)$$

The collisional pressure tensor is thus approximated as:

$$\begin{aligned}
\mathbf{p}_i^{coll} = & \sum_{j=1}^N \frac{1}{2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i^{(1)} f_j^{(1)} \mathbf{k} \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k})^2 d\mathbf{V} \\
& + \sum_{j=1}^N \frac{1}{4} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i^{(0)} f_j^{(0)} \mathbf{k} \cdot \nabla \frac{f_i^{(0)}}{f_k^{(0)}} \mathbf{k} \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k})^2 d\mathbf{V}
\end{aligned} \quad (4.349)$$

which corresponds to equation (A.11) in Manger ([105], p. 129).

Using the integral theorems (E.1), (E.2) and (E.5) for vectors and tensors [25, 105], and changing the integrals from integrating over  $d\mathbf{c}_i d\mathbf{c}_j$  into  $d\mathbf{C}_i d\mathbf{C}_j$ , the novel collisional pressure tensor yields (App E.2.1):

$$\mathbf{p}_i^{coll} = \alpha_i p_i^{coll} \mathbf{e} - \sum_{j=1}^2 \alpha_i (2\mu_i^{coll} \mathbf{S}_i + \mu_i^{coll,B} \nabla \cdot \mathbf{v}_i \mathbf{e} + 2\mu_j^{coll} \mathbf{S}_j + \mu_j^{coll,B} \nabla \cdot \mathbf{v}_j \mathbf{e}) \quad (4.350)$$

The standard deformation strain tensor is given by:

$$\mathbf{S}_i = \frac{1}{2} (\nabla \mathbf{v}_i + (\nabla \mathbf{v}_i)^T) - \frac{1}{3} (\nabla \cdot \mathbf{v}_i) \mathbf{e} \quad (4.351)$$

The collisional particle pressure is given as:

$$p_i^{coll} = \sum_{j=1}^2 d_{ij}^3 g_{0,ij} (1 + e_{ij}) \frac{\pi \alpha_j \rho_i \rho_j}{3(\bar{m}_i + \bar{m}_j)} (\Theta_i + \Theta_j) \quad (4.352)$$

The particle viscosities are computed as:

$$\mu_i^{coll} = \frac{\sqrt{2\pi} \alpha_j \rho_i \rho_j}{72(\bar{m}_i + \bar{m}_j)} (1 + e_{ij}) g_{0,ij} d_{ij}^4 (4\Theta_i^{0.5} + 3\Theta_j^{0.5} - 1.9550\Theta_i^{0.25}\Theta_j^{0.25}) \quad (4.353)$$

The bulk particle viscosity equals two times of the corresponding collisional viscosity.

$$\mu_i^{coll,B} = 2\mu_i^{coll}. \quad (4.354)$$

#### 4.4.2.3 Momentum Source

The source term of the momentum equation is given as:

$$\sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{g}_i) = \sum_{j=1}^N d_{ij}^2 \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} m_i (\mathbf{c}_i' - \mathbf{c}_i) f^{(2)}(\mathbf{r} - 0.5d_{ij}\mathbf{k}, \mathbf{c}_i, m_i, T_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, \mathbf{r} + 0.5d_{ij}\mathbf{k}, \mathbf{c}_j, m_j, T_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_{\xi,j}}, t) (\mathbf{g}_{ij} \cdot \mathbf{k}) d\mathbf{V} \quad (4.355)$$

Applying the collisional dynamics relation (4.347) and the pair distribution function (4.343), Eq. (4.355) becomes (e.g., Eq. (A.25) in Manger [105]):

$$\begin{aligned} \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{c}_i) = & - \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) g_{0,ij} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{ij})^2 \mathbf{k} f_i f_j d\mathbf{V} \quad (4.356) \\ & - \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} \frac{d_{ij}^3}{2} (1 + e_{ij}) g_{0,ij} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{ij})^2 \mathbf{k} f_i f_j \mathbf{k} \cdot \nabla \frac{f_j}{f_i} d\mathbf{V} \end{aligned}$$

Neglecting the second part, and using the integral theorem (App E.2) [25, 105], the collisional source term becomes (App E.2.2):

$$F_i = \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{c}_i) = \sum_{j=1}^N \beta_{ij}(\mathbf{v}_j - \mathbf{v}_i) \quad (4.357)$$

This term denotes the particle-particle drag force. Moreover, the particle-particle drag coefficient derived by Chao [21] includes two contributions: the peculiar drag coefficient and the fluid dynamic drag coefficient:

$$\beta_{ij} = \beta_{ij}^{pec} + \beta_{ij}^{flu} \quad (4.358)$$

The peculiar drag coefficient that is deduced from the effects due to the particle peculiar velocity differences,  $\mathbf{C}_{ij}$ , is modeled as:

$$\beta_{ij}^{pec} = \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) g_{0,ij} (\sqrt{2\pi\Theta_i} + \sqrt{2\pi\Theta_j} - \sqrt{2}\Theta_i^{0.25}\Theta_j^{0.25}) \quad (4.359)$$

The fluid dynamic drag coefficient which is deduced from the effects due to the particle fluid dynamic velocity differences is expressed as:

$$\begin{aligned} \beta_{ij}^{flu} = & \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) \times \\ & g_{0,ij} \left( \frac{\pi}{2} v_{ij} - 1.135 v_{ij}^{0.5} (\Theta_i^{0.25} + \Theta_j^{0.25} - 0.8\Theta_i^{0.125}\Theta_j^{0.125}) \right) \quad (4.360) \end{aligned}$$

Calculating the integral (4.356), employing the rigorous definition  $\mathbf{c}_{ij} = \mathbf{C}_{ij} + \mathbf{v}_{ij}$ , the relationships (4.358), (4.359) and (4.360) are obtained. If the fluid dynamic velocity difference  $\mathbf{v}_{ij}$  is neglected, as in the previous models [99–101, 105, 107], i.e.  $\mathbf{g}_{ij} \approx \mathbf{C}_{ij}$  or  $\mathbf{v}_{ij} \approx 0$ , the fluid dynamic drag coefficient given by (4.360) equals zero, and only the peculiar drag coefficient given by (4.359) contributes to the particle-particle drag.

#### 4.4.2.4 Granular Temperature Source

In order to obtain a suitable collisional dynamic approximation, the collisional kinetic energy losses for particle  $i$  and  $j$  are assumed equal for each collision. Hence, the collisional source term for the granular temperature equation becomes:

$$\begin{aligned} \gamma_i = & - \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) = - \sum_{j=1}^N \frac{d_{ij}^2}{2} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \frac{1}{2} (m_i c_i'^2 + m_j c_j'^2 - m_i c_i^2 - m_j c_j^2) \\ & \times f^{(2)}(\mathbf{r} - 0.5d_{ij}\mathbf{k}, \mathbf{c}_i, m_i, T_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_\xi,i}; \\ & \mathbf{r} + 0.5d_{ij}\mathbf{k}, \mathbf{c}_j, m_j, T_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_\xi,j}, t)(\mathbf{g}_{ij} \cdot \mathbf{k}) d\mathbf{V} \quad (4.361) \end{aligned}$$

The collisional dynamics yields (Manger [105], Eq. (A.35)):

$$\frac{1}{2} (m_i c_i'^2 + m_j c_j'^2 - m_i c_i^2 - m_j c_j^2) = \frac{m_i m_j}{2m_{c,ij}} (e_{ij}^2 - 1) (\mathbf{k} \cdot \mathbf{g}_{ij})^2 \quad (4.362)$$

Using the collisional dynamics relation (4.362), and expanding the pair density function to be expressed by single density functions, one obtains (e.g., Manger [105], Eq. (A.37)):

$$\begin{aligned} \gamma_i = & - \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) = - \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j d_{ij}^2}{4\bar{m}_{c,ij}} g_{0,ij} (e_{ij}^2 - 1) \\ & \times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} (\mathbf{g}_{ij} \cdot \mathbf{k})^3 \left[ f_i^{(0)} f_j^{(0)} + \frac{1}{2} d_{ij} f_i^{(0)} f_j^{(0)} \mathbf{k} \cdot \nabla \ln \frac{f_j^{(0)}}{f_i^{(0)}} \right] d\mathbf{V} \quad (4.363) \end{aligned}$$

Employing the integral theorems (E.1), (E.3) and (E.4) [25, 105], the result is derived in App E.2.3 and expressed as:

$$\begin{aligned}
\gamma_i &= - \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) \\
&= - \sum_{j=1}^N \frac{\pi (e_{ij}^2 - 1) d_{ij}^2 g_{0,ij} \bar{m}_i \bar{m}_j n_i n_j}{8(\bar{m}_i + \bar{m}_j)} (6.4(\Theta_i^{1.5} + \Theta_j^{1.5}) + 2.(\Theta_i \Theta_j^{0.5} + \Theta_i^{0.5} \Theta_j)) \\
&\quad - \sum_{j=1}^N \frac{\pi}{60} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_i + \bar{m}_j} (1 - e_{ij}^2) (\nabla \cdot \mathbf{v}_j (15\Theta_i + 9\Theta_j) + \nabla \cdot \mathbf{v}_j (15\Theta_j + 9\Theta_i))
\end{aligned} \tag{4.364}$$

#### 4.4.2.5 Granular Temperature Fluxes

The collisional heat flux term is:

$$\begin{aligned}
\mathbf{q}_i^{coll} &= \Phi \left( \frac{1}{2} C_i^2 \right) = - \sum_{j=1}^N 0.5 d_{ij}^3 \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \frac{1}{2} m_i (C_i'^2 - C_i^2) f^{(2)}(\mathbf{r} - 0.5 d_{ij} \mathbf{k}, \mathbf{c}_i, m_i, T_i, \\
&\quad \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_\xi,i}, \mathbf{r} + 0.5 d_{ij} \mathbf{k}, \mathbf{c}_j, m_j, T_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_\xi,j}, t) \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k}) d\mathbf{V}
\end{aligned} \tag{4.365}$$

From the collisional dynamics (4.347), using (2.65) and with some manipulations, the following relation is achieved:

$$\begin{aligned}
(C_i'^2 - C_i^2) &= \left( \frac{m_j}{m_{c,ij}} (1 + e_{ij}) (\mathbf{k} \cdot \mathbf{g}_{ij}) \mathbf{k} \right) \cdot \left( \frac{m_j}{m_{c,ij}} (1 + e_{ij}) (\mathbf{k} \cdot \mathbf{g}_{ij}) \mathbf{k} - 2\mathbf{C}_i \right) \\
&\quad + (\mathbf{v}_i' - \mathbf{v}_i) \cdot \left( \frac{m_j}{m_{c,ij}} (1 + e_{ij}) (\mathbf{k} \cdot \mathbf{g}_{ij}) \mathbf{k} + (\mathbf{v}_i' - \mathbf{v}_i) - 2\mathbf{C}_i \right) \\
&\quad + (\mathbf{v}_i' - \mathbf{v}_i) \left( \frac{m_j}{m_{c,ij}} (1 + e_{ij}) (\mathbf{k} \cdot \mathbf{g}_{ij}) \mathbf{k} \right)
\end{aligned} \tag{4.366}$$

Calculating the integrals using (4.366) and the integral theorem (E.3) as outlined in App E.2.4 [25, 105], the following result is obtained:

$$\mathbf{q}_i^{coll} = -\alpha_i \kappa_i^{coll} \nabla \Theta_i \tag{4.367}$$

$$\kappa_i^{coll} = \frac{2\pi \alpha_j \bar{\rho}_i \bar{\rho}_j}{5(\bar{m}_i + \bar{m}_j)} (1 + e_{ij}) g_{0,ij} d_{ij}^4 \sqrt{\Theta_i} \tag{4.368}$$

Using the Maxwellian density distribution function (4.345), the kinetic granular heat flux becomes equal to (2.254):

$$\mathbf{q}_i^{kin} = \alpha_i \rho_i \left\langle \frac{1}{2} C_i^2 \mathbf{C}_i \right\rangle = 0 \tag{4.369}$$

In order to include the kinetic granular heat flux, the mean free path theory [25, 49, 67] is used to calculate the dilute heat conductivity  $\kappa_i^{dilute}$  (i.e., see (4.378)), and further the derived quantities like the granular heat conductivity  $\kappa_i^{kin}$  (i.e., see (4.380)), and the kinetic heat flux  $\mathbf{q}_i^{kin}$  (i.e., see (4.382)) are calculated through them.

#### 4.4.2.6 Kinetic Pressure Tensor

Using the Maxwellian density distribution function (4.345), the kinetic pressure tensor becomes equal to (2.253):

$$\mathbf{p}_i^{kin} = \alpha_i \rho_i \langle \mathbf{C}_i \mathbf{C}_i \rangle = \alpha_i p_i^{kin} \mathbf{e} \quad (4.370)$$

The kinetic pressure is defined as:

$$p_i^{kin} = \bar{\rho}_i \Theta_i \quad (4.371)$$

In order to include the kinetic deviatoric pressure tensor, the mean free path theory [25, 49, 67] is used to calculate the dilute granular viscosity  $\mu_i^{dilute}$  (i.e., see (4.377)), and further the derived quantities like the granular kinetic viscosity  $\mu_i^{kin}$  (i.e., see (4.379)), the kinetic deviatoric pressure tensor  $\mathbf{p}_i^{kin}$  (i.e., see (4.381)) are calculated through them.

In the dilute kinetic theory of granular flow, the number of collisions between particles of type  $i$  and particles of type  $j$  per volume is given by [49, 105]:

$$N_{ij} = \int f_{ij}^{(2)}(r_i, \mathbf{c}_i, T_i, m_i, \omega_{1,i}, \omega_{2,i}, \dots, \omega_{N_{\xi,i}}, r_j, \mathbf{c}_j, T_j, m_j, \omega_{1,j}, \omega_{2,j}, \dots, \omega_{N_{\xi,j}}, t) (\mathbf{g}_{ij} \cdot \mathbf{k}) d_{ij}^2 d\mathbf{V} \quad (4.372)$$

Using (4.343), letting  $g_{0,ik} = 1$  as only the kinetic properties for dilute flow are considered in this context, and using the integral theorems (E.4) (Chapman and Cowling [25]):

$$N_{ij} = 2\sqrt{2\pi} n_i n_j d_{ij}^2 (\Theta_i^{\frac{1}{2}} + \Theta_j^{\frac{1}{2}} - 0.56 \Theta_i^{0.25} \Theta_j^{0.25}) \quad (4.373)$$

The collisional frequency  $Z_i$  for particles of type  $i$  is (Manger [105]; Gidaspow [49], Eq. (7.29), p. 90):

$$Z_i = \sum_{j=1}^N N_{ij} / n_i \quad (4.374)$$

The mean free path for the particles of type  $i$  is (Manger [105]; Gidaspow [49], Eq. (7.31), p. 90):

$$l_i = \frac{\langle C_i \rangle}{Z_i} \quad (4.375)$$

The mean particle speed was approximated by Gidaspow ([49], Eq. (7.10), p. 87) and also given by Manger [105], based on the molecular speed expression (4.46):

$$\langle C_i \rangle = \sqrt{\frac{8\Theta_i}{\pi}} \quad (4.376)$$

From Gidaspow [49], the granular dilute viscosity and heat conductivity were obtained using the empirical mean free path theory:

$$\mu_i^{dilute} = \bar{\rho}_i l_i \langle C_i \rangle = \frac{4\bar{\rho}_i \Theta_i}{\sum_{j=1}^2 \pi \sqrt{2\pi} d_{ij}^2 n_j (\Theta_i^{0.5} + \Theta_j^{0.5} - 0.56\Theta_i^{0.25}\Theta_j^{0.25})} = \bar{\rho}_i \frac{\langle C_i \rangle^2}{Z_i} \quad (4.377)$$

and

$$\kappa_i^{dilute} = \frac{15}{4} \mu_i^{dilute} = \frac{15\bar{\rho}_i \Theta_i}{\sum_{j=1}^2 \pi \sqrt{2\pi} d_{ij}^2 n_j (\Theta_i^{0.5} + \Theta_j^{0.5} - 0.56\Theta_i^{0.25}\Theta_j^{0.25})} \quad (4.378)$$

Hence, the granular kinetic viscosity and heat conductivity could be calculated using similar methods as used by Chapman and Cowling [25], Gidaspow [49] and Mathiesen et al. [107]:

$$\mu_i^{kin} = \frac{2\mu_i^{dilute} (1 + 0.8 \sum_{j=1}^N \alpha_j (1 + e_{ij}) g_{0,ij})^2}{\frac{1}{N} \sum_{j=1}^N (1 + e_{ij}) g_{0,ij}} \quad (4.379)$$

$$k_i^{kin} = \frac{2\kappa_i^{dilute} (1 + 1.2 \sum_{j=1}^N \alpha_j (1 + e_{ij}) g_{0,ij})^2}{\frac{1}{N} \sum_{j=1}^N (1 + e_{ij}) g_{0,ij}} \quad (4.380)$$

Finally, the granular kinetic pressure tensor including the deviatoric part can be calculated by:

$$\mathbf{p}_i^{kin} = \alpha_i p_i^{kin} \mathbf{e} - 2\alpha_i \mu_i^{kin} \mathbf{S}_i. \quad (4.381)$$

#### 4.4.2.7 Granular Kinetic Heat Flux

The granular kinetic heat flux is given by:

$$\mathbf{q}_i^{kin} = -\alpha_i k_i^{kin} \nabla \Theta_i. \quad (4.382)$$

#### 4.4.2.8 Frictional Pressure Tensor

The aforementioned constitutive equations (4.350)–(4.382) are based on the short term particle-particle collisions and translational motions. Theoretically, these equations can well describe rapid binary flows in which the particles are frequently at collisions. In a dense bed at low shear rates, the stress generation mechanism is more likely due to the long term particle-particle contacts such as sliding and rolling which cause large amount of energy being dissipated [97]. This effect should also be included in the dense fluidized bed equations. A common approach is to add a frictional pressure and viscosity to the model [87, 89, 97, 141]. The modeling approach proposed by Srivastava and Sundaresan [141] for mono particle mixtures as outlined in Sect. 4.1.5 was used by Lindborg [97]. Chao [21] extended the mono particle mixture relation to multiple particle mixture problems. Chao [21] assumed that the frictional pressure tensor  $\mathbf{p}_i^{fric}$  and the strain rate tensor  $\mathbf{S}_i$  might be related by using a relation on the same form as the conventional pressure tensor for viscous fluids:  $\mathbf{p}_i^{fric} = \alpha_i p_i^{fric} \mathbf{e} + 2\alpha_i \mu_i^{fric} \mathbf{S}_i$ . It was further assumed that in dense fluidized beds, the total pressure tensor constitutes the linear sum of the kinetic, collisional and frictional tensors as expressed by (4.150):  $\mathbf{p}_i = \mathbf{p}_i^{kin} + \mathbf{p}_i^{coll} + \mathbf{p}_i^{fric}$ . Hence, at a dense state, the empirical frictional pressure relation for mono particle mixtures (4.153) was extended to multiple particle mixtures as:

$$p_i^{fric} = \begin{cases} \frac{\zeta(\sum_{j=1}^N \alpha_j - \alpha^{min})^r}{\sum_{j=1}^N \alpha_j (\alpha^{max} - \sum_{j=1}^N \alpha_j)^s} & \text{if } \sum_{j=1}^N \alpha_j > \alpha^{min} \\ 0 & \text{if } \sum_{j=1}^N \alpha_j \leq \alpha^{min} \end{cases} \quad (4.383)$$

The friction viscosity relation for mono-particle mixtures (4.154) was extended to binary particle mixtures as:

$$\mu_i^{fric} = \frac{\sqrt{2} p_i^{fric} \sin \varphi}{2\alpha_i \sqrt{\mathbf{S}_i : \mathbf{S}_i + \Theta_i / d_i^2}} \quad (4.384)$$

Table 4.17 contains the basic parameters  $\varphi$ ,  $\zeta$ ,  $r$ ,  $s$ ,  $\alpha^{min}$ ,  $\alpha^{max}$  in the friction stress, pressure and viscosity models.

#### 4.4.2.9 Particle-Particle Drag Forces

The normal relative velocity  $\mathbf{g}_{21}^n$  represents the binary velocity difference for head-on *collision*, the tangential velocity  $\mathbf{g}_{21}^t$  denotes the relative *sliding* on the particle surfaces, and the angular velocity  $\omega_{21}$  denotes the relative *rolling* of the binary particles. Accordingly, three corresponding particle-particle drag forces,  $\mathbf{F}_{21}^n$ , and,  $\mathbf{F}_{21}^t$ , and,

**Table 4.17** Empirical parameters for the friction model [97]

| Notation       | Meaning                                    | Value |
|----------------|--------------------------------------------|-------|
| $\varphi$      | Angle of internal friction, <sup>o</sup>   | 28    |
| $\zeta$        | Constant $Nm^{-2}$                         | 0.5   |
| $r$            | Constant                                   | 2     |
| $s$            | Constant                                   | 3     |
| $\alpha^{min}$ | Lower volume fraction limit for friction   | 0.5   |
| $\alpha^{max}$ | Maximum volume fraction limit for friction | 0.62  |

$\mathbf{F}_{21}^\omega$ , can be derived, respectively.  $\mathbf{F}_{21}^n$  is the collisional drag defined in (4.357).  $\mathbf{F}_{21}^t$  and  $\mathbf{F}_{21}^\omega$  are the *frictional* drags due to the *sliding* and *rolling* contacts, respectively. In a dilute fluidized bed, the particles are at random collisions, the contact time  $\Delta t^{con}$  is very short, therefore the head-on collisional drag force,  $\mathbf{F}_{21}^n$ , is dominant, and the *sliding* and *rolling* drag forces,  $\mathbf{F}_{21}^t$ , and,  $\mathbf{F}_{21}^\omega$ , are often neglected. But, for dense fluidized beds, the binary particles at collision are often blocked by other surrounding particles. The binary or multiple long-term *sliding* and *rolling* contacts might become dominant. These *frictional* contributions for the particle-particle drag of the binary types of particles must also be considered. Unfortunately, no rigorous derivation of the frictional drag force term based on the fundamental physics of the long term *rolling/sliding* binary particle contacts (i.e., the  $\Delta t^{con}$  is much larger than that in a dilute system) has been proposed in the literature yet. Nevertheless, Syamlal [145] derived a semi-empirical frictional particle-particle drag relation which considers the *sliding* at the short term collisions. Chao [21] assumed that the long term binary particle-particle drag follows similar rules as the short-term sliding frictional drag, but has a much longer contact time. In order to take into account the long-term particle-particle drag, a corrected semi-empirical particle-particle frictional drag coefficient  $\beta_{12}^{fric}$  based on the short term frictional model from Syamlal [145] is used as a first approximation:

$$\beta_{ij}^{fric} = \frac{\pi \alpha_i \alpha_j \bar{\rho}_i \bar{\rho}_j}{2(m_i + m_j)} d_{ij}^2 (1 + e_{ij}) g_{0,ij} K_{fric} C_{fric} v_{ij} \quad (4.385)$$

Hence, if the particle-particle frictional drag is considered important, the particle-particle drag coefficient (4.358) derived by Chao [21] must be extended and includes three contributions: the peculiar drag coefficient, the fluid dynamic drag coefficient and the frictional drag coefficient:

$$\beta_{ij} = \beta_{ij}^{pec} + \beta_{ij}^{flu} + \beta_{ij}^{fric}. \quad (4.386)$$

#### 4.4.2.10 External Forces

In the same manner as for mono particle mixtures, the external force term includes the gas-particle drag, the gas pressure gradient and the gravity [87, 89]:

$$\alpha_i \rho_i \langle \mathbf{F}_i \rangle = \beta_{0i} (\mathbf{v}_0 - \mathbf{v}_i) - \alpha_i \nabla p_0 + \alpha_i \rho_i \mathbf{g}. \quad (4.387)$$

#### 4.4.2.11 Granular Kinetic Energy Dissipation Due to External Forces

The dissipation term due to the external force is modeled by [67, 97]:

$$\alpha_i \rho_i \langle \mathbf{F}_i \cdot \mathbf{C}_i \rangle = 3\beta_{0i} \Theta_i - \beta_{0i} \langle \mathbf{v}_0' \cdot \mathbf{C}_i \rangle \quad (4.388)$$

In the dissipation term model, the second part which considers the production due to the fluid turbulence-particle peculiar velocity correlation is normally neglected due to the limited knowledge regarding this term [67, 97].

For the first part, Chao [21] did employ the gas-particle drag approximation proposed by Gidaspow [49]:

$$\beta_{0i} = \begin{cases} \frac{150\mu_0(1-\alpha_0)\alpha_i}{\alpha_0 d_i^2} + \frac{1.75\alpha_i \rho_0 |\mathbf{v}_0 - \mathbf{v}_i|}{d_i} & \text{if } \alpha_0 \leq 0.8 \\ \frac{3C_D \rho_0 \alpha_i |\mathbf{v}_0 - \mathbf{v}_i|}{4d_i} \alpha_0^{-1.65} & \text{if } \alpha_0 > 0.8 \end{cases} \quad (4.389)$$

The coefficient  $C_D$  is [164]:

$$C_D = \begin{cases} \frac{24}{Re_i} [1 + 0.15(Re_i)^{0.687}] & \text{if } Re_i < 1000 \\ 0.44 & \text{if } Re_i \geq 1000 \end{cases} \quad (4.390)$$

The particle Reynolds number for particles of type  $i$  is defined as:

$$Re_i = \frac{\alpha_0 d_i \rho_0 |\mathbf{v}_0 - \mathbf{v}_i|}{\mu_0} \quad (4.391)$$

In numerous investigations [12, 45, 62, 63, 70, 87, 107] different empirical expressions for the radial distribution functions (RDF),  $g_{0,ij}$ , were put forth or applied. Chao [21] did apply the RDF proposed by Gao et al. [45]:

$$g_{0,ij} = \frac{d_j g_{0,i} + d_i g_{0,j}}{d_i + d_j} \quad (4.392)$$

in which  $ij$  denotes the interacting effect between particles of type  $i$  and  $j$ .

The interacting effect between particles of type  $j$  was given as:

$$g_{0,j} = \left(1 - \left(\frac{\alpha_j}{\alpha_{max}}\right)^{\frac{1}{3}}\right)^{-1} \quad (4.393)$$

where  $j$  denotes the particle type  $j = 1, 2$ .

#### 4.4.2.12 Interfacial Mass Transfer

##### *Continuity*

The mass transfer rate  $\Gamma_i$  is defined as:

$$\Gamma_i = \alpha_i \bar{\rho}_i \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle. \quad (4.394)$$

##### *Momentum*

The mass transfer-related term  $\alpha_i \bar{\rho}_i \left\langle \frac{\mathbf{c}_i}{m} \frac{dm_i}{dt} \right\rangle$  in the momentum equation is closed by neglecting the velocity fluctuations (Lindborg [97]):

$$\alpha_i \bar{\rho}_i \left\langle \frac{\mathbf{c}_i}{m} \frac{dm_i}{dt} \right\rangle \approx \Gamma_i \mathbf{v}_i \quad (4.395)$$

##### *Granular Temperature*

The mass transfer-related term  $\alpha_i \bar{\rho}_i \left\langle \frac{C_i^2}{2m_i} \frac{dm_i}{dt} \right\rangle$  in the granular temperature equation is closed using a similar approximation (Lindborg [97]):

$$\alpha_i \bar{\rho}_i \left\langle \frac{C_i^2}{2m_i} \frac{dm_i}{dt} \right\rangle \approx \alpha_i \bar{\rho}_i \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle \left\langle \frac{1}{2} C_i^2 \right\rangle \approx \frac{3}{2} \Gamma_i \Theta_i \quad (4.317)$$

##### *Thermal heat in terms of Temperature*

The mass transfer-related term in the thermal heat transport equation (4.334) is also closed using the same approximation as applied by Lindborg [97] and Lathouwers and Bellan [89]:

$$\alpha_i \bar{\rho}_i \left\langle \frac{1}{m_i} \frac{dm_i}{dt} \right\rangle (\langle h_0 \rangle - \langle h_i \rangle) = \Gamma_i \Delta h_i \quad (4.396)$$

where the enthalpy change  $\Delta h_i$  is modeled in Sect. 4.4.5 in accordance to the specific reactions.

The term  $-\nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i h_i' \rangle)$  in the thermal temperature transport equation (4.334) may be approximated by a diffusion term [89, 97]:

$$-\nabla \cdot (\alpha_i \bar{\rho}_i \langle \mathbf{C}_i h_i' \rangle) = \nabla \cdot (\alpha_i k_i^{h,t} \nabla \langle T_i \rangle) \quad (4.397)$$

The thermal heat conductivity  $k_i^{h,t}$  is closed using the expression derived by Lathouwers and Bellan [89]:

$$k_i^{h,t} = \frac{1}{2} \bar{\rho}_i C_{p,i} l_i \langle C_i \rangle \quad (4.398)$$

where  $l_i$  and  $\langle C_i \rangle$  are calculated using Eqs. (4.375) and (4.376).

The term  $-\alpha_i \bar{\rho}_i \langle \frac{Q_i^c}{m_i} \rangle$  at the molecular temperature transport equation (4.334) accounts for the gas-particle heat transfer, which is closed by [89, 97]:

$$Q_{i0} = -\alpha_i \bar{\rho}_i \langle \frac{Q_i^c}{m_i} \rangle = \frac{6\alpha_i k_0^{stat}}{d_i^2} \langle Nu_i \rangle (\langle T_0 \rangle - \langle T_i \rangle) \quad (4.399)$$

Empirical correlations are available for the estimation of the Nusselt number in both packed- and fluidized beds. In this work a correlation proposed by Gunn [54] is applied:

$$Nu_i = (7 - 10\alpha_0 + 5\alpha_0^2)(1 + 0.7Re_i^{0.2}Pr^{0.3}) + (1.33 - 2.4\alpha_0 + 1.2\alpha_0^2)Re_i^{0.7}Pr^{0.3} \quad (4.400)$$

The Prandtl number is defined as :

$$Pr = \frac{\mu_0 C_{p,0}}{k_0^m} \quad (4.401)$$

where  $k_0^m$  is the gas thermal heat conductivity defined by (4.410).

### 4.4.3 Gas Phase Transport Equations

In the governing equations for the multiple particle mixture multi-fluid model, the gas-phase ensemble average  $\bar{\psi}$  and its density-weighted average  $\langle \psi \rangle$ , which were defined by Drew [31] and discussed in Sect. 3.4.3, were applied [87, 89]:

$$\bar{\psi} = \frac{\langle X_0 \psi(\mathbf{r}, t) \rangle_e}{\alpha_0} \quad (4.402)$$

$$\langle \psi \rangle = \frac{\langle X_0 \rho_0 \psi(\mathbf{r}, t) \rangle_e}{\alpha_0 \bar{\rho}_0} \quad (4.403)$$

The subscript 0 represents the continuous gas phase.

In general, an ensemble average  $\langle \psi \rangle_e$  of a field quantity  $\psi(\mathbf{r}, t)$ , in which  $\mathbf{r}$  and  $t$  denote the space and time coordinates, is defined as [87, 89]:

$$\langle \psi \rangle_e = \int \psi(\mathbf{r}, t) P(\Pi) d\Pi \quad (4.404)$$

in which  $P(\Pi)$  denotes the probability that a specific realization  $\Pi$  is met in the ensemble.  $X_0$  is the gas phase indicator, which is unity in the gas phase, and 0 in the particle phases. The gas phase number fraction  $\alpha_0$  is defined as the ensemble average of the indicator function  $\alpha_0 = \langle X_0 \rangle_e$ .

#### 4.4.3.1 Governing Equation for the Continuous Phase

The gas continuity equation is given as:

$$\frac{\partial}{\partial t}(\alpha_0 \bar{\rho}_0) + \nabla \cdot (\alpha_0 \bar{\rho}_0 \mathbf{v}_0) = \Gamma_0 \quad (4.405)$$

The momentum equation is expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_0 \bar{\rho}_0 \mathbf{v}_0) + \nabla \cdot (\alpha_0 \bar{\rho}_0 \mathbf{v}_0 \mathbf{v}_0) = & -\alpha_0 \nabla \bar{p}_0 - \nabla \cdot \alpha_0 (\boldsymbol{\sigma}_0 + \boldsymbol{\sigma}_0^{\text{Re}}) \\ & + \sum_{k=1}^N \beta_{0k} (\mathbf{v}_k - \mathbf{v}_0) + \alpha_0 \bar{\rho}_0 \mathbf{g} + \Gamma_0 \mathbf{v}_0^i \end{aligned} \quad (4.406)$$

in which the viscous stress tensor for the gas phase is modeled using the single phase stress tensor relation (1.77), p. 33. The turbulent stress tensor for the gas phase is modeled by use of the gradient-and Boussinesq hypotheses and approximated by (4.237). The last term  $\Gamma_0 \mathbf{v}_0^i$  is the mass transfer related source, where  $\mathbf{v}_0^i$  is the interface velocity. Further analysis is given at Sect. 4.4.5. A modified turbulent kinetic energy equation was used for the continuous gas phase [65, 66, 93, 96, 97]:

$$\frac{\partial}{\partial t}(\alpha_0 \bar{\rho}_0 k_0) + \nabla \cdot (\alpha_0 \bar{\rho}_0 k_0 \mathbf{v}_0) = \alpha_0 (-\boldsymbol{\sigma}_0^{\text{Re}} : \nabla \mathbf{v}_0 + S_{k_0}) + \nabla \cdot (\alpha_0 \frac{\mu_0^t}{\sigma_0} \nabla k_0) - \alpha_0 \bar{\rho}_0 \varepsilon_0 \quad (4.407)$$

The  $S_{k_0}$  term represents the production of turbulent kinetic energy due to the movement of the particles. This term is approximated by (4.236).

The gas phase turbulent kinetic energy dissipation rate equation yields:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_0 \bar{\rho}_0 \varepsilon_0) + \nabla \cdot (\alpha_0 \bar{\rho}_0 \varepsilon_0 \mathbf{v}_0) = & \alpha_0 C_1 \frac{\varepsilon_0}{k_0} (-\boldsymbol{\sigma}_0^{\text{Re}} : \nabla \mathbf{v}_0 + S_{k_0}) \\ & + \nabla \cdot (\alpha_0 \frac{\mu_0^t}{\sigma_\varepsilon} \nabla \varepsilon_0) - \alpha_0 \bar{\rho}_0 C_2 \frac{\varepsilon_0^2}{k_0} \end{aligned} \quad (4.408)$$

The turbulent viscosity is defined by (4.235). The values used for the empirical parameters in the  $k_0$ - $\varepsilon_0$  turbulence model are given in Table 4.9.

The interfacial mass transfer terms that might occur in the turbulent kinetic energy and the corresponding dissipation rate equations are normally neglected as the influence of these terms in reactor process performance analysis is small.

The gas phase enthalpy transport equation, expressed in terms of temperature, is given by:

$$\alpha_0 \bar{\rho}_0 C_{p,0} \frac{D\langle T_0 \rangle}{Dt} = \nabla \cdot \alpha_0 k_0^{\text{eff}} \nabla \langle T_0 \rangle + \sum_{k=1}^N Q_{0k} + Q_0^R \quad (4.409)$$

The gas phase thermal heat conduction in fluidized beds has been investigated by numerous researchers [8, 14, 84, 97, 116, 144, 170]. In the study by Chao [21], the usual treatment of the effective gas phase heat conductivity,  $k_0^{\text{eff}}$ , was applied. The  $k_0^{\text{eff}}$  was approximated as a linear sum of the molecular and the turbulent contributions in accordance with (4.274) as  $k_0^{\text{eff}} = k_0^m + k_0^t$ . The thermal heat conductivity of the continuous gas phase, with the dispersed binary particle mixture, is modeled as:

$$k_0^m = \frac{k_0^{\text{stat}}}{\alpha_0} \left( 1 - \left( \sum_{k=1}^N \alpha_k \right)^{0.5} \right) \quad (4.410)$$

The turbulent heat conductivity of the gas flow is approximated by use of a Reynolds analogy and the turbulent viscosity determined by the  $k_0$ - $\varepsilon_0$  turbulence model  $k_0^t = \frac{\mu_0^t}{\rho_0 Pr^t}$ , where the turbulent Prandtl number  $Pr^t = 0.7$  was used [97].

The term  $Q_{0k}$  at Eq. (4.409) denotes the gas-particle heat coupling, which is modeled by [89, 97]:

$$Q_{0k} = \frac{6\alpha_k k_0^{\text{stat}}}{d_k^2} \langle Nu_k \rangle (\langle T_k \rangle - \langle T_0 \rangle) \quad (4.411)$$

where  $Q_0^R$  denotes the reaction source term which is modeled in Sect. 4.4.5.

The gas phase species mass transport equations are defined as:

$$\frac{\partial}{\partial t} (\alpha_0 \bar{\rho}_0 \langle \omega_j \rangle) + \nabla \cdot (\alpha_0 \bar{\rho}_0 \mathbf{v}_0 \langle \omega_j \rangle) = \nabla \cdot \left( \bar{\rho}_0 D_{0j}^{\text{eff}} \nabla \langle \omega_j \rangle \right) + \Gamma_{0,j}^{\omega} \quad (4.412)$$

in which  $\Gamma_{0,j}^{\omega}$  denotes the gas component formation rate which will be closed in Sect. 4.4.5. The effective diffusivity for the gas was also modeled as the linear sum of the molecular and turbulent contributions in accordance with (4.281):  $D_{0,s}^{\text{eff}} = D_{0,s}^m + D_0^t$ . The multi-component molecular diffusivities of the components in the mixture is estimated by the Wilke relation [165] defined by (4.283), whereas the binary diffusion coefficients,  $D_{ji}$ , were computed from the empirical relation [44], defined by (4.284). The turbulent diffusion coefficient is estimated by use of the Reynolds analogy:  $D_0^t = \frac{\mu_0^t}{\rho_0 Sc^t}$  where a constant Schmidt number  $Sc^t = 0.7$  was used.

#### 4.4.4 Cold Flow Gas: Binary Particle Mixture system Simulation

Chao [21] and Chao et al. [20, 22, 23] employed a binary particle three-fluid model to study binary particle flows, and size and density segregation and mixing in dilute gas risers and dense gas bubbling fluidized beds. Particle segregation occur due to the physical property differences, the small, light particles called the *flotsam* tend to rise, and the large, heavy particles called the *jetsam* tend to sink. The binary particle mixture also experience a simultaneous mixing tendency. For this reason, the resulting flow behavior is thus determined by the balance of the counteracting segregation and mixing effects.

##### 4.4.4.1 Derivation of a Gas–Binary Particle Three-Fluid Model: Dilute Riser Flow Validation

The basic multi-fluid Eulerian model with a kinetic theory of granular flow closure was developed by Chao et al. [20] and validated for dilute binary particle riser flows. The proposed multi-fluid Eulerian model was derived from binary kinetic theory of granular flows, free path theory and an empirical frictional pressure tensor theory. For model validation the literature data on binary particle size segregation and mixing from Mathiesen et al. [107] was employed. The properties of the gas and the particles in the riser are given in Table 4.18. The dynamic two-dimensional simulation results and the experimental data did show a similar distribution tendency. The particles did generally move upwards at the center and downwards near the wall. Moreover, the particle concentration was radially dense near the cylinder wall and dilute at the center (i.e., a typical annulus-core structure), and axially dense at the bottom and dilute at the top. The two types of particles were segregated by size. Near the bottom, where the large particles did tend to accumulate, the volume fractions of the large particles were larger. The small particles are fluidized easier and did tend to rise and the volume fractions of the small particles at the upper levels were larger. Compared to the modeling work of Mathiesen et al. [106, 107], the validation of the novel model by Chao et al. [20] did show that the coupling terms in the latter model give a stronger and more realistic particle-particle coupling because the effects due to the fluid dynamic velocity differences were considered as distinct from previous work. The model of Chao et al. [20] gave reasonable predictions of the particle volume fraction, particle velocities and velocity fluctuations. Moreover, the model analysis did reveal that the basic particle velocity fluctuations constitute 2 terms: the velocity fluctuations of the discrete particles (or a kind of rms particle peculiar velocity), and the velocity fluctuations of the continuous granular fluid flow (or a kind of rms continuous granular phase field velocity). Furthermore, the simulation results did show that the velocity fluctuations of the continuous granular fluid flow were dominant in a binary riser flow.

**Table 4.18** Physical properties of the gas and solid particles in the riser investigated by Mathiesen et al. [107]

|                                          | Gas phase            | Large particle | Small particle | Mixture |
|------------------------------------------|----------------------|----------------|----------------|---------|
| Mean particle diameter ( $\mu\text{m}$ ) |                      | 185            | 120            |         |
| Density ( $\text{kg/m}^3$ )              | 1.2                  | 2400           | 2400           |         |
| Viscosity ( $\text{kg/ms}$ )             | $1.8 \times 10^{-5}$ |                |                |         |
| Particle restitution coefficient         |                      | 0.99           | 0.99           |         |
| Maximum mixture fraction                 |                      |                |                | 0.63    |
| Initial mixture bed height (m)           |                      |                |                | 0.04    |

**4.4.4.2 Two-Dimensional Dense Gas–Binary Particle System Simulation:  
Particle Density Segregation in BFB System**

Chao [21] and Chao et al. [23] did study binary particle density segregation in a dense gas bubbling fluidized bed. The segregation behavior of the two types of particles with approximately the same particle diameters and different particle densities was studied and validated using experimental data from Formisani et al. [43]. The properties of the particle mixture in the column are given in Table 4.19. In this study the model equations of Chao et al. [20], which were originally developed for binary particle mixtures in dilute riser flows, were slightly modified and adapted to dense BFB flows as follows. In the original model of Chao et al. [20], the terms related to the velocity difference between particle type  $i$  and type  $k$ ,  $v_{ik}$ , are some kind of coupling terms between the particles of type  $i$  and  $k$ . However, for dense BFB flows the binary particle-particle drag was considered dominant. Therefore, for the dense BFB simulations performed by Chao et al. [23], only the binary particle-particle coupling terms resembling the classical drag terms were retained, and the other terms related to  $v_{ik}$  were neglected. In further details, following the equation numbering in the original paper by Chao et al. [20], the first term in the novel collisional pressure tensor (17) was neglected because it was relatively small. Nevertheless, this term was still creating numerical instabilities in the simulations. Likewise, for the collisional pressure the last term in the largest and last parenthesis in (19) was neglected of similar reasons. Moreover, the first term in the collisional heat flux (35) was also neglected. Finally, the particle-particle friction drag (55) was added for the dense fluidized bed simulations. The particle-particle friction drag (55) was not considered for the dilute riser flows, although it was briefly discussed by Chao et al. [20]. It is noted that the empirical frictional particle–particle drag coefficient relation in (55) corresponds to the one proposed Chao et al. [19].

The governing equations used by Chao et al. [23] are listed below, where the variable subscripts 0, 1 and 2 denote each of the three fluids in the order of gas, flotsam and jetsam. Equation (4.413) is a constraint for the gas and particle volume fractions, (4.414) is a universal continuity equation for both the gas and particle phases, (4.415) and (4.416) are the gas and particle momentum equations. Equation (4.316) is the granular temperature equation which describes the transport of the fluctuating kinetic

**Table 4.19** Physical properties of the gas (air) and solid steel and glass particles in the column investigated by Formisani et al. [43]

|                                          | Gas phase                 | Heavy particle | Light particle | System |
|------------------------------------------|---------------------------|----------------|----------------|--------|
| Mean particle diameter ( $\mu\text{m}$ ) |                           | 243            | 223            |        |
| Density ( $\text{kg/m}^3$ )              | $\sim 1.2$                | 7600           | 2480           |        |
| Viscosity ( $\text{kg/ms}$ )             | $\sim 1.8 \times 10^{-5}$ |                |                |        |
| Column height (m)                        |                           |                |                | 0.20   |
| Column ID (m)                            |                           |                |                | 0.10   |

energy/granular temperature ( $\Theta_i = m_i \langle C_i^2/3 \rangle$ ) of the particles. Equations (4.407) and (4.408) are the transport equations for the gas turbulent kinetic energy and the turbulent energy dissipation rate per unit mass. The constitutive equations employed to close the binary particle balance laws derived from the Maxwell-Enskog transport equation are outlined in Sect. 4.4.

#### 4.4.4.3 The Multi-fluid model for Cold Flow Particle Density Segregation

Phase volume constraint:

$$\sum_{k=0}^2 \alpha_k = 1 \quad (4.413)$$

The continuity equation:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k) = 0, \quad k = 0, 1, 2 \quad (4.414)$$

The gas phase momentum equation was similar to (4.406) and expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_0 \rho_0 \mathbf{v}_0) + \nabla \cdot (\alpha_0 \rho_0 \mathbf{v}_0 \mathbf{v}_0) = & -\alpha_0 \nabla p_0 - \nabla \cdot (\alpha_0 (\boldsymbol{\sigma}_0 + \boldsymbol{\sigma}_t)) \\ & + \sum_{d=1}^2 \beta_{0d}(\mathbf{v}_d - \mathbf{v}_0) + \alpha_0 \rho_0 \mathbf{g} \end{aligned} \quad (4.415)$$

The solid phase momentum equations were expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_d \rho_d \mathbf{v}_d) + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \mathbf{v}_d) = & -\alpha_d \nabla p_0 - \nabla \cdot \mathbf{p}_d - \beta_{0d}(\mathbf{v}_d - \mathbf{v}_0) \\ & + \sum_{k=1}^2 \beta_{dk}(\mathbf{v}_k - \mathbf{v}_d) + \alpha_d \rho_d \mathbf{g} \end{aligned} \quad (4.416)$$

where  $d = 1, 2$  and the dispersed phase pressure is calculated from (4.151), thus  $\mathbf{p}_d = \mathbf{p}_d^{\text{coll}} + \mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{fric}}$ , and closed with (4.155) and (4.158).

The granular temperature equations were expressed as:

$$\begin{aligned} \frac{3}{2} \frac{\partial}{\partial t} (\alpha_d \rho_d \Theta_d) + \frac{3}{2} \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \Theta_d) = & -\mathbf{p}_d : \nabla \mathbf{v}_d - \nabla \cdot (\mathbf{q}_d^{\text{kin}} + \mathbf{q}_d^{\text{coll}}) \\ & - 3\beta_{0d} \Theta_d - \gamma_d \end{aligned} \quad (4.316)$$

The gas turbulent kinetic energy equation was expressed as:

$$\frac{\partial}{\partial t} (\alpha_0 \rho_0 k_0) + \nabla \cdot (\alpha_0 \rho_0 k_0 \mathbf{v}_0) = \alpha_0 (-\boldsymbol{\sigma}_0^{\text{Re}} : \nabla \mathbf{v}_0 + S_p) + \nabla \cdot (\alpha_0 \frac{\mu_0^t}{\sigma_{0k}} \nabla k_0) - \alpha_0 \rho_0 \varepsilon_0 \quad (4.407)$$

The turbulent energy dissipation rate equation for the gas phase was formulated as:

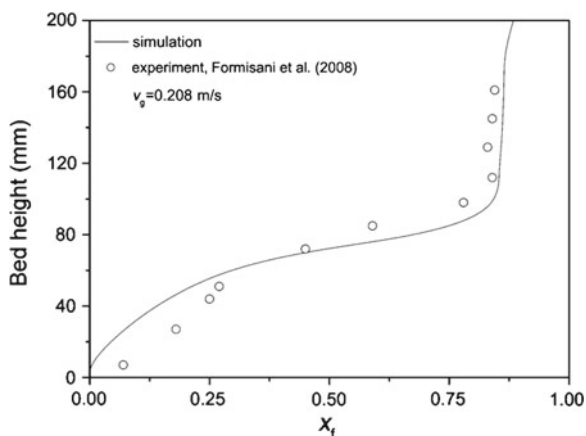

$$\begin{aligned} \frac{\partial}{\partial t} (\alpha_0 \rho_0 \varepsilon_0) + \nabla \cdot (\alpha_0 \rho_0 \varepsilon_0 \mathbf{v}_0) = & \alpha_0 C_1 \frac{\varepsilon_0}{k_0} (-\boldsymbol{\sigma}_0^{\text{Re}} : \nabla \mathbf{v}_0 + S_p) \\ & + \nabla \cdot (\alpha_0 \frac{\mu_0}{\sigma_{0\varepsilon}} \nabla \varepsilon_0) - \alpha_0 \rho_0 C_2 \frac{\varepsilon_0^2}{k_0} \end{aligned} \quad (4.408)$$

The simulation results (see Figs. 4.14 and 4.15) did show that the simulated axial average flotsam-to-total particle volume fraction ratio distribution agrees fairly well with the experimental data of Formisani et al. [43]. The binary particle velocities are closely coupled though the segregation exists. The segregation behavior and the particle velocity profiles are superficial gas velocity dependent. The number and distribution of particle velocity vortices change dramatically with superficial gas velocity. At a comparatively low superficial gas velocity, the particles mainly segregate axially, and at a comparatively high superficial gas velocity, the particles segregate both axially and radially.

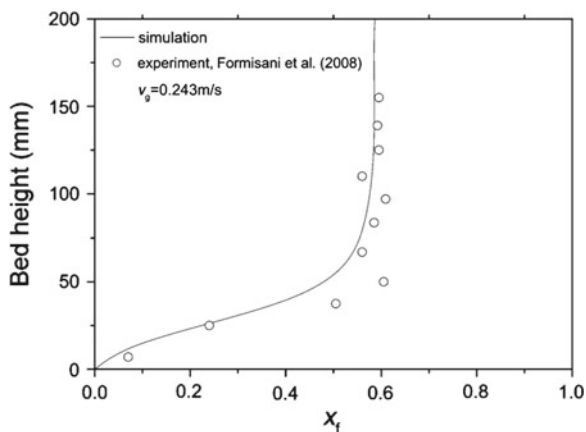

#### 4.4.4.4 Two-Dimensional Dense Gas–Binary Particle System Simulation: Particle Size Segregation in BFB System

Chao et al. [22] did simulate dynamic size segregation in bubbling fluidized bed systems by use of exactly the same three-fluid model equations (4.413)–(4.408) as employed by Chao et al. [23]. Introductory, the empirical friction particle–particle drag coefficient relation proposed Chao et al. [19] was employed.

To validate the given model, some simulated results were compared with experimental data characterizing dynamic particle size segregation in dense gas fluidized beds published by Goldschmidt et al. [52]. In the experimental investigation of Goldschmidt et al. [52] a whole-field, non-intrusive digital image analysis technique was employed enabling measurement of bed expansion and segregation dynamics of colored particles in a dense gas-fluidized bed. The experiments were carried out with

**Fig. 4.14** Axial distribution of flotsam-to-total particle volume fraction ratios due to binary particle density segregation. Reprinted from Chao et al. [23] with permission from Elsevier

**Fig. 4.15** Axial distribution of flotsam-to-total particle volume fraction ratios due to binary particle density segregation. Reprinted from Chao et al. [23] with permission from Elsevier

1.5 and 2.5 mm colored glass beads in a pseudo two-dimensional laboratory scale fluidized bed with a rectangular geometry and well-defined gas inflow conditions. The properties of the particle mixture in the pseudo two-dimensional laboratory scale fluidized bed with a rectangular geometry and well-defined gas inflow conditions are given in Table 4.20. The initial model validation did show that the binary particle-particle drag correlation proposed Chao et al. [19] under-predicted the binary particle-particle coupling in the dense fluidized bed. For this reason, Chao et al. [22] investigated the behavior of six additional binary particle-particle drag closure correlations from the literature [10, 20, 48, 62, 63, 87, 99–101, 145], derived based on the kinetic theory of granular flows (KTGF) for the application to fluidized beds.

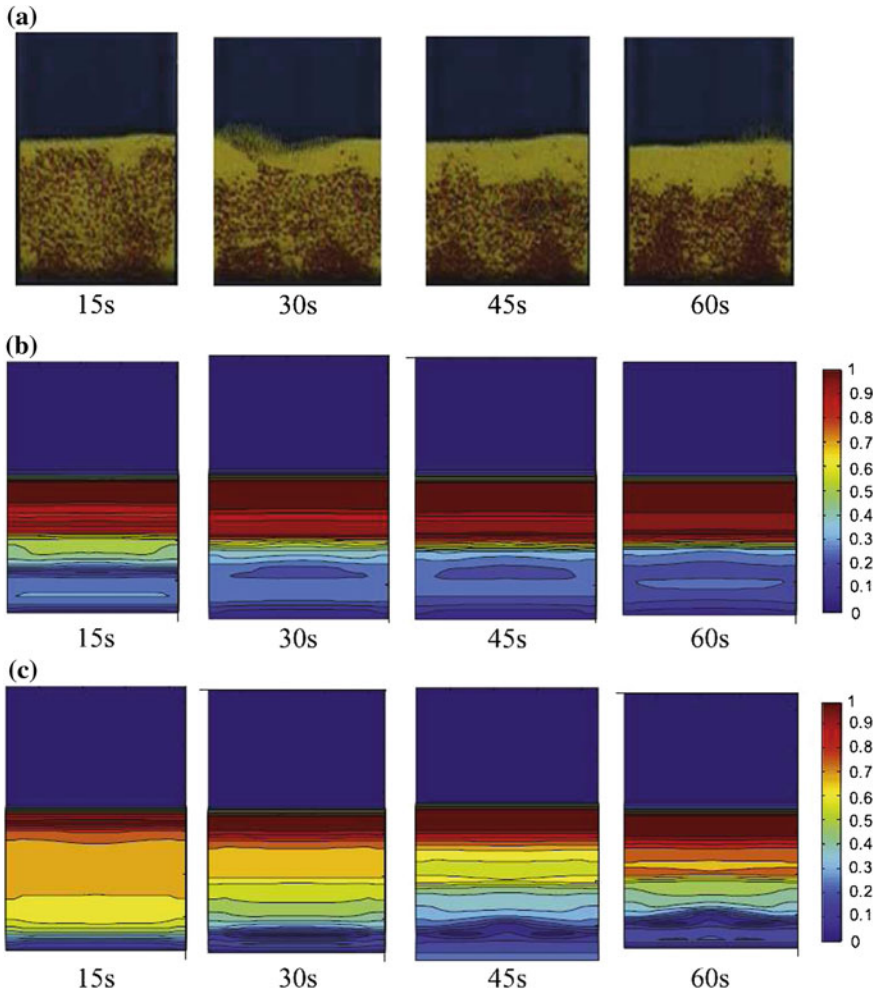

**Table 4.20** Physical properties of the gas (air) and solid steel and glass particles in the column investigated by Goldschmidt et al. [52]

|                                   | Gas phase               | Small particle | Large particle | System         |
|-----------------------------------|-------------------------|----------------|----------------|----------------|
| Bed dimensions (mm <sup>3</sup> ) |                         |                |                | 150 × 15 × 700 |
| Particle diameter (mm)            |                         | 1.5            | 2.5            |                |
| Color                             |                         | Yellow         | Red            |                |
| Number                            |                         | ~27 710        | ~ 5980         |                |
| Density (kg/m <sup>3</sup> )      | ~1.2                    | 2526           | 2523           |                |
| $v^{mf}$ (m/s)                    |                         | 0.78           | 1.25           |                |
| Friction coefficient              |                         | 0.1            | 0.15           |                |
| Restitution coefficient, $e_{ik}$ |                         | 0.99           | 0.99           |                |
| Viscosity (kg/m s)                | ~1.8 × 10 <sup>-5</sup> |                |                |                |
| Particle mass (kg)                |                         |                |                | 0.2471         |
| $x_{small}$                       |                         | 0.5            |                |                |
| Initial bed height (m)            |                         |                |                | 0.075          |
| Superficial velocity (m/s)        | 1.10                    |                |                |                |

Subsequent model validation did reveal that all seven binary particle-particle drag correlations found in the literature under-predicted binary particle-particle coupling in the dense fluidized bed.

Chao et al. [22] further recognized that satisfactory results could be obtained by introducing an extra semi-empirical frictional binary particle-particle drag. The new semi-empirical frictional binary particle-particle drag did supposedly consider the long term particle–particle contact effects and represents a correction to the short term collisional frictional binary particle–particle drag correlation proposed by Syamlal [145]. Moreover, numerous comprehensive calculations did show that the extended model using the semi-empirical frictional binary particle-particle drag might predict the particle segregation rates and the bed heights of the individual particles with a change of gas fluidization velocity, the initial bed height, and the small particle ratio with the same fixed correction coefficient fairly well. Therefore, it was proposed that the frictional binary particle-particle drag which represents the binary particle momentum exchange due to the long term particle contacts (sliding/rolling) must be considered in order to model dense binary fluidized beds.

The measured and predicted segregation patterns obtained for a binary mixture containing  $x_{small} = 50$  mass % small particles fluidized at a superficial gas velocity of 1.10 m/s are shown in Fig 4.16. Initially, an accurately weighed amount of particles was poured into the bed. A well-mixed initial condition was obtained by fluidizing the particles at a velocity somewhat higher than the minimum fluidization velocity of the largest particles for several minutes, where after the gas inflow was suddenly switched off and the bed collapsed. The mass flow controllers were then set for the required flow conditions and the recording of the experiments started just before the gas flow to the bed was switched on again by rapid switching valves. In the figure it is shown that within 15 s, the whole top layer of the bed was occupied by small particles.

**Fig. 4.16** Snapshots of gas-binary particle size segregation: **a** Binary particle size segregation data from Goldschmidt et al. [52] (Yellow: small particles, red: large particle, Freeboard and lower inlet plan: gas. **b** Simulated results for  $\alpha_{\text{small}}/(\alpha_{\text{small}} + \alpha_{\text{large}})$  by use of drag model (4.358). **c** Simulated results for  $\alpha_{\text{small}}/(\alpha_{\text{small}} + \alpha_{\text{large}})$  for drag model (4.386). Reprinted from Chao et al. [22] with permission from Elsevier

As the segregation process did develop further, the flotsam and jetsam did tend to dominate the upper and lower regions of the bed, respectively. The binary particle mixture was almost completely segregated within the 60 s period. Figure 4.16 a,b and c show comparisons between experimental snapshots and the simulated results for the particle segregation at time 15, 30, 45, and 60 s. The qualitative comparisons (b) did show that the simulation using only particle-particle drag (4.358) containing closure relations for the peculiar drag coefficient (4.359), that is deduced from the effects

due to the particle peculiar velocity difference, and the fluid dynamic drag coefficient (4.360), that is deduced from the effects due to the particle fluid dynamic difference, overpredicts the particle segregation significantly and the simulation results at 30, 45 and 60 s are similar as the mixture was almost completely segregated. However, when the binary particle-particle frictional drag (4.385) was considered so that (4.358) was extended as (4.386),

$$\beta_{ij} = \beta_{ij}^{\text{pec}} + \beta_{ij}^{\text{flu}} + \beta_{ij}^{\text{fric}} \quad (4.386)$$

the segregation process could be reproduced fairly well.

#### 4.4.5 Two-Dimensional Simulation of SMR and SE-SMR Processes

It is noted that even though catalyst and sorbent particles are both solids and thermodynamically belong to the same phase, these particles have different transport properties, temperatures, species compositions and morphology and might thus be handled separately.

Chao [21] did investigate the SMR and SE-SMR processes with respect to chemical performance, particle segregation by weight of catalyst and sorbent particles, influence of the superficial gas velocities and solid loading (packed bed heights) on the hydrogen purity, influence of chemical process on the two-dimensional particle flow patterns. The performance of the SE-SMR process has been compared with the performance of a steam methane reforming (SMR) process operated in fluidized bed reactors. To study these effects, two SE-SMR fluidized bed reactors of different sizes were simulated by use of a three-fluid model with a KTGF closure. One 1 m high laboratory scale reactor and a 4 m high industrial scale BFB fluidized bed were employed in this investigation.

The simulation results show that the sorbent particles can adsorb  $\text{CO}_2$  in these reactors, thus a higher purity of the hydrogen product can be obtained in a SE-SMR reactor than in a conventional SMR reactor. The superficial gas velocity is an important parameter. A pseudo-steady SE-SMR bed performance can be obtained provided that the bed is operated at optimized medium level superficial gas velocities. Chao [21] found that the binary sorbent-catalyst particles were well mixed when the bed was operated at 0.2 m/s. The sorbent can adsorb  $\text{CO}_2$  steadily, thus the dry mole fraction of the hydrogen product can get above 0.95 in the 1 m laboratory scale bed, and above 0.97 in the 4 m industrial scale bed. However, when the laboratory scale bed was operated at a lower superficial gas velocity of 0.15 m/s, the binary sorbent-catalyst particles were segregated. In this case, the heavy sorbent particles did accumulate at the bottom of the bed, and the light catalyst particles tend to rise and become distributed at higher sections in the bed. For this reason, the sorbent can not adsorb  $\text{CO}_2$  in an optimized manner, and the hydrogen product purity is decreased compared to the well-mixed bed case. When the bed is operated at a higher superficial gas velocity of 0.3 m/s, the process work load was increased, and the gas residence time in the

reactor was decreased. Therefore, the hydrogen product purity is further decreased. The simulation results obtained for the 4 m industrial scale bed show that a dry mole purity of hydrogen above 0.97 can be obtained due to the increased bed height. These simulation results did also show that there was an optimal bed height limit, at which further increase of the packed bed height can not increase the hydrogen purity. The 1 m high laboratory scale- and the 4 m high industrial scale SE-SMR fluidized bed reactors were simulated using a three-fluid model. The simulation results show that the sorbent particles can adsorb CO<sub>2</sub> in these reactors, thus a higher purity of the hydrogen product can be obtained in a SE-SMR reactor than in a conventional SMR reactor. The superficial gas velocity is a key operational parameter that might be optimized. A pseudo-steady SE-SMR bed performance can be obtained provided that the bed is operated at optimal medium level superficial gas velocity. Moreover, Chao [21] found that the binary sorbent-catalyst particles were well mixed when the bed was operated at 0.2 m/s. The sorbent can adsorb CO<sub>2</sub> steadily, thus the dry mole fraction of the product hydrogen can get above 0.95 in the 1 m laboratory scale bed, and above 0.97 in the 4 m industrial scale bed. When the laboratory scale bed is operated at a lower velocity of 0.15 m/s, the binary sorbent-catalyst particle mixture was segregated. The heavy sorbent particles accumulate at the bottom of the bed, and the light catalyst particles tend to rise and become distributed at higher sections in the bed. For this reason, the sorbent can not adsorb CO<sub>2</sub> effectively, and the hydrogen product purity was decreased compared to the well-mixed bed. When the bed was operated at a higher superficial gas velocity of 0.3 m/s, the processing work load is increased, and the gas residence time in the reactor is decreased. Therefore, the hydrogen product purity is further decreased. The simulation results obtained for the 4 m industrial scale bed show that a dry mole purity of hydrogen above 0.97 can be obtained due to the increased bed height. These simulation results also show that there is an optimal bed height limit, at which further increase of the packed bed height can not increase the hydrogen purity.

#### 4.4.5.1 The Three-fluid Model for the SMR and SE-SMR Processes

Phase volume constraint:

$$\sum_{k=0}^2 \alpha_k = 1 \quad (4.417)$$

The continuity equation:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k) = \Gamma_k, \quad k = 0, 1, 2 \quad (4.418)$$

The gas phase momentum equation was similar to (4.406) and expressed as:

$$\frac{\partial}{\partial t}(\alpha_0 \rho_0 \mathbf{v}_0) + \nabla \cdot (\alpha_0 \rho_0 \mathbf{v}_0 \mathbf{v}_0) = -\alpha_0 \nabla p_0 - \nabla \cdot (\alpha_0 (\boldsymbol{\sigma}_0 + \boldsymbol{\sigma}_t))$$

$$+ \sum_{d=1}^2 \beta_{0d}(\mathbf{v}_d - \mathbf{v}_0) + \alpha_0 \rho_0 \mathbf{g} + \Gamma_0 \mathbf{v}_0^i \quad (4.419)$$

The solid phase momentum equations were expressed as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_d \rho_d \mathbf{v}_d) + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \mathbf{v}_d) = & -\alpha_d \nabla p_0 - \nabla \cdot \mathbf{p}_d - \beta_{0d}(\mathbf{v}_d - \mathbf{v}_0) \\ & + \sum_{k=1}^2 \beta_{dk}(\mathbf{v}_k - \mathbf{v}_d) + \alpha_d \rho_d \mathbf{g} + \Gamma_d \mathbf{v}_d^i \end{aligned} \quad (4.420)$$

where  $d = 1, 2$  and the dispersed phase pressure is calculated from (4.151), thus  $\mathbf{p}_d = \mathbf{p}_d^{\text{coll}} + \mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{fric}}$ , and closed with (4.155) and (4.158).

The granular temperature equations were given as:

$$\begin{aligned} \frac{3}{2} \frac{\partial}{\partial t}(\alpha_d \rho_d \Theta_d) + \frac{3}{2} \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d \Theta_d) = & -\mathbf{p}_d : \nabla \mathbf{v}_d - \nabla \cdot (\mathbf{q}_d^{\text{kin}} + \mathbf{q}_d^{\text{coll}}) \\ & - 3\beta_{0d} \Theta_d - \gamma_d + \frac{3}{2} \Gamma_d \Theta_d \end{aligned} \quad (4.316)$$

The gas phase turbulent kinetic energy equation was expressed as:

$$\frac{\partial}{\partial t}(\alpha_0 \rho_0 k_0) + \nabla \cdot (\alpha_0 \rho_0 k_0 \mathbf{v}_0) = \alpha_0 (-\boldsymbol{\sigma}_0^{\text{Re}} : \nabla \mathbf{v}_0 + S_p) + \nabla \cdot (\alpha_0 \frac{\mu_0^t}{\sigma_{0k}} \nabla k_0) - \alpha_0 \rho_0 \varepsilon_0 \quad (4.407)$$

The gas phase turbulent kinetic energy dissipation rate equation was formulated as:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_0 \rho_0 \varepsilon_0) + \nabla \cdot (\alpha_0 \rho_0 \varepsilon_0 \mathbf{v}_0) = & \alpha_0 C_1^t \frac{\varepsilon_0}{k_0} (-\boldsymbol{\sigma}_0^{\text{Re}} : \nabla \mathbf{v}_0 + S_p) \\ & + \nabla \cdot (\alpha_0 \frac{\mu_0^t}{\sigma_{0\varepsilon}} \nabla \varepsilon_0) - \alpha_0 \rho_0 C_2^t \frac{\varepsilon_0^2}{k_0} \end{aligned} \quad (4.408)$$

The gas enthalpy transport equation, expressed in terms of temperature, was given by:

$$\alpha_0 \bar{\rho}_0 C_{p,0} \frac{D\langle T_0 \rangle}{Dt} = \nabla \cdot \alpha_0 k_0^{\text{eff}} \nabla \langle T_0 \rangle + \sum_{k=1}^N Q_{0k} + Q_0^R \quad (4.421)$$

The thermal enthalpy transport equation for the granular fluids, expressed in terms of temperature, was given by:

$$\alpha_i \bar{\rho}_i C_{p,i} \frac{D\langle T_i \rangle}{Dt} = \nabla \cdot \alpha_i k_i^{\text{eff}} \nabla \langle T_i \rangle - Q_{0i} + Q_0^R, \quad i = 1, 2 \quad (4.422)$$

The gas species transport equations were defined as:

$$\frac{\partial}{\partial t}(\alpha_0 \bar{\rho}_0 \langle \omega_{0,s} \rangle) + \nabla \cdot (\alpha_0 \bar{\rho}_0 \mathbf{v}_0 \langle \omega_{0,s} \rangle) = \nabla \cdot (\bar{\rho}_0 D_{0j}^{\text{eff}} \nabla \langle \omega_{0,s} \rangle) + \Gamma_{0,s}^\omega \quad (4.412)$$

The granular fluid species transport equations were defined as:

$$\frac{\partial}{\partial t}(\alpha_i \bar{\rho}_i \langle \omega_{i,s} \rangle) + \nabla \cdot (\alpha_i \bar{\rho}_i \mathbf{v}_i \langle \omega_{i,s} \rangle) = \nabla \cdot (\bar{\rho}_i D_{ij}^{\text{eff}} \nabla \langle \omega_{i,s} \rangle) + \Gamma_{i,s}^\omega, \quad i = 1, 2 \quad (4.423)$$

The constitutive equations employed to close the binary particle balance laws derived from the Maxwell-Enskog transport equation are outlined in Sect. 4.4.

#### 4.4.5.2 The SMR and SE-SMR Processes

The reactive source terms in the transport equations need to be closed according to the specific chemical reactions in the chemical reactor under investigation. For the SMR reactor, there are the three chemical reactions (4.190), (4.191) and (4.192). For the SE-SMR reactor, there is one more reaction, the  $CO_2$  adsorption reaction:

There are two types of particles in the fluidized bed; the SMR catalyst and the  $CO_2$  sorbent pellets, i.e. in the multi-fluid model definition  $N$  equals 2. Therefore, a three-fluid model is used in this study. For the gas mixture, assumed to be an ideal gas, five species ( $CH_4$ ,  $CO$ ,  $CO_2$ ,  $H_2$ ,  $H_2O$ ) are applied, i.e.,  $N_g = 5$ . For convenience, in this work, the subscripts 0, 1, and 2 are used to denote the gas, catalyst and sorbent phases, respectively. The subscripts  $CH_4$ ,  $CO$ ,  $CO_2$ ,  $H_2$ ,  $H_2O$  are used to denote these five gas components, respectively.

Steam methane reforming on nickel-based catalysts is the main process for industrial production of hydrogen or synthesis gas. Numerous studies have been reported on the kinetics of these reactions [1, 3, 59, 167]. Xu and Froment [167] investigated a large number of detailed mechanisms and proposed the intrinsic rate equations for the steam reforming of methane on the nickel-alumina catalyst, i.e., (4.193), (4.194) and (4.195) which have been widely used. These rate equations were thus used by Chao [21]. The terms,  $R_1^{SMR}$ ,  $R_2^{SMR}$ ,  $R_3^{SMR}$ , are the reaction rates related to the reactions (4.190)–(4.192), respectively. The partial pressures for  $CH_4$ ,  $CO$ ,  $CO_2$ ,  $H_2$ ,  $H_2O$  are  $p_{CH_4}$ ,  $p_{CO}$ ,  $p_{CO_2}$ ,  $p_{H_2}$ ,  $p_{H_2O}$ , respectively. The different chemical kinetics model parameter values employed were taken from the literature [167]. The effectiveness factors are used in order to consider the pore diffusion resistance and surface phenomena in a simple manner. The effectiveness factor values suggested by Lindborg [97] and Carlo et al. [18] were applied. These values are:  $\eta_1 = 0.7$ ,  $\eta_2 = 0.8$ ,  $\eta_3 = 0.4$ .

For the  $\text{CO}_2$  adsorption reaction (4.424), an adsorption rate definition used in many publications [72–74, 94, 97, 98, 142, 143] was employed:

$$R_{\text{CO}_2}^{\text{ads}} = \frac{dX}{dt}, \quad \left[ \frac{\text{kg CO}_2}{\text{kg}_{\text{ads}} \text{ s}} \right] \quad (4.425)$$

where the fractional conversion of the sorbent  $X$  is defined as  $X = q/q_{\text{max}}$ .  $q$  is the adsorbed  $\text{CO}_2$  mass per mass of sorbent, and  $q_{\text{max}}$  is the maximum  $\text{CO}_2$  capture capacity per sorbent mass.

In the SE-SMR process, the mass transfer between the gas and pellets is due to the  $\text{CO}_2$  adsorption only. In the adsorption process, the  $\text{CO}_2$  gas is adsorbed and becomes a part of the solid sorbent particles, hence  $\Gamma_0 = -\Gamma_2$ . For the SMR catalyst, there is no mass transfer between the gas and the solid catalyst pellets, thus the source term is zero:  $\Gamma_1 = 0$ . Considering the unit consistency,  $\Gamma_2$  must be calculated as:

$$\Gamma_2 = f_s \alpha_2 \rho_2 R_{\text{CO}_2} q_{\text{max}} \quad (4.426)$$

where  $f_s = m(t_0)/m(t)$  is the ratio of the initial to the present total mass of the sorbent particles as further discussed in relation to (4.441), which reflects the original effective mass of the sorbent, i.e., excluding the adsorbed  $\text{CO}_2$ .

The gas species reaction rates used in the gas species transport equations were modeled by [18, 167]:

$$\Gamma_{0,\text{CH}_4}^\omega = -\alpha_2 \rho_2 M_{\text{CH}_4} (R_1^{\text{SMR}} + R_2^{\text{SMR}}) \quad (4.427)$$

$$\Gamma_{0,\text{CO}}^\omega = \alpha_2 \rho_2 M_{\text{CO}} (R_1^{\text{SMR}} - R_3^{\text{SMR}}) \quad (4.428)$$

$$\Gamma_{0,\text{CO}_2}^\omega = \alpha_2 \rho_2 M_{\text{CO}_2} (R_2^{\text{SMR}} + R_3^{\text{SMR}}) - \alpha_3 \rho_3 f_s R^{\text{SE}} q_{\text{max}}^{\text{SE}} \quad (4.429)$$

$$\Gamma_{0,\text{H}_2}^\omega = \alpha_2 \rho_2 M_{\text{H}_2} (3R_1^{\text{SMR}} + R_3^{\text{SMR}} + 4R_2^{\text{SMR}}) \quad (4.430)$$

$$\Gamma_{0,\text{H}_2\text{O}}^\omega = -\alpha_2 \rho_2 M_{\text{H}_2\text{O}} (R_1^{\text{SMR}} + R_3^{\text{SMR}} + 2R_2^{\text{SMR}}) \quad (4.431)$$

The terms  $\Gamma_i \mathbf{v}_i$  and  $\Gamma_0 \mathbf{v}_0^i$  in the momentum equations were neglected. Similarly, the mass transfer terms in the granular temperature equations  $\frac{3}{2} \Gamma_i \Theta_i$  were also neglected.

The reaction heat probably involves both the gas and particle phases since the reactions were assumed to take place at the inter-faces between the gas and particles thus both the gas and particle molecules reacting are being heated/cooled. However, in some previous studies [18, 97], both the SMR and  $\text{CO}_2$  reaction heat sources were placed in the particle phase equations. In the study by Chao [21], on the other hand, it was assumed that the SMR reactions occur in the gas phase, whereas the adsorption reaction occurs in the sorbent phase. With these considerations, the reaction heat source term due to the SMR process within the gas thermal temperature transport equation (4.409) was modeled as:

**Table 4.21** Enthalpy change for SMR reactions (kJ/mol) [167]

| 948 K                      |                            |                            |                            | 298 K                      |                            |
|----------------------------|----------------------------|----------------------------|----------------------------|----------------------------|----------------------------|
| $\Delta H_{R_{0,1}}^{SMR}$ | $\Delta H_{R_{0,2}}^{SMR}$ | $\Delta H_{R_{0,3}}^{SMR}$ | $\Delta H_{R_{0,1}}^{SMR}$ | $\Delta H_{R_{0,2}}^{SMR}$ | $\Delta H_{R_{0,3}}^{SMR}$ |
| 224.0                      | -37.3                      | 187.5                      | 206.1                      | -41.15                     | 164.9                      |

$$Q_0^R = \alpha_1 \rho_1 \sum_{r=1}^3 R_{0,r}^{SMR} \Delta H_{R_{0,r}}^{SMR} \quad (4.432)$$

The enthalpy changes for the three SMR reactions were calculated by interpolation using the data [167] in Table 4.21.

The reaction heat source term in the catalyst phase is zero, i.e.  $\Gamma_1 \Delta H_{R_{1,s}} = 0$ . The adsorption reaction was assumed to take place on the sorbent particle surfaces, hence the reactive heat source term was modeled as  $\Gamma_2 \Delta H_{R_{2,CO_2}}$ . The enthalpy change  $\Delta H_{R_{2,CO_2}}$  was calculated as [80]:

$$\Delta H_{R_{2,CO_2}} = -1. \times 10^6 (-157.63 + 8.36 \times 10^{-3} \langle T_2 \rangle - 1.088 \times 10^{-6} / \langle T_2 \rangle^2) \quad (4.433)$$

The gas mixture heat capacity was calculated as [122]:

$$C_{p,0} = \sum_{\xi=1}^{N_\xi} (A_{0,\xi}^0 + A_{0,\xi}^1 \langle T_0 \rangle + A_{0,\xi}^2 \langle T_0 \rangle^2 + A_{0,\xi}^3 \langle T_0 \rangle^3) \frac{\omega_{\xi,c} / M_{\omega_\xi}}{M_\omega} \quad (4.434)$$

The heat capacities for the particles  $C_{p,1}$ ,  $C_{p,2}$  were taken from the literature [80, 97].

The transport equation for the species mass fraction  $\omega_{2,\xi}$  of the adsorbate  $CO_2$  was obtained from (4.338):

$$\begin{aligned} \frac{\partial}{\partial t} (\alpha_2 \bar{\rho}_2 \langle \omega_2 \rangle) + \nabla \cdot (\alpha_2 \bar{\rho}_2 \mathbf{v}_2 \langle \omega_2 \rangle) = & - \nabla \cdot (\alpha_2 \bar{\rho}_2 \langle \mathbf{C}_2 \omega_2' \rangle) \\ & + \alpha_2 \bar{\rho}_2 \langle \frac{dm_2}{dt} (\frac{\partial \omega_2}{\partial m_2} + \frac{\omega_2}{m_2}) \rangle \end{aligned} \quad (4.435)$$

The first term at the RHS was modeled as a diffusion term:

$$- \nabla \cdot (\alpha_2 \bar{\rho}_2 \langle \mathbf{C}_2 \omega_2' \rangle) = \nabla \bar{\rho}_2 D_{\omega_2}^{\text{eff}} \nabla \omega_2 \quad (4.436)$$

The diffusion coefficient  $D_{\omega_2}^{\text{eff}}$  was approximated in accordance with (4.285):

$$D_{\omega_2}^{\text{eff}} = \frac{d_2}{16\alpha_2} \sqrt{\pi \Theta_2} \quad (4.437)$$

If the initial mass of the sorbent particle is denoted by  $m_2^0$ , and the present  $CO_2$  adsorption mass is represented by  $\Delta m_2(t)$ , the following relation holds for the overall

sorbent particle mass (sorbent particle plus CO<sub>2</sub>):

$$m_2(t) = m_2^0(t_0) + \Delta m_2(t) \quad (4.438)$$

Moreover, the CO<sub>2</sub> mass fraction of the adsorbate,  $\omega_{CO_2,2}$ , might be expressed as:

$$\omega_{CO_2,2} = \frac{\Delta m_2(t)}{m_2(t)} = \frac{m_2(t) - m_2^0}{m_2(t)} = 1 - \frac{m_2^0}{m_2(t)} \quad (4.439)$$

Inserting (4.439) into the source term in (4.435), yields:

$$\alpha_2 \bar{\rho}_2 \left\langle \frac{dm_2}{dt} \left( \frac{\partial \omega_2}{\partial m_2} + \frac{\omega_2}{m_2} \right) \right\rangle = \alpha_2 \bar{\rho}_2 \left\langle \frac{dm_2}{dt} \frac{1}{m_2} \right\rangle = \Gamma_2 \quad (4.440)$$

Constitutive equations for several other model parameters were approximated in accordance with the approaches proposed by Lindborg [97]:

$$f_s = \frac{m_0}{m(t)} \quad (4.441)$$

$$S_{k_c} = C_p \beta_{01} (\mathbf{v}_1 - \mathbf{v}_0)^2 + C_p \beta_{02} (\mathbf{v}_2 - \mathbf{v}_0)^2 \quad (4.442)$$

$$D_{0s}^{\text{eff}} = D_{0s}^m + D_0^t \approx D_{0s}^{\text{m,Wilke}} + \frac{\mu_0^t}{\rho_0 \text{Sc}^t} \quad (4.443)$$

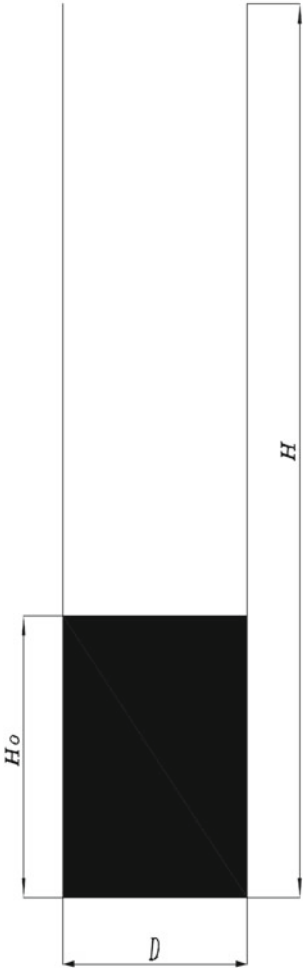

$$k_0^{\text{eff}} = k_0^m + k_0^t = \frac{k_0^{\text{stat}}}{\alpha_0} \left( 1 - \left( \sum_{k=1}^N \right)^{1/2} \right) + \frac{\mu_0^t}{\rho_0 \text{Pr}^t} \quad (4.444)$$

The thermal heat conductivity for the particles,  $k_i^{\text{eff}}$ ,  $i=1,2$ , were derived based on the mean free path analogy as proposed by Lathouwers and Bellan [89]:

$$k_i^{\text{eff}} = \frac{2C_{p,i} \rho_i \Theta_i}{\sum_{k=1}^2 \sqrt{2\pi} d_{ik}^2 n_k (\Theta_i^{1/2} + \Theta_k^{1/2} - 0.56 \Theta_i^{1/4} \Theta_k^{1/4})}. \quad (4.445)$$

#### 4.4.5.3 Three-fluid Model Simulation of SMR and SE-SMR Processes

Chao [21] implemented the model into a in-house program code written in the programming language FORTRAN and simulated a 1 m high laboratory scale and a 4 m high industrial scale SE-SMR fluidized bed reactors using the three-fluid model.

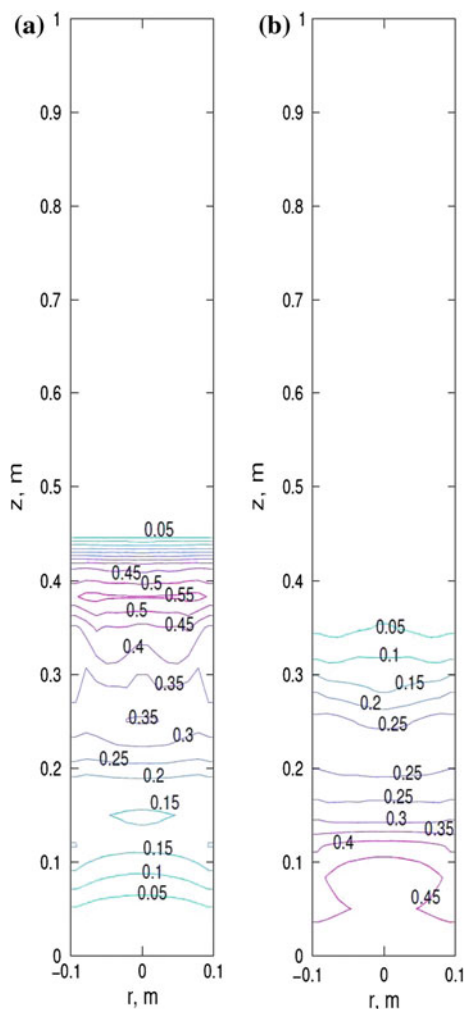

**Fig. 4.17** Sketch of a fluidized bed reactor

**Table 4.22** Simulation parameters [21]

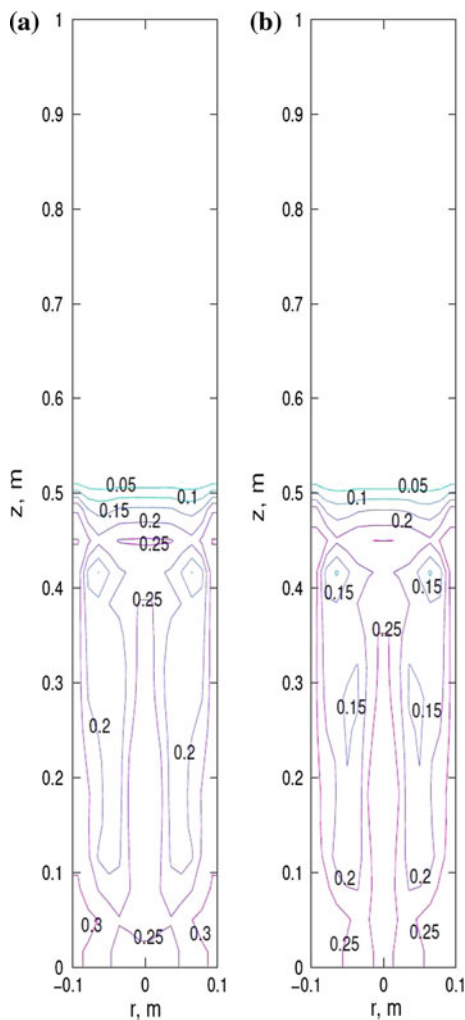

|                                              |                                                                                  |
|----------------------------------------------|----------------------------------------------------------------------------------|
| Size of laboratory scale reactor             | $D=0.1\text{ m}, H=1\text{ m}, H_0=0.375\text{ m}$                               |
| Size of industrial scale reactor             | $D=0.6\text{ m}, H=4\text{ m}$<br>$H_0=1.0\text{ m}; 1.5\text{ m}; 2.0\text{ m}$ |

**Fig. 4.18** Binary particle volume fraction distribution in the laboratory scale reactor (SE-SMR process;  $X = 0.3$ ;  $v_g = 0.15$  m/s) **a** Sorbent **b** Catalyst

The finite volume method with a staggered grid arrangement was applied to discretize the model equations. The grid was uniform in both the radial and the axial coordinates, but the grid spacing was different in the two dimensions. A two-dimensional cylindrical coordinate system was used. The calculation domain was divided into  $20 \times 60$  control volumes in the radial and axial coordinates, respectively. The numerical schemes used were the same as those used by Lindborg [97]. However, since these simulations were very time consuming, the simulations were not run from the fresh sorbent state, i.e.,  $X = 0$ , to the fully-adsorbed state,  $X = X_u$ . The simulations were run for certain  $X$  interval values denoting some sampled points of the  $\text{CO}_2$

**Fig. 4.19** Binary particle volume fraction distribution in the laboratory scale reactor (SE-SMR process;  $X = 0.3$ ;  $v_g = 0.3$  m/s)(a, b)

adsorption process. Generally, each of the simulations was run for 60–100 s. The simulations were performed for a laboratory and an industrial scale bubbling bed reactor as illustrated in Fig. 4.17. The simulation parameters are given in Table 4.22. The reactors were operated in the adiabatic mode. The catalyst and sorbent particles have identical sizes. The packed total solid (constituting the catalyst plus sorbent particles) volume fraction was 0.63.

**Table 4.23** Dry gas mole fractions at the industrial scale reactor outlet  
( $X=0.3$ ;  $v_g=0.2$  m/s) [21]

| Packed bed height $H_0$ | $H_2$  | $CO_2$ | CO     | $CH_4$ |
|-------------------------|--------|--------|--------|--------|
| 1.0 m                   | 0.9713 | 0.0166 | 0.0080 | 0.0041 |
| 1.5 m                   | 0.9742 | 0.0112 | 0.0092 | 0.0054 |
| 2.0 m                   | 0.9750 | 0.0106 | 0.0090 | 0.0054 |

The performance of the SE-SMR process was compared with the SMR process operated in the fluidized bed reactor. The simulation results show that the sorbent particles can adsorb  $CO_2$  in these reactors, thus it was concluded that a higher purity of the hydrogen product can be obtained in a SE-SMR reactor compared to in a conventional SMR reactor. The influences of the superficial gas velocities and the solid loading (packed bed heights) on the reactor performance (hydrogen purity) were investigated. The superficial gas velocity is an important parameter. A steady SE-SMR bed performance was obtained provided that the bed was operated at an optimized medium level superficial gas velocities. Chao [21] found that the binary sorbent-catalyst particle mixture was well mixed when the bed was operated at 0.2 m/s. Under these conditions, the sorbent did adsorb  $CO_2$  steadily thus the dry mole fraction of the hydrogen product did get above 0.95 in the 1 m laboratory scale bed, and above 0.97 in the 4 m industrial scale bed. However, when the laboratory scale bed was operated at a lower superficial gas velocity of 0.15 m/s, the binary sorbent-catalyst particle mixture was segregated. Figure 4.18 shows the binary particle volume fraction distributions for the case in which the bed was operated at a lower superficial gas velocity 0.15 m/s. In this case, the heavy sorbent particles did accumulate at the bottom of the bed, and the light catalyst particles tend to rise and become distributed at higher sections in the bed. For this reason, the sorbent did not adsorb  $CO_2$  in an optimized manner, and the hydrogen product purity was decreased compared to the well-mixed bed case. When the bed was operated at an even higher superficial gas velocity of 0.3 m/s, the process work load is increased, and the gas residence time in the reactor was decreased. Therefore, the hydrogen product purity was further decreased. Figure 4.19 shows the binary particle volume fraction distributions for the case in which the bed was operated at a higher superficial gas velocity 0.3 m/s.

The simulation results obtained for the 4 m industrial scale bed show that a dry mole purity of hydrogen above 0.97 can be obtained due to the increased bed height. The calculated dry gas mole fractions at the reactor outlet are given in Table 4.23. These simulation results also show that there was an optimal bed height limit, at which further increase of the packed bed height can not increase the hydrogen purity.

## Chapter 5

# Interfacial Transport Phenomena Closures

The macroscopic multi-phase models resulting from the local averaging procedures must be supplemented with state equations, constitutive equations, boundary and initial conditions. *The constitutive equations* specify how the phases interact with themselves and with each other. The closure laws or constitutive laws can thus be divided into three types [16]; *Topological, constitutive and transfer laws*, where the first type describes the spatial distribution of phase-specific quantities, the second type describes physical properties of the phases and the third type describes different interactions between the phases.

The accurate modeling of multiphase flows requires that the phase interaction terms given by the jump conditions are correctly parameterized. This problem is very involved since not all of the phase interaction and phase change terms are independent. Most of the existing expressions are of empirical nature, thus experimental data are needed in order to develop and validate laws. Guiding principles for formulating closure laws are given by [3, 31, 35–37]:

1. The principle of *equipresence* states that if one variable is known to depend on one specific variable, then all other variables to be constituted must be allowed to depend on the same variable (i.e. unless another principle shows that a particular dependence cannot occur). This principle prevents a priori prejudicing of the constitutive equations by selectively excluding certain dependencies. It is usually this principle which makes the general approach impractical, since it forces us to include dependencies for which there is no physical evidence. In practice, however, this principle has to be compromised.
2. The principle of *well-posedness* states that the description of the motion should be such that a solution to the initial boundary value problem exists and depends continuously on the initial and boundary conditions.  
In mathematical terms this implies that all eigenvalues of the system of Partial Differential Equations, PDEs, are real.
3. The principle of *material frame indifference (objectivity)* states that variables, for which constitutive equations are needed, cannot depend on the coordinate frame (i.e., Euclidean space, plus time) in which the variables are expressed.

4. The principle of *coordinate invariance* states that constitutive rules must be stated in such a way that they do not depend on the coordinate system. One way to insure that this principle is satisfied is to work with dyadic or invariant notation as is common practice in the more mathematical engineering disciplines.
5. The *dimensional invariance* principle states that the constitutive equations must be dimensionally correct, and that arbitrary functional dependences can only occur through dimensionless variables.
6. The *phase separation* principle states that the bulk phase quantities should be functions of only the average variables for that phase.
7. The *correct low concentration limits* principle states that, in the limit as  $\alpha_k \rightarrow 0$ , the equations for the dispersed phases should approach the appropriate single particle equations, while the equations for the continuous phase should approach the correct equations for that single phase continuous fluid.
8. The *entropy inequality* principle must hold for all locations of the system. The closure law formulation is restricted by the second law of thermodynamics.

To be able to estimate the interfacial momentum, heat and mass transfer fluxes we need a firm understanding of the basic transport processes. A survey of the pertinent modeling concepts that may be adopted describing these phenomena in chemical reactors is given. Both the well known parameterizations used in the conventional reactor models (i.e., basically denoting a closed set of heat and species mass balances), and a few more rigorous formulations which rely on detailed information of the local flow patterns (i.e., for models that consist of a complete set of the governing balance equations for mass, momentum, heat, and species mass) are described. The latter group of model concepts may have the potential of improving the description of the interfacial fluxes in the more advanced multiphase reactor model formulations. The primary interfacial closure laws were originally established in the context of the Lagrangian model formulation in which a single particle is surrounded by a continuous fluid of infinite extent. These concepts have later been adopted in the Eulerian models considering dilute non-colliding particulate flows. In this case a volume (space) averaged macro-scopic model formulation is most convenient as this view allows of an intuitive physical interpretation of the coupling terms. In recent years the approximate Eulerian interfacial closure law parameterizations are adopted for the alternative macroscopic model formulations as well (even though the original physical interpretations of these closures may not be consistent with the different averaging methods).

## 5.1 Interfacial Momentum Transfer Closures

Many authors of scientific literature have addressed the mathematical problem of averaging microscopic balance equations in order to derive macroscopic model formulations. However, the result is always a set of equations in which extra terms involving integrals over the microscopic domains remain. While various hypotheses

may be made about interfacial closure laws expressing these extra terms as functions of the solution variables, it is not clear that such laws always exist, what form they should take and what approximations may be implied in their use. One can thus state that the constitutive equations for the interfacial terms are the weakest link in a multi-fluid model formulation because of considerable difficulties in terms of experimentation and modeling on a macroscopic level. The main difficulties in modeling arise from the existence of interfaces between phases and discontinuities associated with them. In practice one needs to provide appropriate formulations for the interfacial momentum closure laws using analytical expressions which are (to some extent) based on the general modeling principles presented in the introduction of this chapter, and that physically reproduce experimental results with reasonable fidelity. The formulations that will be given for various forces and effects will typically be applicable only for given ranges of particle-fluid conditions.

Introductorily we examine a generally accepted momentum balance formulation for a small (point) particle generally referred to as Newton's second law. The net force is conventionally split into the uncoupled effects of drag, gravity ( $\mathbf{f}_G$ ), body forces other than gravity ( $\mathbf{f}_E$ ), hydrostatic pressure force ( $\mathbf{f}_{hp}$ ), external pressure gradient force ( $\mathbf{f}_p$ ), pressure gradient term ( $\mathbf{f}_{pg}$ ), and wall interactions ( $\mathbf{f}_W$ ). The net drag force or *generalized drag* is usually split into the effects of steady drag ( $\mathbf{f}_D$ ), lift ( $\mathbf{f}_L$ ), virtual—or added mass ( $\mathbf{f}_V$ ), and Basset history force ( $\mathbf{f}_B$ ) terms. A fairly rigorous form of the Newton's second law can be expressed by [7, 26, 79, 81, 85, 86]:

$$\begin{aligned} \frac{d}{dt}(m_p \mathbf{v}_p) &= \sum_k \mathbf{f}_k \\ &\approx \mathbf{f}_D + \mathbf{f}_L + \mathbf{f}_V + \mathbf{f}_B + \mathbf{f}_G + \mathbf{f}_E + \mathbf{f}_{hp} + \mathbf{f}_p + \mathbf{f}_{pg} + \mathbf{f}_W \end{aligned} \quad (5.1)$$

This equation is referred to as the Basset [10]-Boussinesq [18]-Osceen [94] (BBO) equation.

The linear split of the net drag force acting on the particle is not always valid as there can be non-linear interactions between the various forces. Such interactions are not well understood, but are typically small enough to be neglected for many conditions [79].

For a particle moving in a fluid in motion the momentum equation might be extended including the so-called *pressure gradient force* term:

$$\mathbf{f}_{pg} = m_c \frac{D\mathbf{v}_c}{Dt} \quad (5.2)$$

which represents the force generated by the local pressure gradient in the fluid surrounding the particle due to fluid acceleration. In this model  $m_c$  denotes the mass of fluid enclosed in the volume of the particle. The pressure gradient term is naturally associated with the fluid acceleration as determined from the Navier-Stokes equation for the conveying fluid [22, 26].

For gas-rigid particle and gas-droplet flows, where the ratio of the continuous phase density to the dispersed particle material density is small ( $\sim 10^{-3}$ ), the RHS

of the BBO equation is dominated by the steady drag ( $\mathbf{f}_D$ ) and the gravity ( $\mathbf{f}_G$ ) forces. For liquid–solid flows for which the densities are comparable a complete BBO equation might be required. For bubbly flows the important forces are  $\mathbf{f}_D$ ,  $\mathbf{f}_L$ ,  $\mathbf{f}_V$ ,  $\mathbf{f}_G$ , and  $\mathbf{f}_{hp}$ . It is noted that the virtual mass force is of particular importance in this case because the fluid phase density is much larger than the particle density ( $\sim 10^3$ ). In general, the steady drag and gravity forces are the predominant forces in multiphase flow systems, and as such it is helpful to consider the ratio of the other forces to either of these so that their inclusion or neglect can be properly decided. The fluid-particle interaction closures applied in the modern single particle momentum balances originate from the classical work on the Newton's second law as applied to a small rigid sphere in an unsteady, non-uniform flow limited to Stokesian flow conditions ( $Re_p \ll 1$ ), as derived by Stokes [118] and Basset [10]. The formulation of extended force expressions which are valid for larger particle Reynolds numbers to enable a more general description have later been the subject of much experimental and theoretical research. The fundamental modeling principles are outlined in the sequel.

In mathematical terms the total hydrodynamic surface force,  $\mathbf{f}_S$ , exerted by a continuous fluid on a particle is defined as [11, 99] (p. 404) [14, 101]:

$$\mathbf{f}_S = - \iint_A \mathbf{T} \cdot \mathbf{n} da \quad (5.3)$$

where  $\mathbf{T}$  is the total stress tensor for the continuous fluid and  $\mathbf{n}$  is the outward directed unit normal vector to the particle surface  $A$ .

The components  $f_{S,i}$  of the hydrodynamic force on the sphere are given by [14, 101]:

$$f_{S,i} = - \iint_A T_{ij} n_j da \quad (5.4)$$

where  $T_{ij}$  denotes the components of the total stress tensor,  $\mathbf{T}$ , in the  $x_i$ -direction acting on a surface element whose normal is in the  $x_j$ -direction, and  $n_j$  is the  $j$ th component of the unit outward normal vector to the particle surface,  $A$ .

To evaluate the integral in the surface force definition (5.3), and to make the formulation consistent with the conventional momentum balance given (5.1), the conveying fluid pressure is decomposed into three contributions:

$$p_c = \rho_c \mathbf{g} \cdot \mathbf{r} + p_{c,\text{ext}} + p_{c,\text{dyn}} \quad (5.5)$$

The first term on the RHS corresponds to the hydrostatic pressure ( $p_{c,hp}$ ), the second represents any external pressure not induced by gravity ( $p_{c,\text{ext}}$ ), and the third ( $p_{c,\text{dyn}}$ ) denotes the dynamic pressure.

The surface force can then be rewritten as:

$$\begin{aligned}
 \mathbf{f}_S &= - \iint_{A_p} [(\rho_c \mathbf{g} \cdot \mathbf{r} + p_{c,\text{ext}} + p_{c,\text{dyn}}) \mathbf{e} + \boldsymbol{\sigma}_c] \cdot \mathbf{n} da \\
 &= - \iiint_{V_p} \nabla \cdot (\rho_c \mathbf{g} \cdot \mathbf{r} + p_{c,\text{ext}}) \mathbf{e} dv - \iint_{A_p} (p_{c,\text{dyn}} \mathbf{e} + \boldsymbol{\sigma}_c) \cdot \mathbf{n} da \\
 &= - V_p (\rho_c \mathbf{g} + \nabla p_{c,\text{ext}}) + \mathbf{f}_{\text{hydr}} = \mathbf{f}_{hp} + \mathbf{f}_p + \mathbf{f}_{c,\text{hydr}}
 \end{aligned} \tag{5.6}$$

this transformation is restricted to incompressible fluids and constant external pressure gradients.

The net hydrodynamic force, frequently also referred to as the generalized drag force, is usually further divided into numerous contributions like the steady drag, virtual mass, lift, and history forces:

$$\mathbf{f}_{c,\text{hydr}} \approx \mathbf{f}_D + \mathbf{f}_V + \mathbf{f}_L + \mathbf{f}_{\text{hist}} \tag{5.7}$$

In the general case the structure of the hydrodynamic force for incompressible fluids is generally retained.

The *steady drag* is the component of the hydrodynamic force acting on the particle surface in the continuous phase flow direction. One might, for example, imagine a uniform velocity in the  $z$ -direction as sketched in Fig. 5.1, and describe the external flow using the Cartesian coordinate system, then the steady drag force is defined by [14, 30]:

$$f_{D,z} = - \iint_A p \mathbf{e}_z \cdot \mathbf{n} da - \iint_A \mathbf{n} \cdot \boldsymbol{\sigma} \cdot \mathbf{e}_z da \tag{5.8}$$

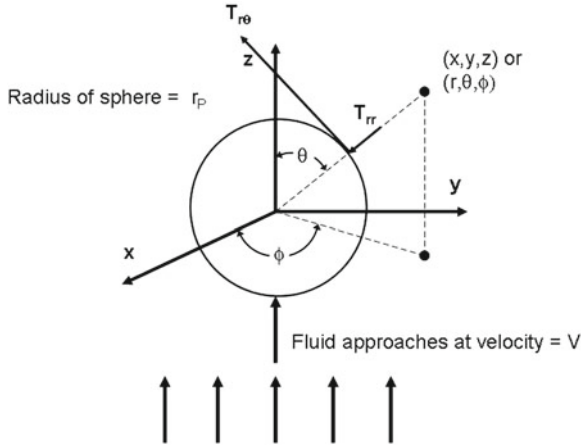

where  $p$  is the pressure,  $\mathbf{e}_z$  is the unit vector in the  $z$ -direction, and  $\boldsymbol{\sigma}$  is the viscous stress tensor.

By use of vector and tensor identities, this expression may be rearranged to:

$$f_{D,z} = - \iint_A p n_z da - \iint_A \sigma_{zj} n_j da \tag{5.9}$$

The steady drag force may be split into two components, the *form* drag and the *friction* drag. The form drag, also called *pressure* drag, is the normal components of the total stress integrated over the surface area, while the friction drag consists of the surface integral of the shear components of the total stress. Consequently, the drag forces are defined as:

$$f_{D,z} = f_{D,\text{form}} + f_{D,\text{friction}} \tag{5.10}$$

**Fig. 5.1** Normal and shear stresses acting on the surface of a sphere, The stresses are due to the flow around the sphere with fluid velocity  $V\mathbf{e}_z$  far from the sphere

The form and friction drag forces are given by:

$$f_{D,\text{form}} = - \iint_A p n_z da - \iint_A \sigma_{zz} n_z da \quad (5.11)$$

$$f_{D,\text{friction}} = - \iint_A (\sigma_{zx} n_x + \sigma_{zy} n_y) da \quad (5.12)$$

The *lift* force is the component of the hydrodynamic force acting on the particle surface normal to the direction of flow, say  $y$ -direction as we are considering a uniform fluid velocity in the  $z$ -direction [30]:

$$f_{L,y} = - \iint_A p \mathbf{e}_y \cdot \mathbf{n} da - \iint_A \mathbf{n} \cdot \boldsymbol{\sigma} \cdot \mathbf{e}_y da \quad (5.13)$$

where  $\mathbf{e}_y$  is the unit vector in the  $y$ -direction.

For applications in Eulerian model formulations the particles are assumed small and the dispersion is sufficiently dilute so that there is no significant particle-particle interactions [57, 58]. The net force on the particles per unit of mixture volume,  $\mathbf{F}_P$ , is then obtained by multiplying  $\mathbf{f}_P$  by the number density of particles,  $N_P$  (e.g., Albråten [1]):

$$\mathbf{F}_P = \mathbf{f}_P N_P \quad (5.14)$$

where  $\mathbf{f}_P$  is the net force on a single sphere.

It is noted that even though this relation (5.14) is often adopted when reactor modelers attempt to approximate the macroscopic interfacial momentum coupling

terms in the averaged multi-fluid model formulations, such a closure is strictly not rigorous. That is, the given relation (5.14) is rigorous in itself but it is not strictly consistent with the coupling terms produced by the averaging procedures. Recollect that the average transfer terms are generally defined in terms of the difference between the total pressure and viscous stresses and their interfacial average counterparts so that these definitions deviate significantly from those used obtaining the classical solutions for the drag force components. The number density of particles per unit mixture volume, can be expressed in terms of the volume fraction of the dispersed phase,  $\alpha_d$ , and the averaged particle volume,  $V_p$ :

$$N_p = \frac{\alpha_p}{V_p} = \frac{\text{Number of Particles}}{\text{Mixture Volume}} \quad (5.15)$$

The volume fraction of the dispersed phase is given by:

$$\alpha_p = \frac{\text{Volume of particulate phase}}{\text{Mixture Volume}} = V_p N_p. \quad (5.16)$$

The average volume of a single particle is given by:

$$V_p = \left(\frac{\pi}{6}\right) d_V^3 \quad (5.17)$$

where  $d_V$  is the volume averaged particle diameter.

Indeed, several important length scales for a dispersed system can be defined [57]:

The Sauter mean diameter:

$$d_S = \frac{6V_p}{A_S} \quad (5.18)$$

The drag diameter:

$$d_D = \frac{3V_p}{2A_P} \quad (5.19)$$

The equivalent diameter:

$$d_V = \left(\frac{6V_p}{\pi}\right)^{1/3} \quad (5.20)$$

The surface diameter:

$$d_A = \left(\frac{A_S}{\pi}\right)^{1/2} \quad (5.21)$$

in which  $A_S$  is the average surface area per particle, and  $A_P$  is the average projected area per particle on a plane normal to the flow. For spherical particles the above defined diameters are all equivalent. For a system with a distribution of particle sizes it is necessary to calculate the corresponding mean values for these parameters.

One can now define the interfacial area concentration or contact area  $a_S$  by:

$$a_S = N_p A_S \quad (5.22)$$

Using the given length scale definitions (5.18) to (5.21) the area concentration can be expressed in a number of forms:

$$a_S = \frac{6\alpha_P}{d_S} = \frac{6\alpha_P}{d_V} \left(\frac{d_A}{d_V}\right)^2 = \frac{6\alpha_P}{d_D} \left(\frac{d_D}{d_S}\right) \quad (5.23)$$

The ratio of the Sauter mean diameter to the drag diameter appears as a shape factor. It is noted that for non-spherical particles or for systems with a particle size distribution, the various shape factors may not be unity. However, for a distribution of spherical particles, the shape factor,  $(\frac{d_{PD}}{d_{PS}})$ , is unity regardless of the particle size distribution. However, in most reactor simulations the shape factors have been set to unity for all multiphase systems.

Obtaining closed expressions describing the hydrodynamic forces experienced by rigid particles, drops or bubbles embedded in various flows has been a subject of active research since the first experimental studies of the drag force on spheres in viscous fluid were made by Newton in 1710 [117]. A brief survey of the important experimental observations, theory and the commonly used generalized drag force models is given in the following subsections. Numerous review papers present the state-of-the-art concerning the steady drag, history, added mass and lift forces. The reviews by [22, 26, 58, 79, 81–84, 88, 119, 122, 145] are recommended for complementary studies.

### 5.1.1 Drag Force on a Single Rigid Sphere in Laminar Flow

Stokes showed in 1851 that for very low Reynolds numbers ( $\text{Re}_P \ll 1$ ) the drag force can be found by theoretical analysis [118]:

$$f_D = 6\pi\mu_f r_P v_{\text{rel}} \quad (5.24)$$

which consists of one third *form drag* (due to pressure) and two thirds *friction drag* (due to shear stresses).

Due to its great importance in reactor simulations, a brief survey of the main steps involved in Stokes' solution of the Navier-Stokes equation for creeping motion about a smooth immersed rigid sphere is provided. The details of the derivation is not repeated in this book as this task is explained very well in many textbooks [14, 15, 88, 140]. Consider an incompressible creeping motion of a uniform flow of speed  $V = |\mathbf{v}| \approx |v_z \mathbf{e}_z|$  approaching a solid sphere of radius  $r_P$ , as illustrated in Fig. 5.1. To describe the surface drag force in the direction of motion it is convenient

to use spherical polar coordinates  $(r, \theta)$ , with  $\theta = 0$  in the  $z$ -direction. Moreover, we assumed symmetry about the  $z$ -axis (placing origin of the external Cartesian coordinate system for the bulk flow at the mass center of the sphere so that it coincides with the origin of the internal spherical coordinate system) reducing the continuity and Navier-Stokes equations significantly because all derivatives  $\partial/\partial\phi$  and all terms with  $v_\phi$  can be disregarded. The approximate 2D flow problem is then transformed by use of the Stokes stream function and solved analytically as the problem yields a product solution  $\psi(r, \theta) = f(r)g(\theta)$ . The two unknown velocity components  $v_r(r, \theta, \psi)$  and  $v_\theta(r, \theta, \psi)$  are related to the Stokes stream function and can thus be expressed in terms of  $(r, \theta)$  only, eliminating the stream function variable using the Stokian analytical solution  $\psi = \psi(\theta, r)$  for creeping motion past a sphere. With  $v_r(r, \theta)$  and  $v_\theta(r, \theta)$  known, the pressure  $p(r, \theta)$  is found by integrating the reduced form of the momentum equation neglecting all the inertia terms. The local surface problem is linked to the uniform bulk velocity through the boundary conditions, revealing the convenience of making the origins of the internal and external coordinate systems coincide. In view of the symmetry assumption adopted the fluid exerts a shear stress  $T_{r\theta}(r_p, \theta)$ , tangential to the particle surface, and a radial normal stress  $T_{rr}(r_p, \theta)$ , perpendicular to the surface. At any point on the surface of the sphere, both stresses have components in the direction of motion. It follows that at any point on the surface the normal stress has a component  $(-T_{rr}(r_p, \theta) \times \cos \theta)$  in the direction of motion. The drag force due to this stress is obtained from (5.9) by integration over the entire surface of the particle. Hence,

$$\begin{aligned} f_{D,z}^{\text{Normal}} &= \int_0^{2\pi} \int_0^\pi \left[ -T_{rr}(r_p, \theta) \cos \theta \right] r_p^2 \sin \theta d\theta d\phi \\ &= 2\pi \int_0^\pi \left[ -\left( p - 2\mu \frac{\partial v_r}{\partial r} \right) \right]_{r_p} \cos \theta \left[ r_p^2 \sin \theta d\theta \right] = 2\pi \mu r_p V \end{aligned} \quad (5.25)$$

In most papers the contribution from the normal viscous stresses is assumed negligible compared to the pressure contribution [14, 15, 22, 140]. Nevertheless, Middleman [88] kept the normal viscous stress contributions<sup>1</sup> and after a lengthy exercise in calculus he shows that the the above mentioned simplification is valid. Actually, for any kind of flow pattern the normal viscous stresses are zero at fluid–solid boundaries for Newtonian fluids with constant density (i.e., in which the continuity equation reduces to  $\nabla \cdot \mathbf{v} = 0$ ) as a consequence of the no-slip boundary condition [15].

Likewise, the viscous shear component  $(T_{r\theta}(r_p, \theta) \times \sin \theta)$  can be integrated to give a viscous force acting in the direction of the external flow:

---

<sup>1</sup> It is not evident whether the normal viscous contribution should be regarded as a component of form drag or of skin friction.

$$\begin{aligned}
f_{D,z}^{\text{Shear}} &= \int_0^{2\pi} \int_0^\pi \left[ T_{r\theta}(r_p, \theta) \sin \theta \right] r_p^2 \sin \theta d\theta d\phi \\
&= 2\pi \int_0^\pi \left[ -\mu \left( r \frac{\partial}{\partial r} \left( \frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right) \right]_{r_p} \cos \theta \left[ r_p^2 \sin \theta d\theta \right] = 4\pi \mu r_p V \quad (5.26)
\end{aligned}$$

The total drag on the sphere in the direction of flow becomes:

$$f_{D,z} = f_{D,z}^{\text{Normal}} + f_{D,z}^{\text{Shear}} = 2\pi \mu r_p V + 4\pi \mu r_p V = 6\pi \mu r_p V \quad (5.27)$$

This result is called the Stokes law. For a freely moving particle the interfacial drag formulation is normally modified and written as (5.24).

Except for the Stokes' regime,<sup>2</sup> an analytical description of the flow field is difficult. It has thus become common practice to apply a generalized steady drag force formulation intended to be valid for all flow regimes. Applying the principle of coordinate invariance, one intends to work with an invariant notation. Considering a particle motion in a continuous fluid the velocity relative to the surrounding fluid, and not only the fluid velocity as indicated by Stokes law, will determine an invariant drag force (i.e., an expression for the force that is independent of the coordinate system). This leads to the standard expression for the steady drag [26, 35, 57, 101]:

$$\mathbf{f}_D^{\text{Steady}} = \frac{1}{2} C_D \rho_f A_P |\mathbf{v}_f - \mathbf{v}_p| (\mathbf{v}_f - \mathbf{v}_p) \quad (5.28)$$

where  $C_D$  is the drag coefficient.

For the problem of describing fluid flow past a rigid sphere, the relative importance of the convective acceleration term (also called the inertia term) and the linear viscous acceleration term can be assessed by dimensional arguments. Consider the drag force on a sphere falling or raising in the  $+z$ -direction within a stagnant fluid or the equivalent drag force exerted by a uniform flow, in the  $-z$ -direction, past a fixed sphere. Physically, these flows are characterized by the size of the sphere, for which we often take the particle diameter,  $d_p$ , as a natural measure, and by the terminal velocity,  $v_\infty$ . Therefore, we may expect  $\mathbf{v} \cdot \nabla \mathbf{v}$  to be of order  $v_\infty^2/d_p$ , and  $\nu \nabla^2 \mathbf{v}$  to be of order  $\nu v_\infty/d_p^2$ . This leads to the estimate:

$$\left| \frac{\mathbf{v} \cdot \nabla \mathbf{v}}{\nu \nabla^2 \mathbf{v}} \right| \sim \left| \frac{v_\infty^2/d_p}{\nu v_\infty/d_p^2} \right| \sim \left| \frac{v_\infty d_p}{\nu} \right| = Re_p \quad (5.29)$$

where  $Re_p$  is the particle Reynolds number.

<sup>2</sup> It is noted that Oseen [94], Proudman and Pearson [100], among others, extended Stokes' theoretical analysis to the narrow range  $Re_p < 5$  by including inertial effects in the flow field away from the particle surface.

From the  $z$ -component of the momentum equation it can be shown that the inertia term may be omitted if  $Re_P \ll 1$ . In other words, when the inertia term is not negligible, the drag formula given by Stokes law is no longer valid. The drag relation is thus modified by introducing a drag coefficient,  $C_D$ , defined by (e.g., [22, 88, 101, 117]):

$$C_D = \frac{f_{D,z}^{\text{Steady}}}{\frac{1}{2} \rho_f v_\infty^2 A_P} \quad (5.30)$$

This dependence of  $f_{D,z}^{\text{Steady}}$  on  $v_\infty$ ,  $d_P$ ,  $\mu$  and  $\rho_f$  may become more obvious writing the equations of motion for incompressible flow in dimensionless form (e.g., [14, 101, 140]).

The variables and terms in the governing equations are made dimensionless by introducing  $r' = r/d_P$ ,  $p' = p/(\rho v_\infty^2)$ ,  $\mathbf{v}' = \mathbf{v}/v_\infty$  and  $\nabla' = d_P \nabla$  into the equations:

$$\mathbf{v}' \cdot \nabla' \mathbf{v}' = -\nabla' p' + \frac{1}{Re_P} \nabla'^2 \mathbf{v}' = -\nabla' \cdot \mathbf{T}' \quad (5.31)$$

and

$$\nabla' \cdot \mathbf{v}' = 0 \quad (5.32)$$

The prime denotes dimensionless variables. The corresponding dimensionless boundary conditions may be written:  $\mathbf{v}'|_{r'=1/2} = 0$  and  $\lim_{r' \rightarrow \infty} \mathbf{v}' = -\mathbf{e}_z$ . At steady state conditions,  $\mathbf{v}'$  and  $p'$  are functions of position,  $\mathbf{r}'$ , only, and therefore the solutions of the equation with the suggested boundary conditions are functions of  $\mathbf{r}'$  and  $Re_P$  only. From the dimensionless momentum equation it follows that the normalized stress tensor can be expressed as:  $T'_{ij} = T_{ij}/(\rho v_\infty^2)$ . Thus, the drag force expression is also a function of  $\mathbf{r}'$  and  $Re_P$  only, as one recalls that the drag force was given by:

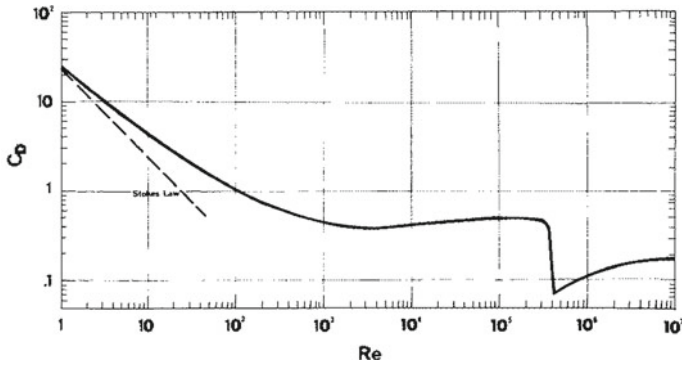

$$f_{D,z} = - \iint_A T_{zj} n_j dA \quad (5.33)$$

The dimensionless surface area can be given by:  $dA' = dA/(\pi d_{P,D}^2)$ . By inserting the dimensionless variables into the expression for the drag force, the drag force becomes:

$$f_{D,z} = - \iint_A \rho_f v_\infty^2 T'_{zj} n_j (\pi d_{P,D}^2) dA' \quad (5.34)$$

By non-dimensionalizing this equation one obtains:

$$f'_{D,z} = \frac{F_{D,z}}{\rho_f v_\infty^2 (\pi d_{P,D}^2)} = - \iint_A T'_{zj} n_j dA' \quad (5.35)$$

**Fig. 5.2** The standard *drag curve* shows the drag coefficient of a rigid sphere as a function of particle Reynolds number. Reprinted from Clift et al. [22] with permission from Dover Publications and Clift R (personal communications)

where  $F'_{D,z}$  denotes the dimensionless drag.

Since the dimensionless variables only depend upon  $\mathbf{r}'$  and  $Re_p$ , it appears that the drag must be of the form:

$$f_{D,z} = d_{p,D}^2 \rho_f v_\infty^2 h(Re_p) \quad (5.36)$$

where  $h$  is a function of  $Re_p$  only.

It has thus been shown that for a given geometry the steady drag force on the particle surface (i.e., integrated over the particle surface at  $\mathbf{r}' = 1/2$ , so the dependency on  $\mathbf{r}'$  vanishes) only varies with the particle Reynolds number. The pre-factor  $1/2$  in the definition of  $C_D$  appears because it is often convenient to introduce the dynamic pressure, given by  $1/2 \rho v_\infty^2$  from the kinetic energy equation. The drag coefficient is based on the projected area normal to the flow rather than the entire surface area, because the area is the source of most of the drag that arise. The choice of area entering the formulation of the drag coefficient is a matter of convenience in practical applications. It follows from the definition of the drag coefficient (5.30) that  $C_D$  is a function of  $Re_p$  only, thus the drag force for any  $\rho$ ,  $v_\infty$  and  $A_p$  is established once the relation  $C_D = C_D(Re_p)$  is determined experimentally.

The *standard drag curve* refers to a plot of  $C_D$  as a function of  $Re_p$  for a smooth rigid sphere in a steady uniform flow field. The best fit of the cumulative data that have been obtained for this drag coefficient is shown in Fig. 5.2. Numerous parameterizations have been proposed to approximate this curve (e.g., many of them are listed by [22]). The variations in  $C_D$  have been examined and explained theoretically as summarized by [22, 26, 90, 117], among others. Table 5.1 summarizes briefly the phenomena that occur at different particle Reynolds numbers,  $Re_p$ . For very low Reynolds numbers,  $Re_p < 1$ , the Stokes law can be used as the inertial terms in the Navier-Stokes equations are negligible. With increasing Reynolds numbers the inertial forces become important and the actual drag coefficient is higher than what

**Table 5.1** Formation of a vortex as  $Re_p$  increases

|                  |                                                     |
|------------------|-----------------------------------------------------|
| $Re_p < 1$       | Stokes' regime                                      |
| $Re_p \geq 1$    | Inertial effects become important                   |
| $Re_p \geq 10$   | A vortex is formed                                  |
| $Re_p$ increases | The vortex increases                                |
| $Re_p \geq 150$  | The vortex starts oscillating                       |
| $Re_p \geq 500$  | The vortex leaves the particle and forms a wake     |
| $Re_p \geq 700$  | Newton's regime                                     |
| $Re_p \geq 10^5$ | Transition from laminar to turbulent boundary layer |

is predicted by Stokes drag formula. The Oseen [94] solution is considered valid for  $Re_p < 5$ . At  $Re_p \sim 10 - 100$  the flow begins to separate and form vortices behind the sphere. In this case the pressure in the wake is further reduced, so the form drag increases. Moreover, at about  $Re_p \sim 150$  the vortex system begins to oscillate and leaves the particle and forms a wake when  $Re_p \sim 500$  [117].

In Newton's regime  $700 < Re_p < 2 \times 10^5$  the (form) drag coefficient is normally approximated by a constant value  $C_D \approx 0.44$ . Beyond  $Re_p \sim 3 \times 10^5$  Newton's drag law is not valid anymore as this value is considered a critical Reynolds number, where the boundary layer becomes turbulent reducing the (form) drag significantly. However, if the particle is not smooth, this transition effect is blurred and less well defined.

Morsi and Alexander [90] provided a set of correlations for the drag coefficient as a function of particle Reynolds number which reproduce Fig. 5.2 fairly well in the  $Re_p$  range  $0 \leq Re_p < 5 \times 10^4$ . The experimental data available were divided into 8 regions in  $Re_p$ , and for each region they fitted a correlation of the form:

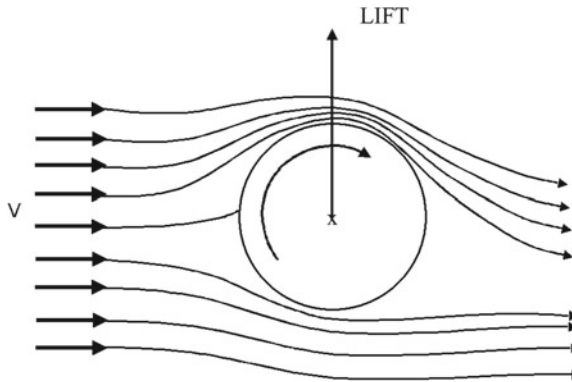

$$C_D = \frac{K_1}{Re_p} + \frac{K_2}{Re_p^2} + K_3 \quad (5.37)$$

The coefficients of (5.37) and the width of the regions were chosen to minimize the difference between the experimental and analytical curves.

The drag coefficient relations given are:

$$C_D = \begin{cases} \frac{24}{Re_p} & \text{for } 0 < Re_p < 0.1, \\ \frac{22.73}{Re_p} + \frac{0.0903}{Re_p^2} + 3.690 & \text{for } 0.1 < Re_p < 1, \\ \frac{29.1667}{Re_p} - \frac{3.8889}{Re_p^2} + 1.222 & \text{for } 1 < Re_p < 10, \\ \frac{46.50}{Re_p} - \frac{116.67}{Re_p^2} + 0.6167 & \text{for } 10 < Re_p < 100, \\ \frac{98.33}{Re_p} - \frac{2778}{Re_p^2} + 0.3644 & \text{for } 100 < Re_p < 1000, \\ \frac{148.62}{Re_p} - \frac{47500}{Re_p^2} + 0.357 & \text{for } 1000 < Re_p < 5000, \\ -\frac{490.546}{Re_p} + \frac{578700}{Re_p^2} + 0.46 & \text{for } 5000 < Re_p < 10000, \\ -\frac{1662.5}{Re_p} + \frac{5416700}{Re_p^2} + 0.5191 & \text{for } 10000 < Re_p < 50000 \end{cases} \quad (5.38)$$

These correlations are often used simulating particulate flows in chemical reactors.

**Fig. 5.3** The Magnus lift force on a rotating particle. The sketch illustrates the flow pattern induced by a rotating particle. The initial particle rotation is not caused by the flow

### 5.1.2 Lift Forces on a Single Rigid Sphere in Laminar Flow

Rigid spheres sometimes experience a lift force perpendicular to the direction of the flow or motion. For many years it was believed that only two mechanisms could cause such a lift. The first one described is the so-called Magnus force which is caused by forced rotation of a sphere in a uniform flow field. This force may also be caused by forced rotation of a sphere in a quiescent fluid. The second mechanism is the Saffman lift. This causes a particle in a shear flow to move across the flow field. This force is not caused by forced rotation of the particle, as particles that are not forced to rotate also experience this lift (i.e., these particles may also rotate, but then by an angular velocity induced by the flow field itself).

#### 5.1.2.1 Rotating Spheres (Magnus Force)

A rotating sphere in uniform flow will experience a lift which causes the particle to drift across the flow direction. This is called the Magnus effect (or force). The physics of this phenomenon are complex. The rotation of a rigid sphere will cause the surrounding fluid to be entrained. When the sphere is placed in a uniform flow, this results in higher fluid velocity on one side of the particle, and lower velocity on the other side. This gives an asymmetrical pressure distribution around the sphere. Originally this was thought to cause lift on the particle that move the particle towards the region of higher local velocity [22], see Fig. 5.3.

Maccoll [80] studied the aerodynamics of a spinning sphere, and observed a negative Magnus effect when the ratio of the equatorial speed of the rotating sphere to the flow speed,  $v_{\text{equa}}/v$ , was less than 0.5.

Krahn [65] explained how the rotation of the sphere would cause the transition from laminar to turbulent boundary layers at different rotational velocities at the two sides of a sphere. The direction of the asymmetrical wake was explained based on the separation points for laminar and turbulent boundary layers. Krahn studied the flow around a cylinder. For a non-rotating cylinder the laminar boundary layer separates at  $82^\circ$  from the forward stagnation point, while the turbulent boundary layer separates at about  $130^\circ$ . Due to the rotation the laminar separation point will move further back, while the turbulent separation point will move forward. For some value of  $v_{\text{equa}}/v$  between 0 and 1 the laminar and turbulent separation points will be at equal distance from the stagnation point. The pressure on the turbulent side will be smaller than on the laminar side causing a negative Magnus force.

Taneda [123] studied a rotating sphere moving linearly in a quiescent liquid, and showed that when the Reynolds number was near  $2.5 \times 10^5$ , and  $v_{\text{equa}}/v < 0.6$  the particle would experience a negative lift force. This is close to the region where Swanson [120] found negative lifts for a rotating cylinder. Taneda found that the Magnus effect was caused by the asymmetric wake due to the rotation of the sphere. He showed that the negative lifts were due to the boundary layers changing from laminar to turbulent at different times on the two sides of the rotating sphere, causing the wake to be distorted opposite to what is shown in Fig. 5.3. It was also shown that disturbances in the main flow would cause the region of negative lift to contract, and shift to  $\text{Rep} \sim 8.5 \times 10^4$ .

Swanson [120] reviewed the investigations of the Magnus force, and presented experimental drag and lift coefficients for an infinite, rotating cylinder at different Reynolds numbers and velocity ratios. For velocity ratios less than 0.55, and Reynolds numbers between  $12.8 \times 10^4$  and  $50.1 \times 10^4$  the cylinder would experience negative lift.

Rubinow and Keller [103] calculated the flow around a rotating sphere moving in a viscous fluid for small Reynolds numbers. They determined the drag, torque, and lift force (Magnus) on the sphere to  $O(\text{Rep})$ . The results were:

$$\mathbf{f}_D = -6\pi r_p \mu_c \mathbf{v}_{\text{rel}} \left(1 + \frac{3}{8} \text{Rep} + O(\text{Rep})\right) \quad (5.39)$$

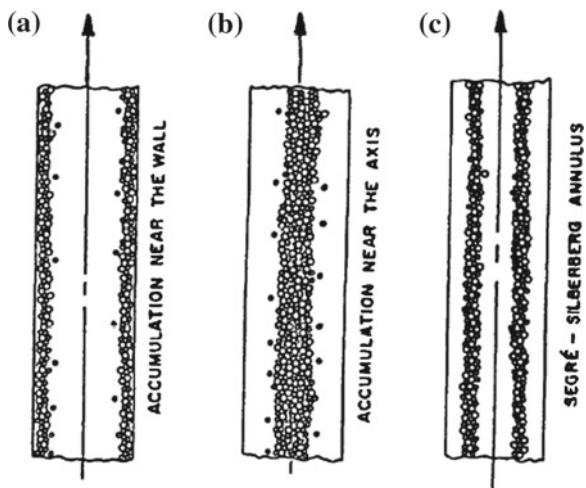

$$\mathbf{f}_L = \pi r_p^3 \rho_c \boldsymbol{\Omega} \times \mathbf{v}_{\text{rel}} (1 + O(\text{Rep})) \quad (5.40)$$

$$\mathbf{t} = -8\pi \mu_c r_p^3 \boldsymbol{\Omega} (1 + O(\text{Rep})) \quad (5.41)$$

Drew and Wallis [37] (p. 61) examined the forces on spheres in two-phase suspensions based on theoretical analyzes. Their result included lift forces that give rise to a net transverse force on particle swarms if the group of spheres are translating and rotating as a unit. Note that this force is different from that due to rotation of each sphere.

Clift et al. [22] summarized the measurements of drag and lift on rotating spheres, and concluded that the phenomena involved are so complex that drag and lift forces on rotating spheres should be determined experimentally.

**Fig. 5.4** Radial migration of particles in shear flow. Radial migration of positive, neutrally, and negative buoyant particles in shear flow. The figure illustrates the observations reported by Segré and Silberberg [107, 108], as sketched by Lawler and Lu [72] and Lahey [68, 69]. Reprinted from Lahey [68] with permission from Elsevier. **a** Positive buoyant particles **b** Negative buoyant particles **c** Neutral buoyant particles

### 5.1.2.2 Spheres in Shear Flow (Saffman Force)

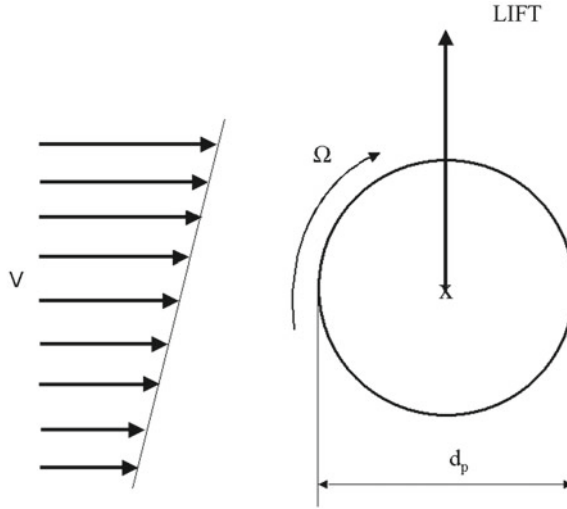

A rigid sphere in shear flow experiences a force that moves the particle normal to the flow direction.

Segré and Silberberg [107, 108] showed experimentally that neutrally buoyant particles would migrate to, and concentrate at approximately 60 % of the pipe radius in laminar flow. They used small tubes and relatively large particles.

Other workers have shown that initially non-rotating particles also experienced lateral motion [68, 69]. The shear flow thus gives rise to a lift force which is caused by the shear solely or rotation induced by the flow. Hence, these observations implied that a Magnus type of force was not adequate. Lawler and Lu [72] and Lahey [68, 69] gave an overview over lateral distributions of positive, neutrally, and negative buoyant particles. The result is sketched in Fig. 5.4.

Subsequently Saffman [105, 106] derived an expression for the lift force on a particle in a shear flow, as illustrated in Fig. 5.5. He incorporated three different Reynolds numbers defined by:

$$\text{Re}_\kappa = \frac{\kappa r_p^2}{\nu_c} \quad \text{Re}_p = \frac{v_{\text{slip}} r_p}{\nu_c} \quad \text{Re}_\Omega = \frac{\Omega r_p^2}{\nu_c} \quad (5.42)$$

**Fig. 5.5** The Saffman force on a particle in a shear flow. The sketch illustrates that this lift force is caused by the pressure distribution developed around the sphere due to particle rotation induced by the shear flow velocity gradient

and assumed that:

$$\text{Re}_\kappa \ll 1 \quad \text{Re}_\Omega \ll 1 \quad \text{Re}_p \ll \text{Re}_\kappa^{1/2} \quad (5.43)$$

That is, Saffman considered three different velocity scales. The conventional particle Reynolds number is expressed in terms of the relative fluid-particle velocity  $v_{\text{slip}}$ , the shear Reynolds number contains the fluid velocity gradient times the particle diameter ( $\frac{dv_z}{dy} d_p$ ), and the rotation Reynolds number contains the fluid rotational speed times the particle diameter ( $\Omega d_p$ ). The lift force was found to be:

$$f_L = 6.46 \mu_c v_{z,c} \left( \frac{dv_{z,c}}{dy} \right)^{1/2} \frac{r_p^2}{\nu_c^{1/2}} \quad (5.44)$$

Saffmann [105] (p. 394) compared the Magnus force developed by Rubinow and Keller [103] with the shear force given above and showed that unless the rotational speed is much larger than the rate of shear  $\kappa = dv_z/dy$ , and for a freely rotating particle  $\Omega = \frac{1}{2} \frac{dv_z}{dy}$ , the lift force due to shear is an order of magnitude larger than the lift force due to forced rotation when the particle Reynolds number is small (for which these models are supposed to be valid).

Lawler and Lu [72] reviewed the classical experimental observations on transversal migration of spherical particles and concluded that neither the original Magnus nor the Saffman force models are capable of explaining all these observations. They thus propose that the lift forces might be expressed in terms of the relative

particle-fluid angular velocity rather than the absolute angular velocity of the particle as used in all the classical models. Crowe et al. [26] also made similar extensions of the classical lift force models.

Dandy and Dwyer [30] computed numerically the three-dimensional flow around a sphere in shear flow from the continuity and Navier-Stokes equations. The sphere was not allowed to move or rotate. The drag, lift, and heat flux of the sphere was determined. The drag and lift forces were computed over the surface of the sphere from (5.8) to (5.13), respectively. They examined the two contributions to the lift force, the pressure contribution and the viscous contribution. While the viscous contribution always was positive, the pressure contribution would change sign over the surface of the sphere. The pressure contribution to the lift was found to be negative for most of the Reynolds numbers and shear rates that were examined. The total lift was always found to be positive, and the results agreed well with those of Saffman [105, 106].

Auton [7], Thomas et al. [125] and Auton et al. [8] determined a lift force due to inviscid flow around a sphere. In an Eulerian model formulation this lift force parameterization is usually approximated for dilute suspensions, giving:

$$\mathbf{F}_L = C_L \rho_c \alpha_d (\mathbf{v}_c - \mathbf{v}_d) \times (\nabla \times \mathbf{v}_c) \quad (5.45)$$

For potential (inviscid) flow  $C_L = 0.5$ .

Drew and Lahey [33] derived the forces on a sphere in inviscid flow. They employed the objectivity principle which implies that the forces should be independent of coordinate system. They found the same formulation for the lift force as given by (5.45), but they stressed that it was not objective in that form. When written in combination with the virtual mass force as:

$$\begin{aligned} \mathbf{F}_{L,V} = & \alpha_d C_V \rho_c \left[ \left( \frac{\partial \mathbf{v}_c}{\partial t} + \mathbf{v}_c \cdot \nabla \mathbf{v}_c \right) - \left( \frac{\partial \mathbf{v}_d}{\partial t} + \mathbf{v}_d \cdot \nabla \mathbf{v}_d \right) \right] \\ & - \alpha_d \rho_c C_V (\mathbf{v}_c - \mathbf{v}_d) \times (\nabla \times \mathbf{v}_c) \end{aligned} \quad (5.46)$$

the combination was supposedly objective.

However, just after this chapter was published, Acrivos pointed out in a personal communication with Drew and Lahey that a fundamental error had been made in the derivation. Therefore, in a corrigendum by Drew and Lahey [34] the conclusions regarding objectivity were modified to apply only approximately to a fluid with very small vorticity. In practice, the sum of the added mass and lift forces is thus not necessarily frame-indifferent when applied to reactor simulations.

### 5.1.3 Lift and Drag on Rigid Spheres in Turbulent Flows

Spheres in turbulent flows have not been extensively studied, partly due to the difficulties in measuring.

Taneda [124] studied the flow past a sphere at particle Reynolds numbers between  $10^4$  and  $10^6$ , and found that the wake is not axisymmetric and that it rotates slowly and randomly about the stream-wise axis. The sphere is thus subject to a random side force.

Willets and Murray [142] studied the lift on spheres fixed in turbulent flows. The spheres were located both near and far from a boundary. They found that particles near a wall experienced lift away from the wall, while a sphere in a shear flow away from a wall experienced a lift towards the wall. The forces were found to be of the same magnitude as the forces in laminar flow, and they were consistent with the laminar results of Segré and Silberberg [107, 108]. Spheres that were not close to a boundary, and not subjected to a velocity gradient, experienced randomly fluctuating instantaneous lift which was strongly associated with the wake deflection. They suggested that the lift was caused by disturbances of the boundary layer separation line induced by small impinging eddies.

Lee and Durst [76] studied turbulent air–glass particles flow using Laser Doppler Anemometer (LDA) measurements, using particles with diameters 100, 200, 400, and 800  $\mu\text{m}$ . They found that the particles would lag behind the air more and more depending on particle size. An exception was that the two smaller particles sizes would have a larger upward velocity at the wall than the air. For the larger particles a particle free layer near the wall was seen. This layer was thicker than the viscous sublayer of the air. They also found that the large particles enhanced turbulence, while the small particles dampened it. The large particles would also cause the air velocity profile to be flatter. The root mean square axial fluctuating velocity was found to increase towards the wall with a sudden drop at the wall. Based on these observations they suggested a new theoretical approach based on the dynamic response characteristics of the particles to the fluid flow.

This new approach is described by Lee and Wiesler [77] and developed into a model that explains the transversal movement of particles as a result of the turbulent diffusion. The basis of their modeling is a particular form of the Maxey–Riley equation [85]:

$$\begin{aligned}
 \frac{\pi}{6} d_p^3 \rho_p \frac{d\mathbf{v}_p}{dt} &= 3\pi\mu_c d_p (\mathbf{v}_c - \mathbf{v}_p) \\
 &+ \frac{\pi}{6} d_p^3 \rho_c \frac{d\mathbf{v}_c}{dt} \\
 &+ \frac{1}{2} \frac{\pi}{6} d_p^3 \rho_c \left( \frac{d\mathbf{v}_c}{dt} - \frac{d\mathbf{v}_p}{dt} \right) \\
 &+ \frac{3}{2} d_p^2 (\pi\rho_c\mu_c)^{(1/2)} \int_0^t \frac{(\frac{d\mathbf{v}_c}{dt'} - \frac{d\mathbf{v}_p}{dt'})}{(t-t')^{(1/2)}} dt' \quad (5.47)
 \end{aligned}$$

They required that the turbulence should be locally isotropic and steady, that the particle Reynolds number should be small, that the particles concentration was small, and that the particle diameter should be much smaller than the length scale of the energy containing eddies for the diffusion controlled range of the model. The model

is based on the ability of the particle to respond to the motion of the surrounding fluid. It depends on particle size and density, turbulence structure of the fluid, and transversal particle concentration differences.

Lee [73] examined earlier studies on cylinders in turbulent flow fields, and found in turbulent flow that the wake would decrease with increasing turbulence intensity, and then disappear, and the mean flow would behave in the same manner as for Stokes flow. He therefore proposed, and showed, that the drag on a particle in turbulent flow could be determined from a Stokes law with the molecular viscosity replaced by an effective viscosity calculated from the volumetric concentration of particles, the flow Reynolds number, the density ratio, and the Froude number. The Froude number, *determining the ratio between the initial- and gravity forces*, is defined as:

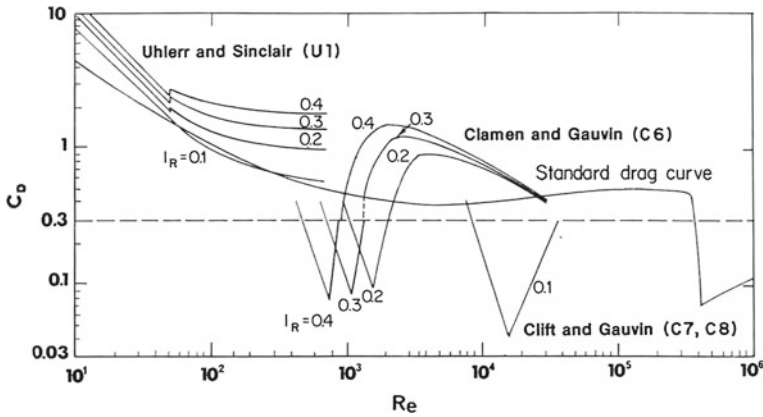

$$Fr = \frac{|\mathbf{v}_c|}{(d_p g)^{0.5}} \quad (5.48)$$

Lee and Börner [75] used LDA measurements to characterize the suspension turbulent flow to enable the calculation of the drag and lift forces. The results were in fair agreement with the measurements of Lee and Durst [76].

Based on the model of Lee and Wiesler [77] and the measurements of Lee and Börner [75] Lee [74] formulated a set of governing equations for the mean motion of particles in a suspension turbulent flow. The model contained both pseudo Stokes drag and pseudo Saffman forces which were expressed in terms of a modified viscosity, and supposedly valid for larger particle Reynolds numbers.

Yamamoto et al. [144] studied lift and drag on cylinders and on spheres in linear shear turbulent flow in a vertical square duct. The cylinders had diameters from 4 to 10 mm, and the spheres had diameters from 20 to 30 mm. The approaching flow had center velocities of 12 to 19 m/s. They found that the lift near the center of the channel was always towards the low velocity side of the duct. For the circular cylinder they found that the lift coefficient varied with the radius, and it was negative near the wall. The lift increased with increasing velocity gradient, but the drag was little affected by the gradient. The fluctuating parts of the drag and lift forces were found to be small.

Clift et al. [22] and Crowe et al. [26] reviewed the literature considering the effects of free stream turbulence on the particle drag coefficient. Generally, in their view there are experimental data indicating that the free stream turbulence reduces the critical particle Reynolds number for the drag coefficient of a sphere. They further refer to several workers that investigated the effects of turbulence and proposed that the particle drag coefficient should be parameterized in terms of certain turbulence characteristics. In most cases two normalized parameters have been used to quantify the effect of the free stream turbulence on the particle drag, these are the relative turbulence intensity  $I_R = \sqrt{v'^2}/|\mathbf{v}_c - \mathbf{v}_p|$  and the ratio between the turbulent integral length scale and the particle diameter  $L_e/d_p$ . In most reports the effect of the turbulent length scale is found to be weak, whereas the relative turbulence intensity and the critical Reynolds number might be correlated. However, there is

**Fig. 5.6** Effect of relative turbulence intensity  $I_R$  on sphere drag coefficient  $C_D$ . Reprinted from Clift et al. [22] with permission from Dover Publications and Clift R (personal communications)

generally considerable discrepancy in the data for the drag coefficient dependence on turbulence. The spread in the data obtained for the drag coefficient of a sphere in turbulent flows is indicated in Fig. 5.6. For this reason the standard drag curve parameterizations are normally used and the effects of turbulence is disregarded. To summarize, no firm conclusions regarding the impact of free stream turbulence on the drag and lift force coefficients can be drawn analyzing the available data. More detailed experiments are obviously needed to better understand the affect of turbulence on the drag and lift force coefficients.

#### 5.1.4 Drag Force on Bubbles

The interphase forces between bubbles and the surrounding liquid are more complex than the forces between rigid spheres and a surrounding liquid. This is because the gas in the bubbles may be circulating causing the interface to move as opposed to the surface of a rigid particle. The bubbles are deformable, and they may have different shapes depending on the different physical properties of the gas and of the surrounding fluid. The shape of bubbles or drops rising or falling unhindered in a liquid can be determined based on three dimensionless numbers.

The Eötvös number is *determining the ratio between the gravitational—and surface tension forces* (i.e., the Eötvös number is equal to the *Bond number*), and defined by:

$$Eo = \frac{g \Delta \rho d_p^2}{\sigma}, \quad (5.49)$$

the Morton number<sup>3</sup>:

$$\text{Mo} = \frac{g\mu_l^4 \Delta\rho}{\rho_l^2 \sigma^3}, \quad (5.50)$$

the particle Reynolds number (i.e., *determining the ratio between the initial- and the viscous forces*):

$$\text{Re}_p = \frac{\rho_l d_p v_{\text{slip}}}{\mu_l}, \quad (5.51)$$

and the Weber number (i.e., *determining the ratio between the initial- and surface tension forces*):

$$\text{We} = \frac{\rho_l v_{\text{slip}}^2 d_p}{\sigma}. \quad (5.52)$$

Only three of these numbers are independent, since the Eötvös number can be expressed as:

$$\text{Eo} = \frac{\text{Re}_p^4 \text{Mo}}{\text{We}^2} \quad (5.53)$$

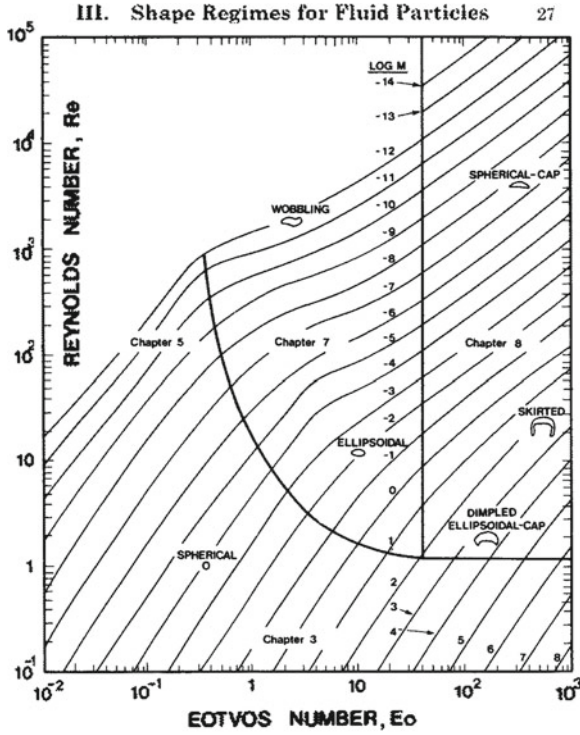

Similarly, the Capillary number,  $Ca$ , *determining the ratio between the viscous—and surface tension forces*, is related to the Weber number,  $We$ , and particle Reynolds number,  $Re_p$ . That is, the Capillary number can be expressed as,  $Ca = \frac{We}{Re_p}$ . When the Reynolds, Morton and Eötvös numbers are determined, the shape of bubbles or drops falling or rising unhindered in a liquid can be determined from the shape regime map in Fig. 5.7. A similar map has been presented earlier by Grace et al. [47].

#### 5.1.4.1 Bubbles or Drops in Creeping Flow

The drag force acting on a spherical *bubble* in the Stokes flow regime (creeping flow) can be derived with only minor changes applying the same solution procedure as used for rigid spheres shown in Sect. 5.1.1. The difference between the two situations is just in the boundary conditions at the surface of the spherical object [14]. For bubbles the surface conditions at  $r = r_p$  are (1)  $v_r = 0$  and (2)  $T_{r\theta} \approx 0$ , meaning that we have neglected the gas viscosity of the bubble so there are no internal friction in the particle. With these boundary conditions one can find an analytical solution for the stream function  $\psi$ , and thus the velocity components  $v_r$  and  $v_\theta$ , and finally the pressure distribution around the particle are known. The  $rr$ -component of the total stress tensor at the surface of the bubble is therefore

---

<sup>3</sup> This dimensionless group is often referred to as the  $M$ -group or the property group (Fan and Tsuchiya [41], p. 19; Middleman [88], p. 227). It is here called the Morton number,  $Mo$ , in accordance with the notation used by Clift et al. [22] and Fan and Tsuchiya [41].  $Mo$  involves only physical properties of the surrounding medium for gas bubbles and the pressure field. A more general form for any fluid particles of density  $\rho_g$  can be given by  $\nabla p_S |\rho_l - \rho_g| \mu_l^4 / (\rho_l^3 \sigma^3)$  where  $\nabla p_S$  is the static pressure gradient in any pressure field and is replaced by  $\rho_l g$  in the gravitational field.

**Fig. 5.7** Shape regimes for bubbles and drops in liquid. Reprinted from Clift et al. [22] with permission from Dover Publications and Clift R (personal communications)

$$\begin{aligned}
 f_{D,z}^{\text{Normal}} &= \int_0^{2\pi} \int_0^\pi \left[ -T_{rr}(r_p, \theta) \cos \theta \right] r_p^2 \sin \theta d\theta d\phi \\
 &= 2\pi \int_0^\pi \left[ -\left( p - 2\mu \frac{\partial v_r}{\partial r} \right) \right]_{r_p} \cos \theta \left[ r_p^2 \sin \theta d\theta \right] = 4\pi \mu r_p V \quad (5.54)
 \end{aligned}$$

Notice that  $\sigma_{rr} \neq 0$  on the surface of the bubble due to the prevailing free slip condition, in contrast to the rigid sphere case in which  $\sigma_{rr}$  vanishes on the surface due to the no-slip condition.

A similar solution for creeping flow past a spherical *droplet* of fluid were derived independently by Hadamard [49] and Rybczynski [104]. In this case the fluid stream has a velocity  $V$  at infinity and viscosity  $\mu_f$ , while the droplet has a viscosity  $\mu_p$  and a fixed interface. The boundary conditions at the droplet interface are (1) zero radial velocities and (2) equality of surface shear and tangential velocity on either side of the interface.

The drag force on the droplet is then given by:

$$f_{D,z} = 6\pi\mu_r V \frac{1 + \frac{2\mu_f}{3\mu_p}}{1 + \frac{\mu_f}{\mu_p}} \quad (5.55)$$

This drag force consists of contributions from pressure (form drag), deviatoric normal stress, and shear stress (friction drag).

The corresponding drag coefficient is given by:

$$C_D = \frac{f_{D,z}}{\frac{1}{2}\pi\rho_f V^2 r_p^2} = \frac{8}{\text{Re}_p} \left( \frac{2 + 3\frac{\mu_p}{\mu_f}}{1 + \frac{\mu_p}{\mu_f}} \right) \quad (5.56)$$

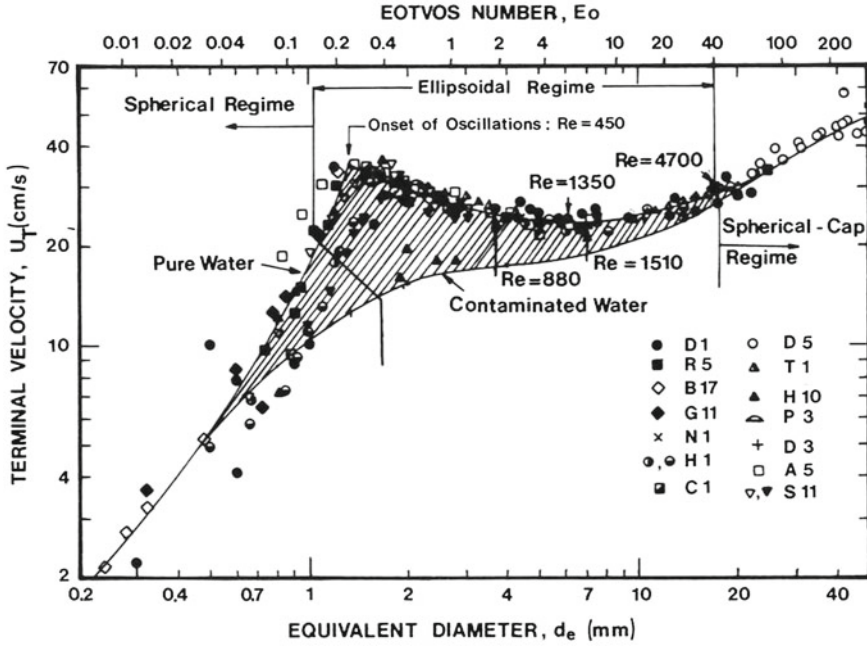

For  $\mu_p \gg \mu_f$ , this solution (5.55) coincides with Stokes' solution for a rigid sphere (5.27), whereas for  $\mu_p \ll \mu_f$ , this solution coincides with the solution for a spherical bubble in liquid (5.54). A liquid droplet in another liquid lies in between these limiting cases.

Langlois [71], White [140], Clift et al. [22] and Zapryanov and Tabakova [145] give further details on the derivation of the viscous drag force on a small spherical droplet.

### 5.1.4.2 Fluid Spheres at Higher Reynolds Numbers

Fluid spheres in flow at higher Reynolds numbers behave different from rigid spheres. As the Reynolds number increases, a wake is formed behind the fluid sphere or ellipsoid [22, 41]. The formation of a wake behind a fluid particle is delayed compared to a solid sphere due to the internal circulation of the gas. The recirculating wake may be completely detached from the fluid sphere. A secondary internal vortex will then not be formed. For smaller particle Reynolds numbers the wake is symmetrical, but as the Reynolds number increases further the vortex sheet breaks down to vortex rings. Further increase of the Reynolds number cause the vortex rings to shed asymmetrically, and the drop or bubble will show a rocking motion. This is one of the two types of secondary motion defined. The other is *oscillations* (shape dilations), and is also thought to be due to the vortex shedding. In most systems the bubbles (or drops) with diameters between 1 and 15 mm are ellipsoidal. The terminal velocity of bubbles in water at 20 °C has been measured by several researchers. The results are summarized in Fig. 5.8. The curves for the drag coefficient and the terminal velocity converge for small and large bubbles. This is likely to be because there is always some surface active contaminants present, even in distilled water, that will prevent the internal circulation of the smallest bubbles. For the large bubbles the surface tension forces are not important. Several different drag formulations are given based on the Reynolds number and the density ratio of the gas and liquid [48, 67, 135].

The drag coefficient parameterizations proposed by Ishii and co-workers [55–57] for bubbles in liquid at different flow regimes are often used in reactor simulations. In the churn-turbulent regime they obtained:

**Fig. 5.8** Terminal velocity of air bubbles in water at 20°C. Reprinted from Clift et al. [22] with permission from Dover Publications and Clift R (personal communications)

$$C_D = \frac{8}{3}(1 - \alpha_g)^2 \quad (5.57)$$

In the distorted bubble regime they gave:

$$C_D = \frac{2}{3}d_b\sqrt{\frac{g\Delta\rho}{\sigma}}\left\{\frac{1 + 17.67(f(\alpha_g))^{6/7}}{18.67f(\alpha_g)}\right\}^2 \quad (5.58)$$

where:

$$f(\alpha_g) = (1 - \alpha_g)^{1.5} \quad (5.59)$$

More recently, Tomiyama and co-workers [127–130] performed detailed experiments investigating the drag coefficient of a single bubble in a stagnant liquid. They proposed a drag coefficient parameterization which is split in three categories. These are pure, gently-contaminated, and contaminated systems, respectively.

For *pure* systems:

$$C_D = \max\left[\min\left[\frac{16}{Re_P}(1 + 0.15Re_P^{0.687}), \frac{48}{Re_P}\right], \frac{8}{3}\frac{E_o}{E_o + 4}\right] \quad (5.60)$$

For *gently-contaminated* systems:

$$C_D = \max \left[ \min \left[ \frac{24}{\text{Re}_P} (1 + 0.15 \text{Re}_P^{0.687}), \frac{72}{\text{Re}_P} \right], \frac{8}{3} \frac{Eo}{Eo + 4} \right] \quad (5.61)$$

For *contaminated* systems:

$$C_D = \max \left[ \frac{16}{\text{Re}_P} (1 + 0.15 \text{Re}_P^{0.687}), \frac{8}{3} \frac{Eo}{Eo + 4} \right] \quad (5.62)$$

The Eötvös number  $Eo$  is defined as

$$Eo = \frac{g(\rho_c - \rho_d)d_p^2}{\sigma_I} \quad (5.63)$$

This parameterization of the drag coefficient for bubbles in stagnant liquids is very often used in the latest reports on bubbly flow simulations.

### 5.1.5 Lift Force on Bubbles

Experiments have shown that bubbles under certain conditions experience lift in the opposite direction to what would be predicted by rigid sphere analysis. Other mechanisms must therefore be important in determining the lift force on bubbles. Lift in turbulent flow is very complex, and few studies have been performed. Several studies on the phase distribution in vertical bubbly flows in pipes and channels are performed, though, and many of these are reviewed by Jakobsen [58]. Typically, they describe how the bubbles will migrate towards the core of the column and rise there when the superficial gas velocity is larger than the small (0 to few cm/s) superficial liquid velocity. When the superficial liquid velocity is larger, the gas will tend to accumulate/peak at the wall. The core peaking of void is contradictory to the lift calculated from classical inviscid analyses [7, 8, 125]. To account for the net lift force acting on a particle swarm the classical lift force model (5.45) is normally adopted [58, 125]. In this case values of  $C_L$  from 0.01 up to 0.5 have been reported for different flow conditions. However, little or no knowledge on the mechanisms causing the changes in the parameter did exist until quite recently [58]. In a series of more recent papers, Tomiyama and co-workers (i.e., [127–130]) performed detailed experiments investigating the transverse migration of single bubbles in simple shear flows and found that the transversal lift force coefficient depends on the Eötvös number. A net transverse force  $\mathbf{F}_L$  acting on a single bubble was proposed on the form (5.45). They further anticipated that the net lift force coefficient consists of three separate contributions accounting for the Magnus lift-, Saffman shear induced lift-, and lift caused by the slanted wake behind a deforming bubble, thus  $C_L = C_L^M + C_L^S + C_L^T$ . The Magnus force coefficient is  $C_L^M \sim 0$  when there is no forced particle rotation. For the Saffman type of shear induced lateral lift  $C_L^S = 0.5$  for potential (inviscid) flows [125].

Interpreting their data it was concluded that when  $Eo$  is low, the bubble will migrate toward the pipe wall as explained with the classical shear-induced or Saffman type of lift force. On the other hand, when  $Eo$  is high, the vortex behind a deformed bubble becomes slanted and for this reason the bubble migrates toward the pipe center. This implies that there is a third transversal lift force contribution caused by the interaction between the wake and external shear field.

Measurements performed under the experimental conditions of  $-5.5 \leq \log(Mo) \leq -2.8$  and  $1.6 \leq Eo \leq 6$  were used as basis making an empirical parameterization for the net transverse lift force coefficient.

For  $Eo < 4$ :

$$C_L = \min \left[ 0.288 \tanh(0.121 Re_P), 0.00105 Eo^3 - 0.0159 Eo^2 - 0.0204 Eo + 0.474 \right] \quad (5.64)$$

For  $4 \leq Eo \leq 10$ :

$$C_L = 0.00105 Eo^3 - 0.0159 Eo^2 - 0.0204 Eo + 0.474 \quad (5.65)$$

For  $Eo > 10$ :

$$C_L = -0.29 \quad (5.66)$$

This parameterization gives  $0 < C_L \leq 0.288$  for small bubbles that migrate towards the pipe wall and *negative* values for large distorted bubbles. The sign of  $C_L$  changes at  $d_p = 5.6$  (mm) from positive to negative.

In one of the latest studies reported by Tomiyama et al. [130] on the lift force the  $C_L$  value was found to be well correlated with  $Re_P$  in accordance with the given parameterization for small bubbles, whereas for intermediate and large bubbles  $C_L$  was considered a function of a modified Eötvös number  $Eo_d$  (i.e., exchanging  $Eo$  with  $Eo_d$  in the above parameterization of  $C_L$ ). The  $Eo_d$  is defined in terms of the maximum horizontal dimension of a bubble as a characteristic length:

$$Eo_d = \frac{g(\rho_c - \rho_d)d_H^2}{\sigma_I} \quad (5.67)$$

To estimate  $d_H$  which occurs in the definition of  $Eo_d$ , an empirical correlation of the aspect ratio  $E$  for spheroidal bubbles in a contaminated system was used:

$$E = \frac{d_V}{d_H} = \frac{1}{1 + 0.163 Eo^{0.757}} \quad (5.68)$$

where  $d_V$  is the maximum vertical dimension of a bubble.

Other lift forces might exist as well, in particular for wall bounded flows. To prevent the model inconsistency that small bubbles intend to penetrate through the

pipe wall, as predicted by the conventional lift force (5.45), Antal et al. [2] proposed the remedy of introducing an additional wall lift force that pushes the dispersed phase away from the wall toward the pipe center. The force was found to be:

$$\mathbf{F}_{L,d}^W = \frac{\alpha_d \rho_c |\mathbf{v}_\parallel|^2}{r_d} [C_{W1} + C_{W2} \left(\frac{r_d}{y_0}\right)] \mathbf{n}_W \quad (5.69)$$

where

$$\mathbf{v}_\parallel = (\mathbf{v}_d - \mathbf{v}_c) - [\mathbf{n}_W \cdot (\mathbf{v}_d - \mathbf{v}_c)] \mathbf{n}_W \quad (5.70)$$

$$C_{W1} = -0.104 - 0.06 v_{\text{slip}} \quad (5.71)$$

$$C_{W2} = 0.147 \quad (5.72)$$

$y_0$  is the distance between the wall and the particle and  $\mathbf{n}_W$  is the unit normal vector outward from the wall.

Later, Tomiyama [127, 129] observed a defect in the original model by Antal et al., namely, that a bubble located far from the wall is attracted to the wall. Based on a best fit of model simulations to experimental data from a square duct with wall-distance  $H$ , a modified wall force was given as:

$$\mathbf{F}_{L,d}^W = C_w \rho_c |\mathbf{v}_{\text{slip}} \cdot \mathbf{e}_z|^2 \mathbf{e}_r \quad (5.73)$$

where

$$C_w = C_{w2} \left( \frac{1}{y_0} - \frac{1}{H - y_0} \right) + \frac{C_{w3} d_V}{2} \left( \frac{1}{y_0^2} - \frac{1}{(H - y_0)^2} \right) \quad (5.74)$$

Subsequently, the original formulation by [2] has been modified in several ways to ensure that the wall force drop to zero at an appropriate distance from the wall [59, 97].

The modified wall lift force model used by Jakobsen et al. [59] for the net force acting on the dispersed phase is given by:

$$\mathbf{F}_{L,d}^W = \max(0, C_{w1} + C_{w2} \frac{d_p}{y_0}) \alpha_d \rho_c \frac{|\mathbf{v}_d - \mathbf{v}_c|^2}{d_p} \mathbf{n}_W \quad (5.75)$$

in which the parameter values used, i.e.,  $C_{w1} = -0.1$  and  $C_{w2} = 0.35$ , are representing an empirical best fit to a set of experimental liquid velocity data for bubble columns (employing a finite grid resolution).

In another attempt to account for turbulence effects Jakobsen [58] performed turbulence modelling of the drag force, and showed that this procedure gave rise to a transversal force acting in the opposite direction compared to the classical lift force [7, 8, 125].

### 5.1.5.1 Experiments and Numerical Simulations

Kariyasaki [61] studied bubbles, drops, and solid particles in linear shear flow experimentally, and showed that the lift force on a deformable particle is opposite to that on a rigid sphere. For particle Reynolds numbers between  $10^{-2}$  and 8 the drag coefficient could be estimated by Stokes' law. The terminal velocity was determined to be equal to that of a particle moving in a quiescent liquid. The fluid particles would deform into airfoil shapes when submitted to shear flow. Kariyasaki proposed to calculate the lift force from a balance of buoyancy, gravity, drag and lift, hence:

$$f_L = \frac{(f_{Buoy} - f_G)(v_{p,r} - v_{c,r})}{|\mathbf{v}_{slip}|} \quad (5.76)$$

The measured lift force on a solid particle compared well with the model of Saffman (5.44) when the shear Reynolds number was small, and with the model of Rubinow and Keller (5.40) when the shear Reynolds number was large. The shear Reynolds number was defined as:

$$\text{Re}_\kappa = \frac{\kappa d_V^2}{\nu_c} \quad (5.77)$$

where  $d_V$  is the equivalent volume diameter and the fluid shear is defined by  $\kappa = \left| \frac{dv_c}{dy} \right|$ .

The lift force on the deformed fluid particle was assumed to be caused by the same mechanisms as those that create lift on a wing. The assumptions made in calculating the lift were:

1.  $|\kappa| \ll |\mathbf{v}_{slip}|/d_a$
2. The particle was shaped as a thin plate with a negligible volume.

The lift force was then expressed by:

$$f_L = 6.84\pi\rho_c \mathbf{v}_{slip}^2 d_V^2 D^2 \frac{\text{Re}_\kappa}{\text{Re}_p |\text{Re}_\kappa|^{1.2}} \quad (5.78)$$

The deformation factor was given as:

$$D = \frac{d_a - d_b}{d_a + d_b} = 0.43 \left( \frac{|\kappa| \rho_c \nu_c d_V}{\sigma} \right)^{0.6} \quad (5.79)$$

where  $d_a$  and  $d_b$  denote the major and minor axes of an ellipsoidal bubble.

Esmaeeli et al. [40] solved the full Navier–Stokes equations for a bubble rising in a quiescent liquid, or in a liquid with a linear velocity profile. The calculations were performed in 2-dimensional flow, but similar results have also been reported for 3-dimensional calculations. The surface tension forces were included, and the interface was allowed to deform. It was shown that deformation plays a major role in the lift on bubbles. Bubbles with a low surface tension have a larger Eötvös number, and are more prone to deform.

**Fig. 5.9** Bubbles rising in vertical shear flow,  $G = 16$ . For bubble a  $Eo = 0.78$  and  $M = 1.2610^{-6}$ . For bubble b  $Eo = 6.24$  and  $M = 6.3110^{-4}$ . Reproduced from Esmaeeli et al. [40] with permission from Elsevier

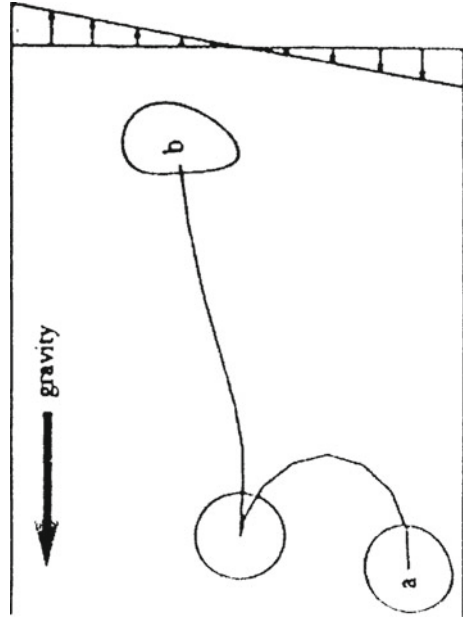

Figure 5.9 shows how two different bubbles rise in vertical shear flow with a non-dimensional shear rate:

$$G = \frac{\omega d_{\text{eff}}^2 \rho_c}{\mu_c} \quad (5.80)$$

where  $\omega$  is the mean vorticity and  $d_{\text{eff}}$  is the effective diameter of the bubble. For bubble (a) the Eötvös number is 0.78, and the Morton number is  $1.26 \times 10^{-6}$ . For bubble (b) the Eötvös number is 6.24 and the Morton number is  $6.31 \times 10^{-4}$ . The bubbles have totally different motion depending on whether the bubble deforms or not. Bubble (a) does not deform significantly, and rotates with the flow as it rises, and eventually experiences a lift to the right. Bubble (b) deforms due to the shear and the upward motion. The bubble thus takes the form of an airfoil, and experiences lift to the left. The circulation of bubble (b) changes as the bubble deforms, and settles in the opposite direction of the circulation of bubble (a).

### 5.1.6 The Added Mass or Virtual Mass Force on a Single Rigid Sphere in Potential Flow

The virtual mass effect relates to the force required for a particle to accelerate the surrounding fluid [26, 58, 141]. When a particle is accelerated through a fluid, the surrounding fluid in the immediate vicinity of the particle will also be accelerated at the expense of work done by the particle. The particle apparently behaves as if it has

a larger mass than the actual mass, thus the net force acting on the particle due to this effect has been called virtual mass or added mass force. The steady drag force model does not include these transient effects.

To define the virtual mass force we postulate a Lagrangian force balance for the sphere:

$$m \frac{dV}{dt} = \left[ \frac{4}{3} \pi \rho_d r_P^3 + m_V \right] \frac{dV}{dt} = \sum_i f_i \quad (5.81)$$

in which the apparent mass can be expressed by:

$$m = \frac{4}{3} \pi \rho_{\text{fluid}} r_P^3 \left( \frac{\rho_d}{\rho_{\text{fluid}}} + \frac{m_V}{\frac{4}{3} \pi \rho_{\text{fluid}} r_P^3} \right) \quad (5.82)$$

where  $C_V = m_V / (\frac{4}{3} \pi \rho_{\text{fluid}} r_P^3)$  is the virtual mass or added mass force coefficient.

The magnitude of this added mass can be found by considering the change in kinetic energy of the fluid surrounding an accelerating particle. By equating the energy added to the fluid to an equivalent body energy, the virtual mass can be calculated. The kinetic energy of the surrounding fluid is given by:

$$E_{k,\text{fluid}} = \int \frac{1}{2} u_{\text{rel}}^2 dm = \frac{1}{2} m_V V^2 \quad (5.83)$$

where the integral is to be taken over all the fluid mass. The integration of the fluid kinetic energy can also be accomplished by a particle-surface integral involving the velocity potential [26].

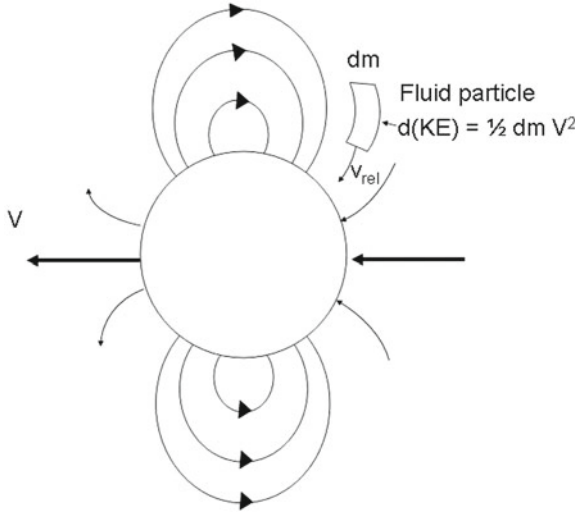

Considering an initially stagnant fluid (see Fig. 5.10),  $E_{k,\text{fluid}}$  denotes the kinetic energy added to the fluid by the particle movement (J),  $dm$  the fluid element (kg),  $v_{\text{rel}}$  the velocity of the fluid relative to the particle (m/s),  $m_V$  is the virtual mass (kg), and  $V$  is the velocity of the particle (m/s).

The motion of a sphere moving through a stagnant incompressible fluid is equivalent to the uniform fluid flow about a fixed sphere. For axisymmetrical potential flow the velocity components of the fluid can be obtained by use of the Stokes' stream function as explained by [26, 141]:

$$\begin{aligned} v_r &= V \cos \theta \left( 1 - \frac{r_P^3}{r^3} \right) \\ v_\theta &= -\frac{1}{2} V \sin \theta \left( 2 + \frac{r_P^3}{r^3} \right) \end{aligned} \quad (5.84)$$

where  $v_r$  denotes the fluid velocity in r-direction (m/s),  $v_\theta$  the fluid velocity in  $\theta$ -direction (m/s), and  $r_P$  is the radius of the sphere (m).

**Fig. 5.10** Streamlines relative to a moving sphere

The velocity components relative to the moving sphere can be found by subtracting the sphere velocity  $v_{r,p} = V \cos \theta$  and  $v_{\theta,p} = -V \sin \theta$ . The relative velocity components are thus given by:

$$\begin{aligned} v_r &= -\frac{V r_p^3 \cos \theta}{r^3} \\ v_\theta &= -\frac{V r_p^3 \sin \theta}{2r^3} \end{aligned} \quad (5.85)$$

The streamlines relative to the moving sphere are sketched in Fig. 5.10.

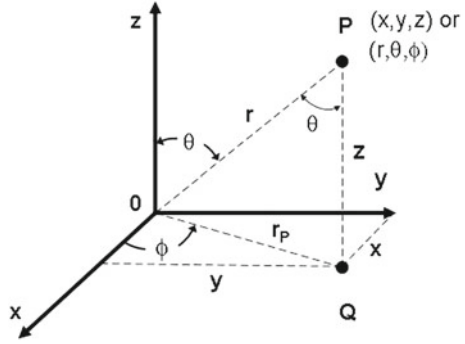

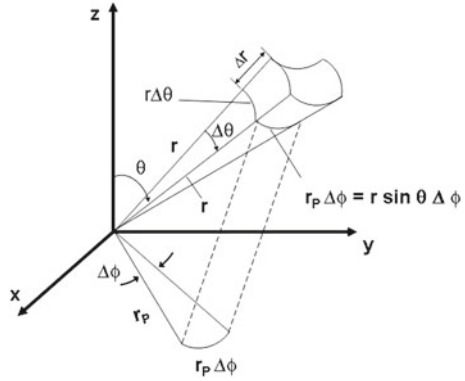

The element of fluid mass  $dm$  relates to the volume element  $dV$ , as for incompressible fluids  $dm = \rho dV$  in which  $\rho$  is a constant. Since the fluid extends from the particle surface, it is convenient to express the mathematical problem in spherical coordinates. Figure 5.11 shows the spherical coordinates of an arbitrary point,  $P$ , in space. From Fig. 5.12 the approximate volume of a rectangular block extending from the surface can be calculated as:

$$\Delta V = r_p \Delta \phi \, r \Delta \theta \, \Delta r = r \sin \theta \Delta \phi \, r \Delta \theta \, \Delta r \quad (5.86)$$

in which we have used the relation  $r_p = r \sin \theta$  considering the triangle  $OPQ$  in Fig. 5.11.

In differential form the arbitrary fluid volume becomes:

$$dV = r^2 \sin \theta \, dr d\theta d\phi \quad (5.87)$$

**Fig. 5.11** Spherical polar coordinates**Fig. 5.12** Volume element represented in spherical polar coordinates

So, the element of fluid mass  $dm$  is given by

$$dm = \rho dV = \rho(r \sin \theta) r dr d\theta d\phi \quad (5.88)$$

Inserting (5.88) and  $v_{rel}^2 = v_r^2 + v_\theta^2$  into (5.83), the integral can be evaluated to obtain the kinetic energy added to the fluid:

$$\begin{aligned} E_{k,fluid} &= \int \frac{1}{2} v_{rel}^2 dm = \int_0^{2\pi} \int_0^\pi \int_{r_P}^\infty \frac{1}{2} (v_r^2 + v_\theta^2) \rho (r \sin \theta) r dr d\theta d\phi \\ &= \int_0^{2\pi} \int_0^\pi \int_{r_P}^\infty \frac{1}{2} \left[ \left( -\frac{V r_P^3 \cos \theta}{r^3} \right)^2 + \left( -\frac{V r_P^3 \sin \theta}{2r^3} \right)^2 \right] \rho r^2 \sin \theta dr d\theta d\phi \\ &= \frac{\rho V^2 r_P^6}{2} \int_0^{2\pi} \int_0^\pi \int_{r_P}^\infty \left[ \frac{(\cos \theta)^2}{r^4} + \frac{(\sin \theta)^2}{4r^4} \right] \sin \theta dr d\theta d\phi \\ &= \frac{\rho V^2 r_P^6}{2} \int_0^{2\pi} \int_0^\pi \left[ (\cos \theta)^2 \left( -\frac{1}{3r^3} \right) + (\sin \theta)^2 \left( -\frac{1}{3r^3} \right) \frac{1}{4} \right]_{r_P}^\infty \sin \theta d\theta d\phi \\ &= \frac{\rho V^2 r_P^6}{2} \int_0^{2\pi} \int_0^\pi \left[ (\cos \theta)^2 \left( \frac{1}{3r_P^3} \right) + (\sin \theta)^2 \left( \frac{1}{3r_P^3} \right) \frac{1}{4} \right] \sin \theta d\theta d\phi \end{aligned}$$

$$\begin{aligned}
&= \frac{\rho V^2 r_P^3}{6} \int_0^{2\pi} \int_0^\pi \left( \cos^2 \theta \sin \theta + \frac{1}{4} (1 - \cos^2 \theta) \sin \theta \right) d\theta d\phi \\
&= \frac{\rho V^2 r_P^3}{6} \int_0^{2\pi} \left[ -\frac{1}{3} \cos^3 \theta + \frac{1}{4} \left( -\cos \theta + \frac{1}{3} \cos^3 \theta \right) \right]_0^\pi d\phi \\
&= \frac{\rho V^2 r_P^3}{6} \int_0^{2\pi} \left[ \frac{2}{3} + \frac{1}{4} \left( 2 - \frac{2}{3} \right) \right] d\phi = \frac{1}{3} \rho \pi r_P^3 V^2
\end{aligned} \tag{5.89}$$

The virtual mass  $m_V$  can now be derived from (5.89) and (5.83):

$$m_V = \frac{2}{3} \rho \pi r_P^3 = \frac{1}{2} \left( \frac{4}{3} \rho \pi r_P^3 \right), \tag{5.90}$$

It follows that the virtual mass force is given by: [82]:

$$f_{V,P} = \frac{1}{2} m_V \frac{dV}{dt} = \frac{1}{2} \rho_c \frac{\pi}{6} d_P^3 V \frac{dV}{dt} \tag{5.91}$$

The virtual mass coefficient for a sphere in an invicid fluid is thus  $C_V = \frac{1}{2}$ .

The basic model (5.91) is often slightly extended to take into account the self-motion of the fluid. In general the added mass force is expressed in terms of the relative acceleration of the fluid with respect to the particle acceleration. Similar analyses can be performed for dispersed bodies other than spheres [26]. In these cases the basic equations are the same, but the mass of fluid displaced can be different.

It is emphasized that the virtual mass force accounts for the form drag (shape effects) due to the relative acceleration between the particle and the surrounding fluid.

### 5.1.7 The Eulerian Formulation of the Added Mass or Virtual Mass Force Acting on Rigid Spheres in Potential Flow

In the Eulerian framework the virtual mass force valid for potential flows is normally expressed by [7, 8, 33, 57, 125]:

$$\mathbf{F}_V = \alpha_d \rho_c f_V \left( \frac{D\mathbf{v}_c}{Dt} - \frac{D\mathbf{v}_d}{Dt} \right) \tag{5.92}$$

where  $C_V$  is usually set to 0.5 as for a single sphere.

In bubbly flow simulations values ranging from 0.25 to 0.75 have been used for different bubble shapes and number densities of bubbles [58]. The added mass effect is obviously more important for light bubbles in liquids than for heavy solid particles or droplets in gas or liquid. Alternative, and supposedly more advanced, added mass force and coefficient formulations have been presented and discussed in the literature

[19, 24, 31, 32, 46, 79, 136, 141]. However, there are still controversies regarding the physics of added mass in particular considering dense dispersions [131].

### 5.1.7.1 Oscillations of a Sphere in Viscous Flow (History Force)

The history force was discovered independently by Boussinesq [18] and Basset [10] in their study of the oscillations of a rigid sphere in a viscous flow. While the virtual mass force accounts for the form drag on the particle due to relative acceleration between the particle and the surrounding fluid, the history term accounts for the corresponding viscous effects. Moreover, the history force originates from the unsteady diffusion of the vorticity around the particle so there is a delay in the boundary layer development as the relative velocity changes with time [22, 81, 82]. This means that when the relative velocity between the particle and the fluid varies, the vorticity present at the particle surface changes and the surrounding flow needs a finite time to readapt to the new conditions.

A general expression for  $\mathbf{f}_B$  in a uniform flow has been put in the form:

$$\mathbf{f}_B = \mu d_P \int_0^t K(t - \tau) \left( \frac{\partial \mathbf{v}_c}{\partial \tau} - \frac{\partial \mathbf{v}_d}{\partial \tau} \right) d\tau \quad (5.93)$$

where the kernel  $K(t - \tau)$  depends on the diffusion process of the vorticity.

The Basset's expression is found in the limit of unsteady Stokes flow for a *rigid sphere* and is given by:

$$K(t - \tau) = \frac{3}{2} \left[ \frac{\pi d_P^2}{\nu(t - \tau)} \right]^{1/2} \quad (5.94)$$

Substituting (5.94) into (5.93) the history force becomes [22, 145]:

$$\mathbf{f}_B = -6\pi\mu r_P^2 \frac{1}{\sqrt{\pi\nu}} \int_0^t \frac{\partial \mathbf{v}_p}{\partial \tau} (t - \tau)^{-1/2} d\tau \quad (5.95)$$

in which it is assumed that the fluid movement is negligible.

The case of a *bubble* is more complicated because of the different origin of the interfacial vorticity. For a rigid surface the vorticity comes from the no-slip condition, while on a bubble it is the vanishing of the shear stress on a curved surface that forces vorticity to be non-zero. For a bubble a closed expression of the kernel is defined by [81, 89]:

$$K(t - \tau) = 4\pi \exp[36\nu(t - \tau)/d_P^2] \operatorname{erfc}[36\nu(t - \tau)/d_P^2] \quad (5.96)$$

For a *drop*, the solution naturally depends on the ratio between the kinetic viscosities of the outer and inner fluids [21, 121, 143, 145]. A closed form of  $K(t - \tau)$  has not been obtained for this case [81].

Magnaudet [81] also compared the magnitudes of different history forces and concluded that the history force acting on a clean bubble is much smaller than the corresponding one acting on a rigid sphere. The history force can be neglected in most cases considering bubbly flows. The extension of the theory to non-uniform flows and to high Reynolds number flows is still controversial. Nevertheless, Clift et al. [22] reviewed numerous investigations and claimed that the history term has a negligible effect on the mean motion of a particle in a turbulent fluid. The impacts on the fluctuations in particle motion might be more severe at high frequencies.

In multiphase reactor flow simulations the impacts of the history forces are normally neglected as the present understanding of these phenomena is far from complete.

### 5.1.8 Interfacial Momentum Transfer Due to Phase Change

The conventional formulas for the interfacial momentum transfer due to phase change are defined in Sect. 3.3 for the different averaging methods commonly applied in chemical reactor analysis. The modeling concepts usually adopted for the different averages are mathematically similar, so we choose to present a representative interfacial momentum transfer term in the framework of the volume averaging method described in Sect. 3.4.1.

In fluid mechanics the interfacial momentum transfer due to phase change (3.153) is normally expressed in terms of interfacial mass flux weighted quantities:

$$\mathbf{M}_k^\Gamma = -\frac{1}{V} \int_{A_I} \rho_k \mathbf{v}_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx \Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^\Gamma \quad (5.97)$$

The modeling of the interfacial mass transfer terms due to phase change  $\Gamma_{Vk}$  is discussed in Sect. 5.2, so only the  $\langle \mathbf{v}_k \rangle_{A_I}^\Gamma$  term is considered in this section.

For catalytic solid surfaces in packed beds and porous materials the speed of displacement of the interface is assumed to be zero,  $\mathbf{v}_I \cdot \mathbf{n}_k = 0$ . For this reason the interfacial momentum transfer due to phase change can be reduced to:

$$\mathbf{M}_k^\Gamma \approx -\frac{1}{V} \int_{A_I} \rho_k \mathbf{v}_k \mathbf{v}_k \cdot \mathbf{n}_k da \approx \Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^\Gamma \quad (5.98)$$

The same model assumption is used for gas–liquid interfaces as well, since the interface is hypothetically pictured as being stagnant [43]. However, one or both of the bulk phases may move.

At catalytic solid surfaces there are normally no phase change, so the interfacial momentum transfer due to phase change simply vanishes. Hence,

$$\Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^\Gamma = 0 \quad (5.99)$$

The rather blurry picture of the gas–liquid interface makes it very difficult to parameterize the  $\langle \mathbf{v}_k \rangle_{A_I}^\Gamma$  variable. Therefore, the interfacial momentum transfer due to phase change is generally neglected at these surfaces too. Further work is obviously required to improve our knowledge about these phenomena and to validate this model assumption.

## 5.2 Interfacial Heat and Mass Transfer Closures

In this section the classical heat and mass transfer theories are examined. The singular surface jump conditions for the primitive quantities, as derived in the framework of the standard averaging procedures, are approximated by the classical chemical engineering stagnant film theory normally used in chemical reactor models. The relevant transport phenomena solutions and the classical theories on heat and mass transfer considering both low- and high mass transfer rates are summarized in the subsequent subsections.

### 5.2.1 Approximate Interfacial Jump Conditions

Fairly rigorous formulas for the interfacial heat and mass transfer terms are defined in Sect. 3.3 for the different averaging methods commonly applied in chemical reactor analysis. However, since the modeling concepts are mathematically similar for the different averages, we choose to examine these constitutive equations in the framework of the volume averaging method described in Sect. 3.4.1. This modeling framework is used extensively in chemical reactor analysis because the basic model derivation is intuitive and relatively easy to understand. It has been pointed out that the macroscopic interfacial transfer terms occurring in the averaged model equations, as described in Sect. 3.3, represent approximate integral values of the averaged interfacial terms as proposed by Ishii [54] making a provisional model for *stratified flows* in nuclear reactor engineering. Specific application dependent constitutive equations and modeling concepts are thus required determining these terms for the different chemical systems, flow regimes, operating conditions, and so forth to reimpose the essential physics that were lost during the averaging process with an appropriate level of complexity. For comparison we briefly display the standard macroscopic transfer functions resulting from the averaging process, before we introduce the particular constitutive equations normally applied in chemical reaction engineering. This might help to elucidate the connection between the conventional fluid mechanics modeling framework and the customary chemical reaction engineering interfacial coupling terms. In the multiphase flow literature these integral terms

are generally approximated as the product of the interfacial area concentration and a mean interfacial flux using the mean value theorem for integrals.

Using the mean value theorem the interfacial mass transfer rate due to phase change (3.149) becomes [12, 54, 63]:

$$\Gamma_{Vk} = -\frac{1}{V} \int_{A_I} \rho_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx a_I \langle \dot{m}_k \rangle_{A_I} \approx a_I \rho_k \langle v_{n,k}^{\text{rel}} \rangle_{A_I}$$

where  $\langle v_{n,k}^{\text{rel}} \rangle_{A_I}$  denotes the average interfacial velocity of phase  $k$ , relative to the velocity of phase  $k$  at the interface, normal to the interface and in a direction outward of phase  $k$ . This means that  $\langle v_{n,k}^{\text{rel}} \rangle_{A_I}$  represents the normal interface velocity solely due to phase change.

Similarly, the interfacial heat transfer (3.180), as related to (3.206), and the species transfer (3.184) due to phase change are normally expressed in terms of interfacial mass flux weighted quantities

$$h_k^\Gamma = -\frac{1}{V} \int_{A_I} \rho_k h_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx \Gamma_{Vk} \langle h_k \rangle_{A_I}^\Gamma$$

$$J_{k,s}^\Gamma = -\frac{1}{V} \int_{A_I} \rho_k \omega_{k,s} (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx \Gamma_{Vk} \langle \omega_k \rangle_{A_I}^\Gamma$$

It is noted that in the general case the interface velocity is not equal to the neighboring phase velocities  $\mathbf{v}_I \neq \mathbf{v}_k$ .

The initial engineering applications of the two-fluid framework to model chemical reacting flows focused on combustion processes. Unlike the normal behavior of chemical reactors, in many of the homogeneous combustion applications the details of the chemical reaction kinetics are effectively ignored because the reactions are very fast and thus assumed to be in local instantaneous chemical equilibrium. That is, all the reactions are assumed to occur much faster than the turbulent micro-mixing. The rate determining step is thus the turbulent micro-mixing properties of the flow, so turbulence modeling was considered especially important. To describe heterogeneous systems like spray and solid particle combustion processes the two-fluid model has been considered useful [66, 93, 113, 114, 116]. It is noted that for these systems the burning rate  $\langle v_{n,k}^{\text{rel}} \rangle_{A_I}$ , i.e., the rate at which the particles shrink, is normally defined in accordance with the modeling approach explained by Ishii [54]. Moreover, in the combustion processes involving droplet vaporization the multicomponent mass diffusion and heating of the liquid phase are usually the rate-controlling phenomena determining the overall burning rate [114]. In recent years the conventional modeling framework has also been adopted for the description of multicomponent transport phenomena during metal alloy solidification [12, 91, 92].

In the field of chemical reaction engineering, on the other hand, the elementary modeling principles still being used in the modern fluid dynamic reactor models did not evolve from any averaging concept, since the classical reaction engineering

models were postulated long before the averaging concepts were proposed. The present aim is thus to link the classical approach used in reactor analysis with the conventional fluid dynamic formulas given above.

Although many physical processes of interest to chemical reaction engineers involve absorption, heterogeneous reaction, surface mass transport, and interfacial mass transfer at moving and deforming interfaces, their main focus is concerned with the phenomena occurring at two particular types of interface systems. These are (1) the adsorption and reaction processes taking place at catalytic solid surfaces and (2) the condensation/evaporation of fluid mixtures going on at gas–liquid interfaces.

In the case of adsorption and reaction at a fixed catalytic surface the speed of displacement of the interface is assumed to be zero<sup>4</sup> [138]. In this case the interfacial transfer terms due to phase change can be reduced to:

$$\Gamma_{Vk} = -\frac{1}{V} \int_{A_I} \rho_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx -\frac{1}{V} \int_{A_I} \rho_k \mathbf{v}_k \cdot \mathbf{n}_k da \quad (5.100)$$

$$h_k^\Gamma = -\frac{1}{V} \int_{A_I} \rho_k h_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx -\frac{1}{V} \int_{A_I} \rho_k h_k \mathbf{v}_k \cdot \mathbf{n}_k da \quad (5.101)$$

$$J_{k,s}^\Gamma = -\frac{1}{V} \int_{A_I} \rho_k \omega_{k,s} (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k da \approx -\frac{1}{V} \int_{A_I} \rho_k \omega_{k,s} \mathbf{v}_k \cdot \mathbf{n}_k da \quad (5.102)$$

where one of the phases represents a rigid solid which is in contact with the second one being a fluid phase. The interface is a catalytic surface at which chemical reactions can take place, and both the bulk phases are continuous. Further discussions and a fundamental description of the species mass transfer phenomena are given by Whitaker [138, 139].

In the case of phase change at gas–liquid mixtures interfaces profound understanding of (1) the thermodynamics of fluid mixtures, (2) phase equilibria, (3) heat transfer, and (4) mass transfer are required. The classical two-film theory concept of Colburn and Drew [23] is normally adopted [15, 134]. In this approach the interfacial transfer models are derived considering a *stagnant* surface or interface enclosed by two thin and stagnant hypothetical films. For dynamic (i.e., no global equilibrium) cases one imagines resistances to both heat and mass transfer through the films on both sides of the interface and that thermodynamic equilibrium prevails at the interface only, thereby the bulk phases are not necessarily uniform at steady state. In this context it is emphasized that in chemical reaction engineering a detailed description of the movement of the interfaces have not been considered important even for gas–liquid systems, in the sense that the complexity of such an approach will lead to impracticable computational costs and little gain in understanding and physical modeling of the important chemical processes. Henceforth, if otherwise not explicitly stated, for the examination of the engineering heat and mass transfer theories both the

<sup>4</sup> The fundamental analysis applies to packed and porous beds only, but in practice the same modeling approach is generally used for dispersed catalyst particles as well.

hypothetical films and the embedded interface are assumed to be stagnant,  $\mathbf{v}_I \cdot \mathbf{n}_k = 0$ . However, the bulk phases may still move relative to each other. It follows that the definitions of the interfacial heat and mass transfer fluxes are not stringent and to a certain extent based on fragmentary arguments, therefore the transfer coefficients can be interpreted in several ways [15, 115]. Basically, the transfer coefficients are either treated as an alternative model to the fundamental diffusion models (i.e., the Fourier's and Fick's laws) or the transfer coefficients are taking both diffusive and convective mechanisms into account through extended theories and/or empirical parameterizations. However, the distinction between these approaches is rather blurred so it is not always clear which of the fundamental transport processes that are actually implemented. In an attempt to explain the chemical engineering modeling approach in a precise manner Bird et al. [13, 15] proposed to distinguish between the definition of the transfer coefficients for problems with low- and high net mass transfer rates although no precise partition was made. It was assumed that for systems with a slightly soluble component, small diffusivities, and small net mass transfer rates the analytical expressions derived from pure diffusive flux considerations can be used. For high net mass transfer rates the transfer coefficients depend on the convective mass transport in addition to the diffusive mechanisms. To describe the transfer under such conditions, Bird et al. adopted the approach of Colburn and Drew [23] consisting in replacing the analytical formula derived for pure diffusion through the hypothetical films by a similar but entirely empirical expression in which the pre-factor in front of the driving force is substituted by an empirical mass transfer coefficient. These mass transfer coefficients are assumed to be functions of the physical properties of the mixture and the conditions of the flow. Other theories, again, impose various semi-empirical convective effects and compare the classical stagnant film mass diffusion transport estimates with the extended mass transfer expressions. By similarity arguments one then postulate semi-empirical relationships between the transport and transfer coefficients. The impact of convection on the mass transfer coefficient are then supposedly lumped into the film thickness parameter [43]. It is hardly necessary to remark that prudence is required working with these concepts to make sure that the different formulas and the transfer coefficients are used in a consistent manner.

The advantage of working in terms of the traditional joint diffusive and convective flux concept is that the contribution of convection is automatically taken into account and we do not need separate models for the interfacial transfers due to phase change. The disadvantage is that the transfer coefficients show a more complicated dependence upon concentration and mass transfer rates. In a scientific view the loss in physical rigor might outweigh the possible gain in computational ease [115]. Nevertheless, in this work we follow the approach chosen in most chemical reactor analysis in which the transfer coefficients are defined in terms of the combined fluxes including both diffusive and convective contributions.

The combined volumetric species mass transfer rate across a hypothetical fluid film  $R_{n_{k,s}}$  represents the species mass transfer from a solid surface of area  $A_I$  and mass fraction  $\langle \omega_{k,s} \rangle_{A_I}$  to an adjacent moving fluid stream with mass fraction  $\langle \omega_{k,s} \rangle_{V_k}$ . For a binary fluid mixture the combined volumetric species mass transport rate is

approximated by:

$$\begin{aligned} R_{n_{k,s}} &= a_I \langle \mathbf{n}_{k,s} \rangle_{A_I} = J_{k,s}^j + J_{k,s}^\Gamma \approx a_I \rho_k \frac{D_{k,s}}{l_{k,s}} (\langle \omega_{k,s} \rangle_{A_I} - \langle \omega_{k,s} \rangle_{V_k}) \\ &= a_I \rho_k k_{c,s} (\langle \omega_{k,s} \rangle_{A_I} - \langle \omega_{k,s} \rangle_{V_k}) \end{aligned} \quad (5.103)$$

in which it is assumed that the mean interfacial flux is proportional to the difference between the interfacial average and the intrinsic volume average of the mass fraction.  $D_{k,s}$  is the binary diffusion coefficient in the phase denoted by  $k$ , and  $l_k$  is the thickness of the film on the phase  $k$  side of the interface. In this case  $J_{k,s}^\Gamma$  denotes the convective contributions to the interfacial species mass transfer flux, as no phase change takes place at these interfaces. If the no slip condition applies at the surface, the convective flux contribution is zero.

The surface average combined convective mass transfer flux  $\langle \mathbf{n}_{k,s} \rangle_{A_I}$  (kg/m<sup>2</sup>s) is generally approximated by:

$$\begin{aligned} \langle \mathbf{n}_{k,s} \rangle_{A_I} &= J_{k,s}^j + J_{k,s}^\Gamma \approx a_I \rho_k \frac{D_{k,s}}{l_{k,s}} (\langle \omega_{k,s} \rangle_{A_I} - \langle \omega_{k,s} \rangle_{V_k}) \\ &= a_I \rho_k k_{c,s} (\langle \omega_{k,s} \rangle_{A_I} - \langle \omega_{k,s} \rangle_{V_k}) \end{aligned} \quad (5.104)$$

It is further noted that the use of interfacial mass flux weighted transfer terms is generally not convenient treating multicomponent reactive systems, because the phase change processes are normally not modeled explicitly but deduced from the species composition dependent joint diffusive and convective interfacial transfer models. Moreover, the rigorous reaction kinetics and thermodynamic models of mixtures are always formulated on a molar basis.

Basically the fundamental convective heat transfer refers to the conductive flux mechanisms by which heat is transferred between a solid surface and a fluid moving over the surface in such a way that the fluid is stagnant at the wall because of the no slip behavior. The volumetric heat transfer rate  $R_{Q_k}$  (W/m<sup>3</sup>s) represents the heat transfer from a solid surface of area  $A_I$  and temperature  $\langle T_S \rangle_{A_I}$  to an adjacent moving fluid stream of temperature  $\langle T_k \rangle_{V_k}$  (K). The volumetric heat transfer rate can be approximated by:

$$R_{Q_k} = -\frac{1}{V} \int_{A_I} \mathbf{q}_k \cdot \mathbf{n}_k da = a_I \langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle \approx h_k^{\text{cond}} a_I (\langle T_S \rangle_{A_I} - \langle T_k \rangle_{V_k}) \quad (5.105)$$

The corresponding surface average convective heat transfer flux  $\langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_A$  is generally approximated by:

$$\left\langle \frac{\dot{Q}_k}{A_I} \right\rangle_A = \langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_A \approx h_k^{\text{cond}} (\langle T_S \rangle_{A_I} - \langle T_k \rangle_{V_k}) \quad (5.106)$$

where  $h_k^{\text{cond}}$  is the heat transfer coefficient ( $\text{Wm}^2\text{K}$ ) associated with pure conduction at the wall.

Alternatively, the convective heat transfer rate may refer to the combined conductive and convective flux mechanisms by which heat is transferred between a solid surface and a fluid moving over the surface provided that the fluid is not stagnant at the wall because of fluid-wall slip. In this case the volumetric heat transfer rate  $R_{Q_k}$  ( $\text{W/m}^3\text{s}$ ) is given by:

$$\begin{aligned} R_{Q_k} &= -\frac{1}{V} \int_{A_I} (\mathbf{q}_k + \rho_k h_k \mathbf{v}_k) \cdot \mathbf{n}_k da = a_I \langle (\mathbf{q}_k + \rho_k h_k \mathbf{v}_k) \cdot \mathbf{n}_k \rangle \\ &\approx h_k^{\text{cond, conv}} a_I (\langle T_S \rangle_{A_I} - \langle T_k \rangle_{V_k}) \end{aligned} \quad (5.107)$$

The corresponding surface average combined convective heat transfer flux is normally approximated by:

$$\begin{aligned} \left\langle \frac{\dot{Q}_k^{\text{cond, conv}}}{A_I} \right\rangle &= \left\langle \frac{\dot{Q}_k^{\text{cond}} + \dot{Q}_k^{\text{conv}}}{A_I} \right\rangle_A = \langle (\mathbf{q}_k + \rho_k h_k \mathbf{v}_k) \cdot \mathbf{n}_k \rangle_A \\ &\approx h_k^{\text{cond, conv}} (\langle T_S \rangle_{A_I} - \langle T_k \rangle_{V_k}) \end{aligned} \quad (5.108)$$

where  $h_k^{\text{cond, conv}}$  is the combined convective heat transfer coefficient accounting for conductive and convective heat transfer ( $\text{W/m}^2\text{K}$ ).

In both convective heat transfer definitions it is presumed that the solid surface is warmer than the fluid so that heat is being transferred from the solid to the fluid. Equations (5.105) and (5.107) are sometimes called *Newton's law of cooling* but are merely the defining equation for the  $h_k$  parameters [15, 53, 87].

The convective heat transfer coefficient generally depends on conditions in the boundary layer, surface geometry, fluid motion, and thermodynamic and transport properties of the fluid. A thorough examination of the heat transfer coefficient theory and many examples are given by Bird et al. [15], Kays and Crawford [62], Middleman [87] and Incropera and DeWitt [53].

The approximate modeling approaches found to be suitable for the purpose of determining the interfacial heat and mass transfer fluxes in reactor analysis can be summarized as follows:

### *Chemical Species Mass Transfer*

1. Considering a binary fluid mixture at a *catalytic solid surface* the species mass transport is approximated by the transfer flux across a hypothetical fluid film:

$$\begin{aligned} R_{n_{k,s}} &= a_I \langle \mathbf{n}_{k,s} \rangle_{A_I} = j_{k,s}^j + J_{k,s}^{\Gamma} \approx a_I \rho_k \frac{D_{k,s}}{l_{k,s}} (\langle \omega_{k,s} \rangle_{A_I} - \langle \omega_{k,s} \rangle_{V_k}) \\ &= a_I \rho_k k_{c,s} (\langle \omega_{k,s} \rangle_{A_I} - \langle \omega_{k,s} \rangle_{V_k}) \end{aligned} \quad (5.109)$$

The interfacial species mass jump balance (3.186) can now be expressed as:

$$R_{n_{\text{fluid},s}} + R_{n_{\text{solid},s}} \approx \rho_{\text{Bulk}} \langle R_{I,s} \rangle^{\text{m}}, \quad (5.110)$$

and we can eliminate the solid phase transfer term from the bulk phase transport equations [137]. In addition, the net diffusive mass flux for each phase vanishes for binary systems as  $\sum_s J_{k,s}^j = 0$  adopting Fick's law. Nevertheless, this diffusive flux definition is commonly used also for dilute pseudo-binary systems. In these particular cases the latter relationship is only approximate.

2. For a non-reactive two-phase *gas-liquid interface* the mass transport is approximated by the net transfer flux across the two stagnant fluid films. For each film we may write a transfer rate term on the form:

$$\begin{aligned} R_{n_{k,s}} &= J_{k,s}^j + J_{k,s}^\Gamma \approx a_I \rho_k \frac{D_{k,s}}{l_{k,s}} (\langle \omega_{k,s} \rangle_{A_I}^{\text{eq}} - \langle \omega_{k,s} \rangle_{V_k}) \\ &= a_I \rho_k k_{c,s} (\langle \omega_{k,s} \rangle_{A_I}^{\text{eq}} - \langle \omega_{k,s} \rangle_{V_k}) \end{aligned} \quad (5.111)$$

It is still assumed that the mean interfacial flux is proportional to the difference between the interfacial average and the intrinsic volume average of the mass fraction. In addition, the interfacial surface averaged concentrations are assumed to be in local instantaneous thermodynamic equilibrium.

For dilute mixtures Henry's law is frequently used to relate the interfacial concentrations:

$$\langle \omega_{g,s} \rangle_{A_I}^{\text{eq}} = \langle H_s \rangle_{A_I} \langle \omega_{l,s} \rangle_{A_I}^{\text{eq}} \quad (5.112)$$

where  $\langle H_s \rangle_{A_I}$  is a surface averaged value for a modified Henry's law constant for species  $s$  in the mixture. The conventional Henry's law is always defined on a mole basis. When a similar expression for the second film is established, the interfacial concentrations can be eliminated (the derivation is shown in the subsequent subsections). Assuming there are no surface reactions in the hypothetical films or at the gas-liquid interface, the interfacial species mass jump balance (3.183) reduces to:

$$R_{n_{g,s}} + R_{n_{l,s}} = 0 \quad (5.113)$$

The net diffusive mass flux for each phase still vanishes for binary systems as  $\sum_s J_{k,s}^j = 0$  using Fick's law, whereas for dilute pseudo-binary systems the latter relationship is only approximate.

### Mixture Mass Transfer

1. For *catalytic solid surfaces* the interfacial mass transfer rate is defined by (3.149) as:

$$\Gamma_{Vk} = \sum_s R_{n_{k,s}} = \sum_s (J_{k,s}^\Gamma + J_{k,s}^j) = \sum_s J_{k,s}^\Gamma = 0 \quad (5.114)$$

The net rate of mass generation in phase  $k$  is given by the sum of the component mass transfer terms. In this case the convective and diffusive fluxes through the hypothetical film must cancel each other. For a two-phase system the interfacial *mass* jump balance (3.148) is expressed as  $\Gamma_{Vg} = -\Gamma_{Vl} = 0$ .

2. For *gas–liquid interfaces* the interfacial mass transfer rate through each of the two films, is used to approximate (3.149), as expressed by:

$$\begin{aligned}\Gamma_{Vk} &= \sum_s R_{n_{k,s}} = \sum_s (J_{k,s}^\Gamma + J_{k,s}^j) = \sum_s J_{k,s}^\Gamma \\ &\approx a_I \rho_k \sum_s k_{c,s} (\langle \omega_{k,s} \rangle_{A_I}^{\text{eq}} - \langle \omega_{k,s} \rangle_{V_k})\end{aligned}\quad (5.115)$$

That is, the net rate of mass generation in phase  $k$  is given by the sum of the component mass transfer fluxes for binary mixtures using Fick's law. For a two-phase system the interfacial *mass* jump balance (3.148) is expressed as  $\Gamma_{Vg} + \Gamma_{Vl} = 0$ .

Again, it is mentioned that the binary mass flux definitions given above are commonly used also for pseudo-binary systems. In these particular cases the above relationships are only approximate.

#### Mixture Heat Transfer

1. Similar constitutive equations are used to approximate the integrals representing the interfacial heat transfer rates by convection and conduction through the stagnant films in the vicinity of a catalytic solid surface. Hence, the film model can be used to approximate the interfacial heat transport (3.172) by:

$$\begin{aligned}R_{Qk} &= -\frac{1}{V} \int_{A_I} (\mathbf{q}_k + \rho_k h_k \mathbf{v}_k) \cdot \mathbf{n}_k da = h_k^\Gamma + E_k^E \\ &\approx a_I h_k (\langle T_k \rangle_{A_I} - \langle T_k \rangle_k)\end{aligned}\quad (5.116)$$

The  $E_k^E$  contribution vanishes when the fluid is really stagnant at the interface (no slip).

The final form of the interfacial jump heat balance for a catalytic surface (3.178) yields:

$$R_{Qg} + R_{Ql} = E_g^E + h_g^\Gamma + E_l^E + h_l^\Gamma \approx \rho_{\text{Bulk}} \langle R_{l,s} (-\Delta H_R) \rangle_{A_I}^m \quad (5.117)$$

At the catalytic solid surfaces the interfacial heat transfer due to phase change vanishes, instead the convective contributions in (3.180) are incorporated into the convective heat transfer coefficients.

2. For *gas–liquid systems* involving phase change the mixture enthalpy consists of a sensible heat and a latent heat of vaporization. The corresponding heat jump

condition (3.178) can be expressed as  $E_g^E + h_g^\Gamma + E_l^E + h_l^\Gamma \approx 0$ , or alternatively [114]:

$$\begin{aligned} & -\frac{1}{V} \int_{A_I} (\mathbf{q}_g + \rho_g \mathbf{v}_g h_g) \cdot \mathbf{n}_g \\ & = \frac{1}{V} \int_{A_I} (\mathbf{q}_l + \rho_l \mathbf{v}_l ([h_l - \Delta h_{lg,\text{mix}}^{\text{vap}}] + \Delta h_{lg,\text{mix}}^{\text{vap}})) \cdot \mathbf{n}_l da \end{aligned} \quad (5.118)$$

in which  $h_{lg,\text{mix}}^{\text{vap}}$  represents the net latent heat of vaporization of the multicomponent mixture (J/kg).

In the chemical engineering community the interfacial heat balance concept proposed by Colburn and Drew [23] to treat the latent heat of vaporization term may be more familiar. A consistent expression for the net latent heat of vaporization of the multicomponent mixture  $h_{lg,\text{mix}}^{\text{vap}}$  in terms of the pure vapor  $s$  enthalpies  $h_{lg,s}^{\text{vap}}$  can be derived from the Colburn and Drew theory [9, 23, 134] (Sect. 4.1.8). In their two-film model approach the heat balance includes (1) the heat flux at the interface due to condensation  $R_{Q_{l,\lambda}}$ , (2) sensible heat loss by the gas film, and (3) sensible heat loss by the liquid film.

The interfacial heat jump balance (3.178) is then approximated by:

$$R_{Q_l} \approx R_{Q_{l,\lambda}} - R_{Q_g} \quad (5.119)$$

neglecting the species mixing effects.

To be consistent with the mass transfer model, the interfacial heat transfer flux through each of the films consists of both conductive (3.172) and convective (3.180) contributions. The heat transfer terms are approximated by:

$$\begin{aligned} R_{Q_k} &= -\frac{1}{V} \int_{A_I} (\mathbf{q}_k + \rho_k h_k \mathbf{v}_k) \cdot \mathbf{n}_k da = h_k^\Gamma + E_k^E \\ &\approx a_I h_k (\langle T_k \rangle_{A_I} - \langle T_k \rangle_k) \end{aligned} \quad (5.120)$$

That is, the interfacial heat transfer per unit volume is modeled as the product of the interfacial area concentration and a mean normal interfacial flux which is proportional to the difference between the interfacial average and the intrinsic volume average of the temperature of phase  $k$ .

The latent heat of vaporization for multicomponent mixtures is dependent upon the mixture composition and given by: [114]:

$$\begin{aligned} R_{Q_{l,\lambda}} &= \frac{1}{V} \int_{A_I} \rho_l \mathbf{v}_l \Delta h_{lg,\text{mix}}^{\text{vap}} \cdot \mathbf{n}_l da = \frac{1}{V} \int_{A_I} \sum_s \rho_{l,s} \mathbf{v}_{l,s} \Delta h_{lg,s}^{\text{vap}} \cdot \mathbf{n}_l da \\ &= \frac{1}{V} \int_{A_I} \sum_s \frac{\mathbf{n}_{l,s} \cdot \mathbf{n}_l}{M_{w,s}} (\bar{h}_{g,s} - \bar{h}_{l,s}) da \end{aligned}$$

$$= \frac{1}{V} \int_{A_I} \sum_s \frac{\mathbf{n}_{l,s} \cdot \mathbf{n}_l}{M_{w,s}} \Delta \bar{h}_{lg,s} da \quad (5.121)$$

The net latent heat of vaporization of the multicomponent mixture  $\Delta h_{lg,\text{mix}}^{\text{vap}}$  can thus be calculated from the following relation:

$$\Delta h_{lg,\text{mix}}^{\text{vap}} = \frac{\sum_s \frac{\mathbf{n}_{l,s} \cdot \mathbf{n}_l}{M_{w,s}} \Delta \bar{h}_{lg,s}}{\sum_s \mathbf{n}_{l,s} \cdot \mathbf{n}_l} = \frac{\sum_s \frac{\mathbf{n}_{l,s} \cdot \mathbf{n}_l}{M_{w,s}} \Delta \bar{h}_{lg,s}}{\mathbf{n}_{l,\text{tot}} \cdot \mathbf{n}_l} = \frac{\sum_s \frac{\mathbf{n}_{l,s} \cdot \mathbf{n}_l}{M_{w,s}} \Delta \bar{h}_{lg,s}}{\rho_l \mathbf{v}_l \cdot \mathbf{n}_l} \quad (5.122)$$

where  $\bar{h}_{g,s}$  is the partial molar enthalpy of component  $s$  in the gas, and  $\bar{h}_{l,s}$  is the partial molar enthalpy of component  $s$  in the liquid.  $\mathbf{n}_{l,s}$  denotes the liquid phase combined mass flux for species  $s$ , whereas  $\mathbf{n}_l$  is the outward directed unit vector for the liquid. For non-volatile/non-condensing species the convective and diffusive fluxes through the hypothetical films must be zero or cancel out.

For non-ideal multicomponent mixtures the multiphase flow calculation can be combined with a more rigorous thermodynamic equilibrium calculation to determine the mixture properties at the interface as discussed by [60, 70, 98]. However, describing the chemical reactor performance under industrial operation conditions the heat balance is normally dominated by the heat of reaction term, the transport terms and the external heating/cooling boundary conditions, hence for chemical processes in which the phase change rates are relatively small the latent heat term is often neglected.

Future work might consider extensions of these interfacial transfer concepts to ameliorate the simulation accuracy by utilizing the local information provided by the multi-fluid models. For multiphase reactive systems these processes can be rate determining, in such cases there are no use for advanced flow calculations unless these fluxes can be determined with appropriate accuracy.

### 5.2.2 Fundamental Heat and Mass Transport Processes

The molecular transport processes refer to the transfer of continuum properties by molecular movement through a medium which can be a fluid or a solid. Each molecule of a system has a given quantity of the property mass, energy and momentum associated with it. When concentration gradients exist in any of these property fields, a net transport occurs. In dilute fluids such as gases where the molecules are relatively far apart, the rate of transport of the property should be relatively fast since few molecules are present to block the transport by interaction. In dense fluids such as liquids the molecules are closer together and transport or diffusion proceeds more slowly. The molecules in solids are even more close-packed than in liquids and molecular migration is even more restricted. Therefore, the molecular diffusion coefficient for gases is larger than for liquids and solids.

The conventional parameterizations used describing molecular transport of mass, energy and momentum are the Fick's law (mass diffusion), Fourier's law (heat diffusion or conduction) and Newton's law (viscous stresses). The mass diffusivity,  $D_c$ , the kinematic viscosity,  $\nu$ , and the thermal diffusivity,  $\alpha$ , all have the same units ( $\text{m}^2/\text{s}$ ). The way in which these three quantities are analogous can be seen from the following equations for the fluxes of mass, momentum, and energy in one-dimensional systems [13, 111]:

$$j_{c,y} = -D_c \frac{d(\rho_c)}{dy} \quad (\text{Fick's law for constant } \rho) \quad (5.123)$$

$$q_y = -\alpha \frac{d(\rho C_p T)}{dy} \quad (\text{Fourier's law for constant } \rho C_p) \quad (5.124)$$

$$\sigma_{yx} = -\nu \frac{d(\rho v_x)}{dy} \quad (\text{Newton's law for constant } \rho) \quad (5.125)$$

where  $j_{c,y}$  is the flux of species  $c$  per area in  $\text{kg}/(\text{sm}^2)$ ,  $D_c$  is the mass diffusion coefficient in  $\text{m}^2/\text{s}$ ,  $\rho_c$  is the mass concentration of  $c$  in the mixture,  $q_y$  is the heat flux in  $\text{J}/(\text{sm}^2)$ ,  $\alpha = k/(\rho C_p)$  is the thermal diffusivity of the conducting medium,  $T$  is the temperature in  $K$ ,  $\tau_{yx}$  is the shear stress in  $\text{kg}/(\text{sm}^2)$ ,  $\nu$  is the kinematic viscosity coefficient and  $v_x$  is the  $x$ -velocity component in  $\text{m}/\text{s}$ . Note that these analogies are less obvious in two- and three dimensional problems, however, because  $\sigma$  is a tensor quantity with nine components, whereas  $\mathbf{j}_c$  and  $\mathbf{q}$  are vectors with three components.

In general, there are more than one driving force involved producing diffusive transport for any one fluid property as examined in Chap. 2. The origin of molecular mass diffusion might be related a combination of one or more of the following non-equilibrium phenomena; concentration gradients, pressure gradients, thermal gradients or external forces. Heat conduction is also related to atomic and molecular activity. Conduction may be viewed as the transfer of energy from the more energetic to the less energetic particles of a substance due to interactions between the particles. For a gas the temperature at any point in space is associated with the energy of molecules in proximity to the point. This energy is related to the random translational motion, as well to the internal rotational and vibrational motions, of the molecules. Higher temperatures are associated with an increase in molecular energies, and when neighboring molecules collide, a net transfer of energy from the more energetic to the less energetic molecules must occur. In the presence of a temperature gradient, energy transfer by conduction must then occur in the direction of decreasing temperature. We may speak of the net transfer of energy by random molecular motion as a diffusion of energy. The situation is much the same in liquids, although the molecules are more closely spaced and the molecular interactions are stronger and more frequent. Similarly, in a solid, conduction may be attributed to atomic activity in the form of lattice vibrations. The modern view is to ascribe the energy transfer to lattice waves induced by atomic motions. In a non-conductor, the energy transfer is exclusively via these waves, in a conductor it is also due to the translational motion of the free electrons. In reaction engineering the ordinary diffusion processes taking place

close to an interface have been analyzed in two ways. First, as just mentioned, the interfacial transport fluxes can be described in a fundamental manner adopting the Fourier's and Fick's laws which are expressed in terms of the *transport coefficients* known as conductivity and diffusivity. Second, the interfacial transport fluxes can alternatively be approximated in terms of the engineering *transfer coefficients* for convective heat and mass transport.

### 5.2.3 Mass Transport Described by Fick's law

This section contains a simple introduction to steady state and unsteady species mole (mass) diffusion in dilute binary mixtures. First, the physical interpretations of these diffusion problems are given. Secondly, the physical problem is expressed in mathematical terms relating the concentration profiles to the diffusion fluxes. Emphasis is placed on two diffusion problems that form the basis for the interfacial mass transfer modeling concepts used in reaction engineering. The basic theory is reviewed in many textbooks on chemical reaction engineering [6, 15, 27, 52, 87]. These texts may be recommended for complimentary studies.

Adolf Fick developed the law of diffusion by means of analogies with Fourier's work on thermal conduction [42]. Mathematically, the mass diffusion flux is thus expressed as:

$$\mathbf{j}_c = -\rho D_c \nabla \omega_c \quad (\text{Fick's law}) \quad (5.126)$$

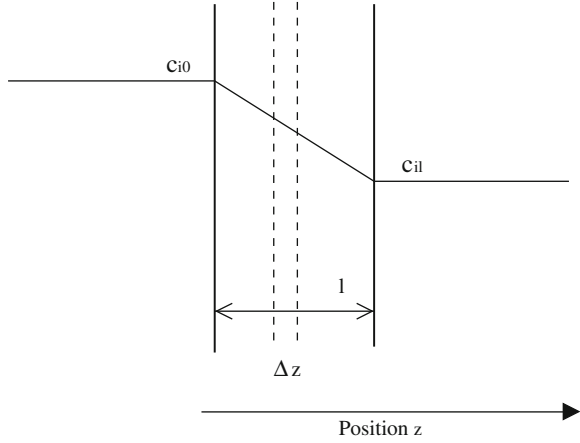

This equation states that the flux of species is proportional to concentration gradient and occurs in the direction opposite to the direction of the concentration gradient of that species. The proportionality coefficient is the molecular diffusion coefficient. This diffusion coefficient formulation is useful for fundamental studies where we want to know concentration versus position and time.

#### 5.2.3.1 Steady Diffusion Across a Thin Film with a Fixed Boundary

Consider a very thin film between two well-mixed fluids. Each of the fluids are dilute binary mixtures, consisting of the same solvent and solute having different concentrations. The solute diffuses from the higher concentrated solution into the less concentrated one. The diffusion across this thin film is considered to be a steady-state problem. There are no concentration changes with time, as indicated in Fig. 5.13.

To describe this problem in mathematical terms, either the differential species mass balance (1.39) can be reduced appropriately or alternatively a species mass shell balance over a thin layer,  $\Delta z$ , can be put up and combined with Fick's law. The resulting equation for steady diffusion in the thin layer is of course the same in both cases. The simple ordinary differential equation is integrated twice with the appropriate boundary conditions in order to get a relation for the concentration profile that is needed to determine the diffusive flux.

**Fig. 5.13** Steady diffusion across a thin film

Assuming that the diffusion coefficient is constant, the governing equations describing the problem are listed below:

The species mole balance<sup>5</sup>:

$$0 = -\frac{dJ_i^*}{dz} \quad (5.127)$$

The Fick's law for binary diffusion (i.e., in 1D):

$$J_i^* = -D \frac{dc_i}{dz} \quad (5.128)$$

Combining these relations we obtain the following differential equation:

$$0 = D \frac{d^2 c_i}{dz^2} \quad (5.129)$$

that can be solved using appropriate boundary conditions:

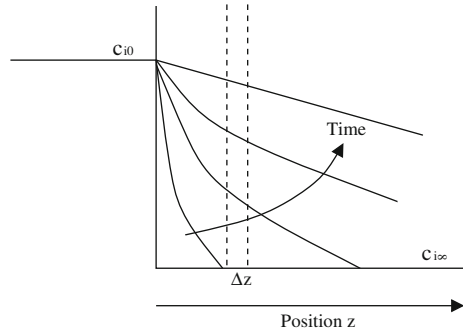

$$\begin{aligned} z = 0 & \quad c_i = c_{i0} \\ z = l & \quad c_i = c_{il} \end{aligned}$$

The solution of the above differential equation yields the concentration profile:

$$c_i = c_{i0} + \frac{1}{l}(c_{il} - c_{i0})z \quad (5.130)$$

<sup>5</sup> The classical models are generally expressed in terms of diffusive mole fluxes.

**Fig. 5.14** Diffusion in a semi-infinite slab

The resulting concentration profile is linear and independent on the diffusion coefficient.

The diffusive flux is then found by differentiating the concentration profile:

$$J_i^* = -D \frac{dc_i}{dz} = \frac{D}{l} (c_{i0} - c_{il}) \quad (5.131)$$

This flux formulation determine the basis for the basic film theory.

### 5.2.3.2 Unsteady Diffusion in a Semi-Infinite Slab with a Fixed Boundary

Consider a volume of solution that start at an interface and extends a very long distance away from the interface. We want to describe how the concentration varies in the solution as a result of a concentration change at its interface. The concentration profile will change with time, as sketched in Fig. 5.14.

To develop a model for this mathematical problem we can either simplify the differential species mass balance equation (1.39) appropriately or combine the transient shell species mass balance written for the thin layer  $\Delta z$  with Fick's law for binary diffusion. The resulting partial differential equation is called *Fick's second law*. A simple way to obtain a solution for this differential equation is to adopt the method of combination of variables. It is then necessary to define a new independent variable that enable us to transform the partial differential equation into an ordinary differential equation.

The equations describing the problem can be listed as follows:

The species mole balance:

$$\frac{\partial c_i}{\partial t} = -\frac{\partial J_i^*}{\partial z} \quad (5.132)$$

By use of the Fickian mole diffusion flux closure the Fick's second law is obtained:

$$\frac{\partial c_i}{\partial t} = D \frac{\partial^2 c_i}{\partial z^2} \quad (5.133)$$

The initial and boundary conditions needed are:

$$\begin{array}{lll} t = 0 & \text{all } z & c_i = c_{i\infty} \\ t > 0 & z = 0 & c_i = c_{i0} \\ t > 0 & z = \infty & c_i = c_{i\infty} \end{array}$$

The definition of the new independent variable is given as:

$$\zeta = \frac{z}{\sqrt{4Dt}} \quad (5.134)$$

Transforming Ficks second law and the initial and boundary conditions yield:

$$\frac{d^2 c_i}{d\zeta^2} + 2\zeta \frac{dc_i}{d\zeta} = 0 \quad (5.135)$$

and

$$\begin{array}{ll} \zeta = 0 & c_i = c_{i0} \\ \zeta = \infty & c_i = c_{i\infty} \end{array}$$

Two of the conditions have the same form after the transformation. However, the two reminding boundary conditions are sufficient solving the transformed ordinary differential equation.

The solution of the ordinary differential equation can be formulated as an error function. The concentrations profile is thus given as:

$$\frac{c_i - c_{i0}}{c_{i\infty} - c_{i0}} = 1 - \text{erf}(\zeta) = \frac{2}{\sqrt{\pi}} \int_0^\zeta e^{-\zeta^2} d\zeta \quad (5.136)$$

The flux can now be found by combining Ficks law for binary diffusion with the given concentration profile. The resulting flux relation can be expressed as:

$$J_i^* = \sqrt{\frac{D}{\pi t}} e^{-z^2/4Dt} (c_{i0} - c_{i\infty}) \quad (5.137)$$

The interfacial flux (i.e., the flux at  $z = 0$ ) at a particular time,  $t$ , is given by:

$$J_i^*|_{z=0} = \sqrt{\frac{D}{\pi t}} (c_{i0} - c_{i\infty}) \quad (5.138)$$

Analysis of the results obtained for the unsteady problem shows that the predicted concentration profile is time and position dependent, and that the diffusive flux at the interface is proportional to the square root of the diffusion coefficient.

Before we leave this mathematical exercise it is emphasized that we did consider an semi-infinite slab to explain the physical basis of the more advanced interfacial heat and mass transfer concepts to be introduced shortly in Sect. 5.2.5. Moreover, it is noted that the boundary condition at  $z = \infty$  might be replaced by a more practical one at a bounded or semi-infinite distance from the interface. In this case the solution relies on the assumption that we are considering a finite time period so that the ambient concentration is kept unaltered. In other words, if the diffusion process proceeds only a relatively short time period after the change in concentration at the interface occurs, the ambient concentration at a semi-infinite distance from the interface will not change. On the other hand, after a longer time period the concentration profile slinther into the steady state limit. In this case the ambient concentration might be changed due to the diffusive mass transfer flux so the semi-infinite slab concept is not valid anymore. The penetration and surface renewal mass transfer models rely on the assumption that the residence time of the interfacial element is sufficiently short so the inherent diffusion processes can be described using a semi-infinite slab approximation.

### 5.2.3.3 Unsteady Diffusion in a Semi-Infinite Slab with a Moving Boundary

For completeness in this subsection we briefly outline a generic analytical method of solution for a class of problems in unsteady-state linear diffusion, which involve two phases or regions separated by a moving plane interface. In particular we examine situations in which diffusion occurs in two distinct regions separated by a moving boundary or interface [25, 28]. Moreover, the two regions are separated by a plane surface and diffusion takes place only in the direction perpendicular to this plane. The concentration is initially uniform in each region. The component mass diffusion may then result in a net movement of the matter in one or both regions relative to the interface. In mathematical terms the position in medium 1 can be specified by a coordinate in the  $z_1$  system which is fixed with respect to medium 1, and position in medium 2 is specified by a coordinate in the  $z_2$  system, fixed with respect to medium 2. The media are thus separated at time  $t$  by the plane  $z_1 = Z_1 = Z_2$ , which is initially at  $z_1 = z_2 = 0$ . Medium 1 occupies a semi-infinite slab of the space  $Z_1 < z_1 < \infty$ , medium 2 a semi-infinite slab of the space  $-\infty < z_2 < Z_2$ . To adopt the conventional Fick's law of binary diffusion we assume that in both media one of the components present moves by diffusion relative to the  $z_1$  and  $z_2$  coordinates and is transferred from one medium to the other. The concentration of the diffusing component at time  $t$  is denoted by  $c_1$  at  $z_1$  and by  $c_2$  at  $z_2$ .

Fick's second law (5.135) is obeyed in the two media, and for simplicity we assume that the diffusion coefficient is constant and independent of the concentrations. At any time in the calculation the concentrations  $c_1(Z_1)$  and  $c_2(Z_2)$  at either side of the interface are assumed to be related by an equilibrium law, like for example the

Henry's law for gas absorption. The diffusion component is conserved at the interface so a jump condition can be expressed as:

$$D_1 \left( \frac{\partial c_1}{\partial z_1} \right)_{z_1=Z_1} - D_2 \left( \frac{\partial c_2}{\partial z_2} \right)_{z_2=Z_2} + c_1(Z_1) \frac{dZ_1}{dt} - c_2(Z_2) \frac{dZ_2}{dt} = 0 \quad (5.139)$$

Since by assumption there is a constant proportionality between the rates of movement of the two media relative to the interface, it follows that:

$$Z_2 = \text{Constant} \times Z_1 \quad (5.140)$$

The solution to the diffusion problem has the same form as that for the conventional Fick's second law (5.136):

$$\frac{c_{1i\infty} - c_{1i}}{c_{1i\infty} - c_{1i0}} = 1 - \text{erf}\left(\frac{z_1}{2\sqrt{D_1 t}}\right) \quad (5.141)$$

where  $c_{1\infty}$  and  $c_{10}$  are given by the initial and boundary conditions:

$$\begin{array}{lll} t = 0, & z_1 > 0, & c_{1i} = c_{1i\infty}, \\ t > 0, & z_1 = 0, & c_{1i} = c_{1i0}. \end{array}$$

Similarly, for medium 2, we get:

$$\frac{c_{2i(-\infty)} - c_{2i}}{c_{2i(-\infty)} - c_{2i0}} = 1 + \text{erf}\left(\frac{z_2}{2\sqrt{D_2 t}}\right) \quad (5.142)$$

where  $c_{2i(-\infty)}$  and  $c_{20}$  are given by the initial and boundary conditions:

$$\begin{array}{lll} t = 0, & z_2 < 0, & c_{2i} = c_{2i(-\infty)}, \\ t > 0, & z_2 = 0, & c_{2i} = c_{2i0}. \end{array}$$

Eliminating the unknown interface quantities using the equilibrium relation and the rates of movement of the two media relative to the interface, the component mass jump condition can be used to calculate the position of the interphase.

Danckwerts [28] mentioned a few examples of chemical engineering processes that might be described in this way. However, in chemical reaction engineering this modeling approach is merely of mathematical interest, as it is rarely used for practical applications because of the numerous restrictions involved. For this reason the method is not further elucidated in this book.

### 5.2.4 Heat Transfer Described by Fourier's Law

Fourier's law of heat conduction states that heat transfer by molecular interactions at any point in a solid or fluid is proportional in magnitude and coincident with the direction of the negative gradient of the temperature field [44]:

$$\mathbf{q} = -k\nabla T \quad (\text{Fourier's law}) \quad (5.143)$$

Fourier's law is the simplest form of a general energy flux and is strictly applicable only when the system is uniform in all respects except for the temperature gradient, that is, there are no mass concentration gradients or gradients in other intensive properties. In general, there could occur more than one driving force in a conductive transport process. Given a system with gradients of temperature, pressure, mass concentration, magnetic field strength, and so on, there is no a priori justification for ignoring the possibility that each of these gradients might contribute to the energy flux. The simplest expression that could describe this relationship would be a linear combination of terms, one for each of the existing potential gradients. Experience shows that there are, in fact, measurable *coupled* effects, such as energy fluxes due to mass concentration gradient, and that this general form of the linear rate equation is necessary under certain rare conditions. The relationships between the coefficients of this equation have been the subject of several investigations. This field of science is called irreversible thermodynamics [64].

### 5.2.5 Heat and Mass Transfer Coefficient Concepts

Fairly rigorous expressions for the interfacial heat and mass transfer terms are defined in Sect. 3.3 for the different averaging methods commonly applied in chemical reactor analysis. However, since the modeling concepts are analogous for the different averages, we choose to examine these constitutive equations in the framework of the volume averaging method described in Sect. 3.4.1. This modeling approach is used extensively in reactor analysis because the basic model derivation is intuitive and quite easy to understand. Physically, the interfacial heat and mass transfer terms occurring in the averaged model equations described in Sect. 3.3 represent advection of an interfacial quantity of phase  $k$  due to the relative motion of the interface, as proposed by Ishii [54] making a provisional model for *stratified flows* in nuclear reactor engineering. It is noted that in these units bulky quantities of fluid mass are transferred accross the interface due to phase change or various fragmentation/disintegration mechanisms (e.g., evaporation, condensation, boiling, liquid film fragmentation and disintegration, jet fragmentation, fluid particle fragmentation, etc.). However, this modeling approach is not necessarily convenient for the purpose of describing dispersed reactive flows in general. The use of mass weighted interfacial fluxes is certainly not applicable treating multicomponent reactive systems

since the rigorous reaction kinetics and thermodynamic models normally operates on a molar basis. Besides, in dynamic cases the classical interfacial heat and mass transfer theories (e.g., the hypothetical stagnant two-film model is commonly used) one imagines resistances to both heat and mass transfer on both sides of the interface, and that thermodynamic equilibrium prevails at the interface only, thereby the bulk phases are not necessarily uniform at steady state. Moreover, it is emphasized that in these theories the interface is generally assumed to be stagnant,  $\mathbf{v}_I = 0$ . In reaction engineering the possibility of describing the movement of the interfaces is not considered important, in the sense that the complexity of such an approach will lead to impracticable computational costs and little gain in understanding and physical modeling of the important chemical processes. The definitions of the heat and mass transfer fluxes are thus merely based on empirical arguments, so in the literature there are given more than one way to interpret the transfer coefficients [15, 115]. Basically, the transfer coefficients are either treated as an alternative model to the fundamental diffusion models (i.e., the Fourier's and Fick's laws) or the transfer coefficients are taking both diffusive and convective mechanisms into account through empirical parameterizations. However, in reaction engineering practice the distinction between these approaches is rather blurred so it is not always clear which of the fundamental transport processes that are actually implemented. The advantage of working in terms of the traditional joint diffusive and convective flux concept is that the contribution of convection is automatically taken into account and we do not need separate models for the interfacial transfers due to phase change. The disadvantage is that the transfer coefficients show a more complicated dependence upon concentration and mass transfer rates. In a scientific view the loss in physical rigor might outweigh the possible gain in computational ease [115]. Nevertheless, in most chemical reactor analysis the transfer coefficients are defined in terms of the combined fluxes including both diffusive and convective contributions [27].

In the following sections a survey of the elementary diffusion theories that are determining the basis for the mass transfer coefficient concepts is given. No heat and mass transfer models dealing with simultaneous chemical reactions are considered to maintain attention to the fundamental principles.

### 5.2.5.1 Mass Transfer in Regions Close to a Stagnant Interface

The description of the interfacial transport processes in terms of mass transfer coefficients is an approximate engineering concept that normally results in simpler mathematical problems than the alternative description in terms of the more fundamental Fick's law. The definition of the mass transfer coefficient is thus based on an oversimplified picture of the actual physics. The mass transfer coefficient concept relies on the hypothesis that the changes in concentrations are limited to two hypothetical stagnant films, one on each side of the stagnant interface. The transfer flux is thus transferring mass between the interface and the well mixed bulk solution. The amount of matter transferred is expected to be proportional to the concentration difference and the interfacial area. The proportionality coefficient,  $k_c$ , is called

the mass transfer coefficient. The mass transfer coefficient is usually defined by the following flux relation:

$$\langle N_i \rangle_{A_I} = k_c \left( \langle c_{i,k} \rangle_{A_I} - \langle c_{i,k} \rangle_{V_k} \right) \quad (5.144)$$

where  $\langle N_i \rangle_{A_I}$  is the flux at the interface in ( $\text{mol/s m}^2$ ),  $k_c$  is the mass transfer coefficient in ( $\text{m/s}$ ), and  $(\langle c_{i,k} \rangle_{A_I} - \langle c_{i,k} \rangle_{V_k})$  is the concentration difference (driving force) in ( $\text{mol/m}^3$ ).

Correspondingly, the mean interfacial mass flux is assumed to be proportional to the difference between the interfacial average and the intrinsic volume average of the quantity determining the driving force of the fluxes [91, 92].

The species transfer can thus be expressed as a mass flux  $\langle n_{i,k} \rangle_{A_I}$  ( $\text{kg/s m}^2$ ) in line with (3.185), simply by multiplying the conventional mole flux by the molecular weight  $M_{\omega_i}$ :

$$\langle n_{i,k} \rangle_{A_I} = M_{\omega_i} \langle N_{i,k} \rangle_{A_I} = k_c \left( \langle \rho_{i,k} \rangle_{A_I} - \langle \rho_{i,k} \rangle_{V_k} \right) \quad (5.145)$$

where  $(\langle \rho_{i,k} \rangle_{A_I} - \langle \rho_{i,k} \rangle_{V_k})$  is the concentration difference (driving force) in ( $\text{kg/m}^3$ ).

It is noted that although the combined mole and mass fluxes are related as  $\mathbf{n}_s = M_{w_s} \mathbf{N}_s$ , when there are negligible convection fluxes as calculated either by mole or mass averaged velocities the corresponding diffusive fluxes are not necessarily related in the same way since:  $\mathbf{j}_s \neq M_{w_s} \mathbf{j}_s^* = \mathbf{j}_s^*$ . The concentration difference can also be re-defined in different ways, thus there exists a variety of modifications of the basic mass transfer coefficient definition as well. Therefore, care should be taken to ensure that the mass transfer coefficient parameterizations adopted for modeling purposes, correspond to the model formulation used. The mass transfer coefficient concept is usually less accurate than Fick's law, but it is very useful for practical problems where only average concentrations are available.

### 5.2.5.2 The Mole Flux Equation for an Ideal Gas

The driving force is usually defined as a concentration difference between the interface and the bulk phase. For gases, however, it is more common to use the pressure difference as the driving force. We can thus formulate two different definitions of the mass transfer flux, and then derive an expression for the relation between the concentration based and the pressure based mass transfer coefficients. The flux is the same, so the definitions must be equal:

$$R_{n_{i,k}} = J_{i,k}^{\Gamma_{kV}} + J_{i,k}^j = M_{\omega_i} k_p \left( \langle p_{i,k} \rangle_{A_I} \frac{\langle T_k \rangle_{V_K}}{\langle T_k \rangle_{A_I}} - \langle p_{i,k} \rangle_{V_k} \right) \quad (5.146)$$

where  $k_c$  and  $k_p$  are the mass transfer coefficients defined with concentration and pressure as the driving force, respectively.  $\langle \rho_{i,k} \rangle_{A_I}$  and  $\langle \rho_{i,k} \rangle_{V_k}$  are the mass concentrations at the interface and bulk-face in ( $\text{kg}/\text{m}^3$ ).  $\langle p_{i,k} \rangle_{A_I}$  and  $\langle p_{i,k} \rangle_{V_k}$  are the pressures at the interface and in the bulk phase having the unit (Pa).

The concentration and pressure are related by the equation of state for an ideal gas:

$$c = \frac{n}{V} = \frac{p}{RT} \quad (5.147)$$

where  $V$  is the volume in ( $\text{m}^3$ ) and  $R$  is the universal gas constant in ( $\text{J}/\text{K mol}$ ).

The relation between the different mass transfer coefficients is:

$$k_p = \frac{k_c}{R \langle T_k \rangle_{V_k}} \quad (5.148)$$

It is thus possible to express the flux as:

$$\langle N_i \rangle_{A_I} = \frac{k_c}{R \langle T_k \rangle_{V_k}} \left( \langle p_{i,k} \rangle_{A_I} \frac{\langle T_k \rangle_{V_K}}{\langle T_k \rangle_{A_I}} - \langle p_{i,k} \rangle_{V_k} \right) \quad (5.149)$$

### 5.2.5.3 Mass Transfer Across a Stagnant Interface

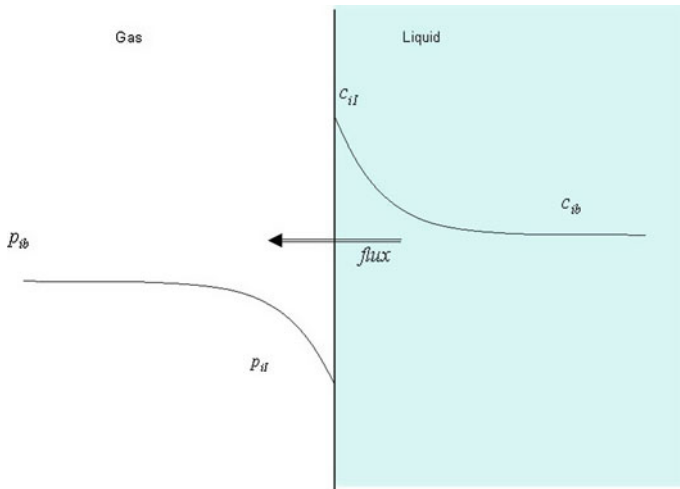

In the context of reactor technology, mass transfer across an interface means mass transfer from one well mixed bulk phase into another well mixed bulk phase. This case occurs more frequently than mass transfer from an interface into one bulk phase, which we have discussed above. Mass transfer across an interface between two well mixed bulk phases can then be described in terms of the flux relation (henceforth for convenience we drop the averaging symbol):

$$N_i = K_c \Delta c_i \quad (5.150)$$

where  $N_i$  is the solute flux relative to the interface in ( $\text{mol}/\text{s m}^2$ ),  $K_c$  is the overall mass transfer coefficient in ( $\text{m}/\text{s}$ ) and  $\Delta c_i$  is the concentration difference in ( $\text{mol}/\text{m}^3$ ).

Note that we can express the flux using either the concentration difference related to the phase at the left hand-side of the interface or the other concentration difference related to the phase at the right-hand side of the interface. *In this way two different overall mass transfer coefficients can be defined for the two-phase mixture.* To derive a relation for the overall mass transfer coefficient we consider a gas–liquid interface, as sketched in Fig. 5.15. Formulate the expressions for the fluxes at both sides of the interface and relate the two unknown interfacial concentrations to each other by use of an equilibrium relation like Henry's law. The flux relations can then be combined in order to eliminate the interfacial concentrations obtaining an overall driving force.

It is further assumed that within the system containing the two stagnant 1D films steady state has been reached, so that the fluxes at both sides of the interface are

**Fig. 5.15** Mass transfer across a gas–liquid interface

equal. It is also assumed that the interface processes are in a state of thermodynamic equilibrium.

The species mole flux at the gas side can be expressed as:

$$N_i = k_g(p_{il} - p_{ib}) \quad (5.151)$$

The flux at the liquid side can be expressed as:

$$N_i = k_l(c_{ib} - c_{il}) \quad (5.152)$$

The equilibrium processes at a dilute interface is usually described using Henry's law:

$$p_{il} = H_i c_{il} \quad (5.153)$$

where the  $H_i$  denotes the Henry law constant for species,  $i$ .

The flux across the interface can be expressed in terms of the concentration difference at the liquid side:

$$N_i = K_L(c_{ib} - c_i^*) \quad (5.154)$$

where  $K_L$  is the overall *liquid-side* mass transfer coefficient defined by:

$$K_L = \frac{1}{1/k_l + 1/k_g H_i} \quad (5.155)$$

$c_i^*$  is the hypothetical liquid phase concentration which would be in equilibrium with the bulk gas. The hypothetical equilibrium concentration is calculated from Henry's

law:

$$c_i^* = \frac{p_{ib}}{H_i} \quad (5.156)$$

The flux across the interface could alternatively be expressed in terms of the gas side concentration difference:

$$N_i = K_G(p_i^* - p_{ib}) \quad (5.157)$$

$K_G$  is the overall *gas-side* mass transfer coefficient, given by:

$$K_G = \frac{1}{1/k_G + H_i/k_L} \quad (5.158)$$

$p_i^*$  is the hypothetical gas phase concentration which would be in equilibrium with bulk liquid:

$$p_i^* = H_i c_{ib}. \quad (5.159)$$

### 5.2.5.4 Parameterization of the Engineering Transfer Coefficients

In this section the formal mathematical concepts for deriving the engineering transfer coefficients are examined.<sup>6</sup> The basic theory is thoroughly discussed by Astarita et al. [6], Bird et al. [15], Hines and Maddox [52], Cussler [27], Middleman [87], Arpaci et al. [5], Sherwood et al. [110] and Sideman and Pinczewski [111]. These texts might be recommended for supplementary studies.

Heat and mass transfer coefficients are usually reported as correlations in terms of dimensionless numbers. The exact definition of these dimensionless numbers implies a specific physical system. These numbers are expressed in terms of the characteristic scales. Correlations for mass transfer are conveniently divided into those for fluid–fluid interfaces and those for fluid–solid interfaces. Many of the correlations have the same general form. That is, the Sherwood or Stanton numbers containing the mass transfer coefficient are often expressed as a power function of the Schmidt number, the Reynolds number, and the Grashof number. The formulation of the correlations can be based on dimensional analysis and/or theoretical reasoning. In most cases, however, pure curve fitting of experimental data is used. The correlations are therefore usually problem dependent and can not be used for other systems than the one for which the curve fitting has been performed without validation. A large list of mass transfer correlations with references is presented by Perry [95].

---

<sup>6</sup> The methods of completely empirical experimentation and dimensional analysis are very important in engineering practice but excluded from this survey as these methods are well known and described in most introductory textbooks on unit operations in chemical engineering. In principle *dimensional analysis* consists in an algebraic treatment of the symbols for units, and this method is sometimes considered intermediate between formal mathematical development and a completely empirical study. These methods are used to attack problems for which no mathematical closure equations can be derived.

The dimensionless numbers commonly used in correlations of heat and mass transfer coefficients are listed below (e.g., [110], Chap. 5.2; [27], p. 224; [53], pp. 355–356):

The *Sherwood number*,  $Sh = k_c l / D$ , that determine the ratio between the effective mass transfer velocity and the molecular diffusivity (i.e., a dimensionless concentration gradient at the interface).

The *Nusselt number*,  $Nu = hl/k$ , that determine the ratio between the effective heat transfer velocity and the molecular conductivity (i.e., a dimensionless temperature gradient at the interface).

The *Stanton number* for mass,  $St_m = k_c / v_{z,av}$ , that determine the ratio between the mass transfer velocity and the flow velocity, a modified Sherwood number.

The *Stanton number* for heat,  $St_h = h / (C_P \rho v_{z,av}) = \frac{Nu}{Re Pr}$ , that determine the ratio between the convective heat transfer flux at the interface and the thermal capacity of the fluid, a modified Nusselt number.

The *Reynolds number*,  $Re = ul/\nu$ , that determine the ratio between the inertia force and the viscous force.

The *Lewis number*,  $Le = \alpha/D$ , that determine the ratio between the diffusivity of heat and the diffusivity of mass.

The *Prandtl number*,  $Pr = \nu/\alpha$ , that determine the ratio between the diffusivity of momentum and the diffusivity of heat.

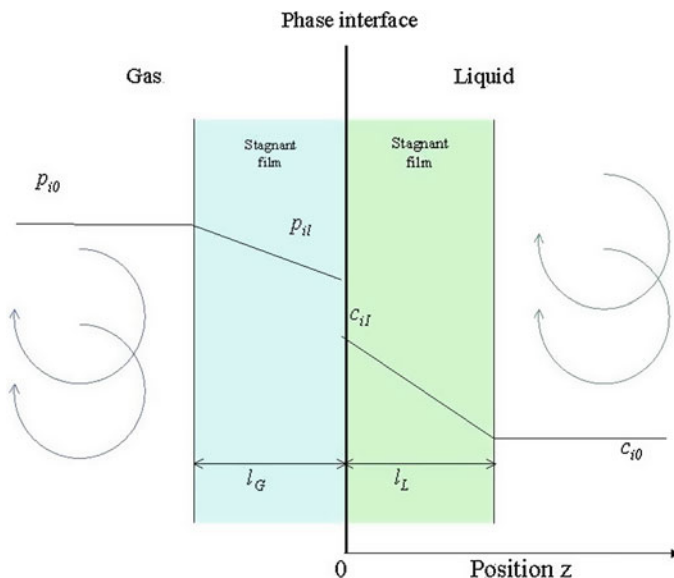

The *Péclet number*,  $Pe = v_{z,av} l / D = Re Pr$ , that determine the ratio between the flow velocity and the mass diffusion velocity.

The *Schmidt number*,  $Sc = \nu/D$ , that determine the ratio between the kinetic viscosity or the diffusivity of momentum and the molecular diffusivity of mass.

The *Grashof number*,  $Gr = l^3 \Delta \rho g / \rho \nu^2$ , that determine the ratio between the buoyancy force and the viscous force for free convection problems.

where  $l$  is a characteristic length, which has to be chosen for the given system under consideration, and  $g$  is the gravitational acceleration.

The heat and mass transfer fluxes at the interface are influenced by the fluid dynamics of the phases near the interface. In most situations the flow in this region is so complicated that the governing equations cannot be solved without introducing simplifying assumptions. The fluid dynamic model adopted should, however, still be able to capture the main characteristics of the actual flow, as the heat and mass transfer coefficients may be very sensitive upon these variables. We may now distinguish between two conceptually different approaches for incorporating the effects of the actual flow phenomena into the coefficient parameterizations. First, we have the semi-empirical chemical engineering theories using simplified relations determining imaginative flow patterns. These models are physical re-constructions, which are more easily analyzed than the actual flow situation. Unfortunately, these relations often contain several parameters that need to be fitted to experimental (input-output) data. Second, we have the more formal mechanical engineering approach that is based on analytical solutions of the governing equations for rather idealized flows systems. Although the resulting parameterizations are strictly only valid for the particular idealized flow system for which they were derived, the relations obtained are often

**Fig. 5.16** Gas–liquid interface: Film theory

successfully applied describing complex flows as well. For turbulent flows, most of the concepts available determining the fluxes close to solid surfaces were originally developed determining interfacial heat transfer fluxes for single component flow calculations. These concepts have later been extended to mass transfer problems by use of a so-called similarity hypothesis.

### 5.2.5.5 The Film Theory

The film theory is the simplest model for interfacial mass transfer. In this case it is assumed that a stagnant film exists near the interface and that all resistance to the mass transfer resides in this film. The concentration differences occur in this film region only, whereas the rest of the bulk phase is perfectly mixed. The concentration at the depth  $l$  from the interface is equal to the bulk concentration. The mass transfer flux is thus assumed to be caused by molecular diffusion through a stagnant film essentially in the direction normal to the interface. It is further assumed that the interface has reached a state of thermodynamic equilibrium. The mass transfer flux across the stagnant film can thus be described as a steady diffusion flux. It can be shown that within this steady-state process the mass flux will be constant as the concentration profile is linear and independent of the diffusion coefficient. Consider a gas–liquid interface, as sketched in Fig. 5.16. The mathematical problem is to formulate and solve the diffusion flux equations determining the fluxes on both sides of the interface within the two films. The resulting concentration profiles and flux equations can be expressed as:

The concentration profile within the gas phase resembles (5.130) and is expressed in terms of species partial pressure:

$$p_i = p_{i0} + \frac{z}{l_G}(p_{iL} - p_{i0}) \quad (5.160)$$

The diffusive flux yields:

$$J_i^* = -D_G \frac{dp_i}{dz} = \frac{D_G}{l_L}(p_{i0} - p_{iL}) \quad (5.161)$$

The mole concentration profile within the liquid phase resembles (5.130) and is given by:

$$c_i = c_{iL} + \frac{z}{l_L}(c_{i0} - c_{iL}) \quad (5.162)$$

The corresponding diffusive flux yields:

$$J_i^* = -D_L \frac{dc_i}{dz} = \frac{D_L}{l_L}(c_{iL} - c_{i0}) \quad (5.163)$$

By comparing the equations determining the diffusive fluxes with the corresponding definitions of the mass transfer coefficients, we obtain the relationships between the mass transfer coefficients and the diffusion coefficients. As before we assume that the mass transfer rate is low, so that the flux is considered purely diffusive.

The definition of the mass transfer coefficient can thus be expressed as:

$$N_i = k_g(p_{i0} - p_{iL}) = k_l(c_{iL} - c_{i0}) \quad (5.164)$$

The corresponding diffusive flux can be expressed using Ficks law:

$$N_i = J_i^* = \frac{D_G}{l_G}(p_{i0} - p_{iL}) = \frac{D_L}{l_L}(c_{iL} - c_{i0}) \quad (5.165)$$

The relationships between the mass transfer and diffusion coefficients yield:

$$k_l = \frac{D_L}{l_L} \quad (5.166)$$

$$k_g = \frac{D_G}{l_G} \quad (5.167)$$

In dimensionless form, the relations can be expressed in terms of a Sherwood number:

$$Sh = \frac{k_c l}{D} \quad (5.168)$$

This relation determines the ratio between the mass transfer and diffusion rates. The film model can then be expressed as:

$$Sh = 1 \quad (5.169)$$

The result obtained from the film theory is that the mass transfer coefficient is directly proportional to the diffusion coefficient. However, the experimental mass transfer data available in the literature [6], for gas–liquid interfaces, indicate that the mass transfer coefficient should rather be proportional with the square root of the diffusion coefficient. Therefore, in many situations the film theory doesn't give a sufficient picture of the mass transfer processes at the interfaces. Furthermore, the mass transfer coefficient dependencies upon variables like fluid viscosity and velocity are not well understood. These dependencies are thus often lumped into the correlations for the film thickness,  $l$ . The film theory is inaccurate for most physical systems, but it is still a simple and useful method that is widely used calculating the interfacial mass transfer fluxes. It is also very useful for analysis of mass transfer with chemical reaction, as the physical mechanisms involved are very complex and the more sophisticated theories do not provide significantly better estimates of the fluxes. Even for the description of many multicomponent systems, the simplicity of the model can be an important advantage.

For heat transfer the film theory is the most commonly used model, and the physical picture of a laminar film in which the whole temperature difference is situated leads to a result analogous to the mass transfer coefficient model [5]. After integrating Fourier's law over the film, a comparison with the heat transfer coefficient model (5.106) yields:

$$q = \frac{k}{l}(T_S - T_f) \quad (5.170)$$

$$h = \frac{k}{l} \quad (5.171)$$

$$Nu = \frac{hl}{k} = 1 \quad (5.172)$$

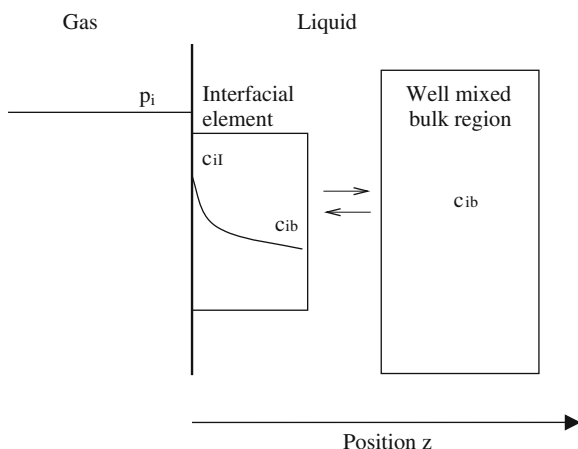

where  $k$  denotes the conductivity of the fluid,  $l$  the film thickness,  $h$  the convective heat transfer coefficient, and  $T_S$  and  $T_f$  refer to the surface and fluid temperatures, respectively.

### 5.2.5.6 The Surface-Renewal Theories

The surface-renewal models intend to provide an improved representation of the physical interface phenomena compared to the basic film theory. The surface-renewal models are based on the well known idea that turbulent flows consist of small fluid elements or eddies that may form discrete entities having certain characteristic flow properties. Within the interface region these fluid elements are arriving from the

**Fig. 5.17** The principles of Surface-Renewal theories

bulk phase and after residing at the interface for a period of time (the exposure time) they are replaced and mixed with the bulk fluid again, as sketched in Fig. 5.17. The replacement of the eddies is caused by the turbulence properties of the flow. During the exposure time mass exchange between the fluid element on one side and the adjoining phase on the other side due to unsteady diffusion processes, and the interfacial element can be treated as a semi-infinite slab since the exposure time is less than the time required for diffusive transport across the whole slab. The bulk of both phases are assumed to be well mixed.

Excellent reviews on the surface-renewal theories are given by Sideman and Pinczewski [111], Astarita et al. [6], and Thomson [126].

### 5.2.5.7 The Penetration Theory

The penetration theory can be viewed as the original surface-renewal model. This model was formulated by Higbie [51]. This model is based on the assumption that the liquid surface contains small fluid elements that contact the gas phase for a time that is equal for all elements. After this contact time they penetrate into the bulk liquid and each element is then replaced by another element from the bulk liquid phase. The basic mechanism captured in this concept is that at short contact times, the diffusion process will be unsteady. Considering that the fluid elements may diffuse to an infinite extent into the liquid phase, the model formulation developed earlier for diffusion into a semi-infinite slab can be applied describing this system. After some time the diffusion process will reach a steady state, thus the penetration theory predictions will then correspond to the limiting case described by the basic film theory. However, when the transient flux development is determining a notable amount of the total flux accumulated, the two models will give rise to different mass transfer coefficients.

The concentration profile resembles (5.136) and can be expressed by:

$$\frac{c_i - c_{il}}{c_i - c_{il}} = 1 - \operatorname{erf}\zeta = \frac{2}{\sqrt{\pi}} \int_0^\zeta e^{-\zeta^2} d\zeta \quad (5.173)$$

The diffusive flux can be expressed by:

$$J_i^* = \sqrt{\frac{D}{\pi t}} e^{-z^2/4Dt} (c_i - c_{il}) \quad (5.174)$$

where the instantaneous interfacial diffusion flux (i.e., at  $z = 0$ ) resembles (5.138) and is given by:

$$J_i^*|_{z=0} = \sqrt{\frac{D}{\pi t}} (c_i - c_{il}) \quad (5.175)$$

This is the solution for an instantaneous flux rate at the interface, since we are considering dilute solutions any diffusion-induced convection can be neglected. This means that the total mole flux is equal to the diffusion flux, and that we can write the instantaneous mass transfer rate directly in the form derived for the diffusion flux:

$$N_i(t)|_{z=0} = \sqrt{\frac{D}{\pi t}} (c_i - c_{il}) \quad (5.176)$$

The instantaneous mass transfer rate is expressed as a function of time. In order to calculate an average mass transfer coefficient we need to average the instantaneous coefficient over the total exposure time period. To do this we need to know the age distribution function, which represents the fraction of elements having ages between  $t$  and  $t + dt$  at the surface. *In the penetration theory, it is assumed that all the elements reside at the interface for a time period of the same length.*

As a consequence of this assumption the age distribution function is [6]:

$$E(t) = \frac{1}{t_e} \quad t \leq t_e \quad (5.177)$$

$$E(t) = 0 \quad t > t_e \quad (5.178)$$

where  $t_e$  is a fixed contact time (s).

The averaged mass transfer rate yields:

$$\langle N_i \rangle_{te} = \int_0^{t_e} N_i(t)|_{z=0} E(t) dt \quad (5.179)$$

$$\langle N_i \rangle_{te} = 2 \sqrt{\frac{D}{\pi t_e}} (c_i - c_{il}) \quad (5.180)$$

Based on this model a relation between the mass transfer and diffusion coefficients can be expressed as:

$$k_c = 2\sqrt{\frac{D}{\pi t_e}} \quad (5.181)$$

The mass transfer coefficient parameterizations based on (5.181) can be written in terms of dimensionless groups. Two examples are listed here [27]:

$$Sh = \frac{kl}{D} = \left(\frac{6}{\pi}\right)^{1/2} \left(\frac{lv_x}{\nu}\right)^{1/2} \left(\frac{\nu}{D}\right)^{1/2} \quad (5.182)$$

$$St = \frac{k}{v_x} = (const.) \left(\frac{\mu}{\rho D}\right)^{-1/2} \left(\frac{Lv_x \rho}{\mu}\right)^{-1/2} \quad (5.183)$$

The exposure time,  $t_e$ , equals the relationship between the penetration depth and characteristic velocity [6]. This theory predicts that the mass transfer coefficient is proportional to  $D^{1/2}$ , which indicates that the penetration model is more realistic than the film theory. This model contains a fitting parameter, the contact time  $t_e$ , into which all details on the true fluid dynamics are lumped.

An analogue heat transfer coefficient relation has been derived by the penetration concept. The heat transfer theory is reviewed by Thomson [126].

### 5.2.5.8 The Danckwerts Surface Renewal Model

The classical Danckwerts surface-renewal model is analogous to the penetration theory. The improvement is in the view of the eddy replacement process. *Instead of Higbie's assumption that all elements have the same residence time at the interface, Danckwerts [29] proposed to use an averaged exposure time determined from a postulated time distribution.* The residence time distribution of the surface elements is described by a statistical distribution function  $E(t)$ , defined so that  $E(t)dt$  is the fraction of the interface elements with age between  $t$  and  $t + dt$ . The rest of the formulation procedure is similar to that of the penetration model.

The normalized age distribution function was given by

$$E(t) = \frac{1}{\tau} \exp\left(-\frac{t}{\tau}\right) = s \exp(-st) \quad (5.184)$$

where it is assumed that the rate of disappearance of surface elements of a certain age is proportional to the number of elements of the same age.  $s$  is the average surface renewal rate which is equal to the reciprocal of the average residence time of the elements  $\tau$ .

The averaged mass transfer rate is defined by:

$$N_i = \int_0^{t_e} n_i(t)|_{z=0} E(t) dt \quad (5.185)$$

$$N_i = \sqrt{\frac{D}{\tau}} (c_{il} - c_{ib}) \quad (5.186)$$

In this case the relation between mass transfer and diffusion coefficient can be expressed as:

$$k_c = \sqrt{\frac{D}{\tau}} = \sqrt{Ds} \quad (5.187)$$

The surface-renewal theory intends to provide a better representation of the physical mechanisms than the penetration theory, but it predicts the same dependency of the mass transfer coefficient upon the diffusion coefficient. The penetration theory can thus be looked upon as a special case of the surface renewal theory where the distribution function takes the form of (5.184). Moreover, both theories also contain an unknown fitting parameter and are thus in practice equivalent. For the quantitative determination of the transfer coefficient we need to relate  $s$ ,  $\tau$  or  $t_e$  to the measurable parameters of the system under consideration. For this reason these concepts have no predictive value.

The original Danckwerts model has later been extended to relate the renewal rate  $s$  to many flow parameters, and to account for the existence of the micro scale flow of the fluid within the individual eddies. Further modifications relate to the fact that not all the penetrating eddies reach the whole way to the interface. Many model extensions have thus been developed based on the basic surface-renewal concept. A review of these models is given by Sideman and Pinczewski [111]. The various extensions are motivated by the inherent assumptions regarding, the governing equations, the boundary conditions, the age distribution function and/or the mean contact time.

An analogue heat transfer coefficient relation has been derived by the surface renewal concept. The heat transfer theory is reviewed by Thomson [126].

### 5.2.5.9 Laminar Boundary Layer Theory: The Integral Method

The integral boundary layer method for determining the transfer coefficients is explained in this section. The basic boundary layer theory has been summarized in many textbooks in chemical engineering, among them the books of Hines and Maddox [52], Incropera De Witt [53], Cussler [27], Middleman [87] and Bird et al. [15] are considered very informative.

While the film and surface-renewal theories are based on a simplified physical model of the flow situation at the interface, the boundary layer methods couple the heat and mass transfer equation directly with the momentum balance. These theories thus result in analytical solutions that may be considered more accurate in comparison to the film or surface-renewal models. However, to be able to solve the governing equations analytically, only very idealized flow situations can

be considered. Alternatively, more realistic functional forms of the local velocity, species concentration and temperature profiles can be postulated while the functions themselves are specified under certain constraints on integral conservation. From these integral relationships models for the shear stress (momentum transfer), the conductive heat flux (heat transfer) and the species diffusive flux (mass transfer) can be obtained. The prescribed shape of the velocity profile for the fluid flowing parallel to a flat plate may be expressed as:

$$v_x = a_0 + a_1 y + a_2 y^2 + a_3 y^3 \quad (5.188)$$

The parameters in this expression are assumed to be independent of  $y$  the direction normal to the plate, but may vary with  $x$  the direction parallel to the plate. The velocity profile need to fulfill the following boundary conditions (i.e., no slip and no pressure variation in the  $x$ -direction):

$$y = 0, \quad v_x = 0 \quad \frac{\partial^2 v_x}{\partial y^2} = 0 \quad (5.189)$$

$$y = \delta, \quad v_x = v_{x,0} \quad \frac{\partial v_x}{\partial y} = 0 \quad (5.190)$$

In this context the momentum boundary layer thickness  $y = \delta$  is conveniently defined as the point beyond which the velocity takes on its free stream value.<sup>7</sup> The second condition stating that the velocity gradient vanishes at  $y = \delta$ , ensures that we obtain a continuous gradient as the velocity attains its free stream value.

Applying these boundary conditions we can determine the values for the parameters:

$$\begin{aligned} a_0 &= a_2 = 0 \\ a_1 &= \frac{3}{2} \frac{v_{x,0}}{\delta} \\ a_3 &= -\frac{1}{2} \frac{v_{x,0}}{\delta^3} \end{aligned}$$

These results give the following dimensionless velocity profile:

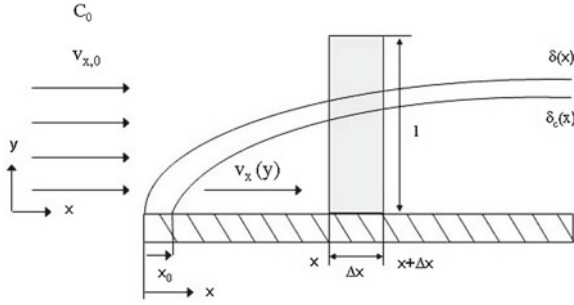

$$\frac{v_x}{v_{x,0}} = \frac{3}{2} \left( \frac{y}{\delta} \right) - \frac{1}{2} \left( \frac{y}{\delta} \right)^3 \quad (5.191)$$

The velocity gradient at the wall can then be expressed as:

$$\frac{\partial v_x}{\partial y} \Big|_{y=0} = \frac{3}{2\delta} \quad (5.192)$$

---

<sup>7</sup> This definition merely represents a simplifying model assumption as opposed to the conventional definition in which the thickness of boundary layer  $\delta$  is arbitrarily taken as the distance away from the surface where the velocity reaches 99 % of the free stream velocity.

**Fig. 5.18** Balance on fluid element of the laminar boundary layer

At this point it should be kept in mind that  $\delta$  is an unknown function of  $x$ . The velocity function,  $v_x(x, y)$ , is expressed in terms of the unknown function  $\delta(x)$ . The main advantage of the integral method is that it is easier to obtain a solution for  $\delta(x)$  than to solve the Navier Stokes equations for  $v_x(x, y)$ . A drawback is that we are using an approximate velocity field which to some extent reduces the accuracy of the result.

The next step in the procedure is to formulate mass and momentum balances for an element of the boundary layer, as sketched in Fig. 5.18. The *mass balance* equates the net rate of mass flow across the two vertical boundaries to the rate of mass flow across the horizontal boundaries. Assuming no mass flow across the lower horizontal boundary, the mass balance becomes:

$$\int_0^l \rho v_x dy|_x - \int_0^l \rho v_x dy|_{x+\Delta x} - \rho v_{y,l} \Delta x = 0 \quad (5.193)$$

Dividing by  $\Delta x$  and letting  $\Delta x \rightarrow 0$ , gives a relation for  $v_y$ :

$$v_{y,l} = -\frac{d}{dx} \int_0^l v_x dy \quad (5.194)$$

The *momentum balance* states that any difference in x-directed momentum flow must be equal to the net x-directed shear force acting on the solid surface. This gives the momentum balance on the element:

$$\int_0^l \rho v_x^2 dy|_x - \int_0^l \rho v_x^2 dy|_{x+\Delta x} - \rho v_{x,l} v_{y,l} \Delta x = -\sigma_w \Delta x \quad (5.195)$$

Again, dividing by  $\Delta x$  and letting  $\Delta x \rightarrow 0$  gives:

$$-\sigma_w = -\frac{d}{dx} \int_0^l \rho v_x^2 dy - \rho v_{x,l} v_{y,l} \quad (5.196)$$

A combination of (5.194) and (5.196) eliminates  $v_{y,l}$ , and we may write:

$$-\sigma_w = \frac{d}{dx} \int_0^l (v_{x,l} - v_x) \rho v_x dy \quad (5.197)$$

Inside the boundary layer, the shear stress is given by Newton's law of viscosity:

$$-\sigma_w = \mu \frac{\partial v_x}{\partial y} \Big|_{y=0} \quad (5.198)$$

By combining (5.198), (5.197) and (5.192) we get:

$$\mu \frac{3}{2\delta} = \frac{d}{dx} \int_0^l (v_{x,l} - v_x) \rho v_x dy \quad (5.199)$$

By introducing the relation for the velocity profile (5.191) into (5.199) and performing the integration we get a differential equation for the boundary layer thickness. In this operation it is convenient to replace  $l$  by  $\delta$  in the upper limit of the integral. This problem reformulation is allowed as the integrand vanishes for  $l > \delta$  because  $v_x = v_{x,l} = v_{x,0}$ . The integral solution is [15, 27, 87]:

$$\delta \frac{d\delta}{dx} = \frac{140}{13} \frac{\mu}{\rho v_{x,0}}$$

This ODE is solved by introducing the following initial condition:

$$x = 0 \quad \delta = 0 \quad (5.200)$$

The solution is:

$$\frac{\delta}{x} = 4.64 \left( \frac{v_{x,0} x}{\nu} \right)^{-1/2} = 4.64 Re^{-1/2} \quad (5.201)$$

This means that *the fluid mechanics of the problem is solved*. The boundary layer thickness is given as a function of the distance  $x$  from the plate edge through (5.201). Hence, the velocity  $v_x$  can be calculated from (5.191).

To proceed determining an expression for the mass transfer coefficient, the same solution method is applied to the corresponding concentration boundary layer problem. Again, a polynomial profile of third order is postulated for the unknown field:

$$c = a'_0 + a'_1 y + a'_2 y^2 + a'_3 y^3 \quad (5.202)$$

The parameters are evaluated by applying the concentration boundary conditions:

$$y = 0 \quad c = c_0 \quad \frac{\partial^2 c}{\partial y^2} = 0 \quad (5.203)$$

$$y = \delta_c \quad c = 0 \quad \frac{\partial c}{\partial y} = 0 \quad (5.204)$$

In this case we have defined a concentration variable that vanishes beyond the boundary layer. It is imagined a physical situation in which a species is dissolving from the surface of a plate and being transported by diffusion and convection into a fluid that does not contain this species except very near the plate, as sketched in Fig. 5.18.

To satisfy these boundary conditions, the dimensionless concentration profile must have the form:

$$\frac{c}{c_0} = 1 - \frac{3}{2} \frac{y}{\delta_c} - \frac{1}{2} \left( \frac{y}{\delta_c} \right)^3 \quad (5.205)$$

The concentration gradient at  $y = 0$  can be expressed as:

$$\frac{\partial c}{\partial y} \Big|_{y=0} = -\frac{3c_0}{2\delta_c} \quad (5.206)$$

Next, a species mole (or mass) balance is made over the boundary layer element in Fig. 5.18. The net rate of convection of the species across the vertical planes of the control volume must be balanced by the rate corresponding to the flux from the solid surface:

$$\int_0^l c v_x dy \Big|_x - \int_0^l c v_x dy \Big|_{x+\Delta x} - c_l v_{y,l} \Delta x = -n_w \Delta x \quad (5.207)$$

The species mole (mass) flux at the interface can be defined both in terms of Fick's first law and the mass transfer coefficient concepts:

$$-N_w = D \frac{\partial c}{\partial y} \Big|_{y=0} = -\frac{d}{dx} \int_0^{\delta_c} c v_x dy = -k_c (c_0 - c_{\delta_c}) \quad (5.208)$$

in which the upper integration limit  $y = l$  has been replaced by  $y = \delta_c$ . It is imagined that beyond the upper edge of the concentration boundary layer  $c = 0$  and  $v_{x,l} = 0$ , provided that the concentration boundary layer thickness is always thinner than the hydrodynamic boundary layer.

It occurs that  $v_x$  is a known function of  $x$  and  $y/\delta$  as given by (5.191) and (5.201),  $c$  is given in terms of  $y/\delta_c$  by (5.205) and the concentration gradient at  $y = 0$  is given by (5.206), hence (5.208) yields a relationship between  $\delta_c$  and  $\delta$ . With the additional assumption that  $\delta_c \ll \delta$ , the species mole (mass) balance problem reduced to:

$$\frac{4}{3} x \frac{d}{dx} \left( \frac{\delta_c}{\delta} \right)^3 + \left( \frac{\delta_c}{\delta} \right)^3 \approx \frac{D}{\nu} = Sc^{-1} \quad (5.209)$$

where  $Sc$  is the Schmidt number.

Besides, if  $\delta_c$  is smaller than  $\delta$ , the former may also develop slower, thus the following boundary condition is induced [27]:

$$x = 0 \quad \frac{\delta_c}{\delta} = 0 \quad (5.210)$$

Integration now gives:

$$\left(\frac{\delta_c}{\delta}\right)^3 = \frac{D}{\nu} + bx^{-3/4} \quad (5.211)$$

Because  $(\frac{\delta_c}{\delta})$  does not become infinite as  $x$  approaches zero, the term containing  $x$  vanishes as  $b$  must be zero [13].

The momentum boundary layer thickness  $\delta$  can now be eliminated by use of (5.201):

$$\frac{\delta_c}{x} = 4.64 \left(\frac{\nu}{v_{x,0}x}\right)^{1/2} \left(\frac{D}{\nu}\right)^{1/3} = 4.64 Re^{-1/2} Sc^{-1/3} \quad (5.212)$$

Finally, the concentration boundary layer problem is almost solved as the mass transfer coefficient  $k_c$  can be calculated from (5.208):

$$-N_w = k_c c_0 = D \frac{\partial c}{\partial y}|_{y=0} = -D \frac{3c_0}{2\delta_c} \quad (5.213)$$

Eliminating  $\delta_c$  by (5.212), we find:

$$N_w = 0.332 \frac{Dc_0}{x} \left(\frac{xv_{x,0}}{\nu}\right)^{1/2} \left(\frac{\nu}{D}\right)^{1/3} \quad (5.214)$$

Comparing this result with the first two terms in (5.213), we get a relation for the local value of the mass transfer coefficient:

$$\frac{k_c x}{D} = 0.332 \left(\frac{xv_{x,0}}{\nu}\right)^{1/2} \left(\frac{\nu}{D}\right)^{1/3} \quad (5.215)$$

By averaging over the plate length  $L$ , an average mass transfer coefficient is obtained  $\langle k_c \rangle_L = \frac{1}{L} \int_0^L k_c(x) dx$ . This quantity can be calculated from a relation expressed in terms of an averaged Shearwood number:

$$\langle Sh \rangle_L = \frac{\langle k_c \rangle_L L}{D} = 0.664 \left(\frac{Lv_{x,0}}{\nu}\right)^{1/2} \left(\frac{\nu}{D}\right)^{1/3} = 0.664 Re^{1/2} Sc^{1/3} \quad (5.216)$$

The integral method thus leads to a mass transfer coefficient which vary with the  $2/3$  power of the diffusion coefficient. This parameter dependency is between the linear one of the film theory and the square-root variation of the penetration and surface-renewal theories.

It is noted that the integral method gives only approximate values for the mass transfer coefficient as the model derivation is based on several simplifying assumptions regarding the concentration and velocity profiles. Nevertheless, the given relation has been confirmed by experiments for laminar boundary layer flows over a flat plate (e.g., [110], p. 80 and p. 201; [27], p. 345).

Based on the boundary layer analysis for laminar flow past a plate we might suggest that the mass transfer coefficient generally depends on the Reynolds number and the Prandtl number:

$$Sh = A Re^m Sc^n \quad (5.217)$$

It is possible to show adopting an analogous procedure that for heat transfer the Nusselt number depends on the Reynolds and Prandtl number in a similar manner (e.g., [110], p. 160):

$$Nu = A Re^m Pr^n \quad (5.218)$$

The Reynolds analogy states that  $Sc = Pr = 1$ , indicating that the transfer coefficients are functions of  $Re$  only.

Each of the modified Reynolds analogy relations (5.217) and (5.218) includes an additional  $Sc$  and  $Pr$  dependency, respectively. These relationships are often referred to as the Chilton–Colburn analogies [20, 53] (p. 364). Experimental analyses show that (5.217) and (5.218) can be used for a number of convective heat and mass transfer systems, and might be sufficiently accurate even for problems involving complex geometries [53].

### 5.2.5.10 Turbulent Boundary Layer Theory: Eddy Viscosity Concept

In this section the heat and mass transport coefficients for turbulent boundary layers are examined. In this case the model derivation is based on the governing Reynolds averaged equations. In these equations statistical covariances appear which involve fluctuating velocities, temperatures and concentrations. The nature of these terms is not known a priori and their effects must be estimated by semi-empirical turbulence modeling. The resulting parameterizations allow us to express the unknown turbulent fluctuations in terms of the mean flow field variables. It is emphasized that the Reynolds equations are not actually solved, merely semi-empirical relations are derived for the wall fluxes through the inner boundary layer. Due to experimental difficulties, turbulence closures exist only for the turbulent momentum transport phenomena. In particular, approximate semi-empirical models for the turbulent viscosity parameter have been derived. To achieve constitutive relations for the corresponding heat and mass transport properties further empiricism is introduced through the analogy theories for turbulent flows. The simplest of these analogies are frequently referred to as the *Reynolds analogy for turbulent flows*. The basic *similarity hypothesis* states simply that the turbulent transport processes of momentum, heat and mass are caused by the same mechanisms, hence the functional properties of the transfer coefficients are similar. The different transport coefficients can thus be

related through certain dimensionless groups. The closure problem is thus shifted and henceforth consist in formulating sufficient parameterizations for the turbulent Prandtl ( $Pr_t$ )- and Schmidt ( $Sc_t$ ) numbers.

The modeling procedure can be sketched as follows. First an approximate description of the velocity distribution in the turbulent boundary layer is required. The universal velocity profile called *the Law of the wall* is normally used. The local shear stress in the boundary layer is expressed in terms of the shear stress at the wall. From this relation a dimensionless velocity profile is derived. Secondly, a similar strategy can be used for heat and species mass relating the local boundary layer fluxes to the corresponding wall fluxes. From these relations dimensionless profiles for temperature and species concentration are derived. At this point the concentration and temperature distributions are not known. Therefore, based on the similarity hypothesis we assume that the functional form of the dimensionless fluxes are similar, so the heat and species concentration fluxes can be expressed in terms of the momentum transport coefficients and velocity scales. Finally, a comparison of the resulting boundary layer fluxes with the definitions of the heat and mass transfer coefficients, indicates that parameterizations for the engineering transfer coefficients can be put up in terms of the appropriate dimensionless groups. The reports by Sideman and Pinczewski [111] and Arpaci and Larsen [4] provide extensive reviews of the analogy theories.

### *Turbulent Flow Fields*

The application of Navier-Stokes equations to turbulent flows are described in Sect. 1.27. The Reynolds averaged equations for incompressible flows are normally adopted deriving the transfer coefficients for heat and mass. For convenience the governing Reynolds averaged equations valid for fully developed turbulent boundary layer flow are listed below [111, 140]. In these equations several simplifications are made, in particular  $\frac{\partial}{\partial t} = 0$  and the dominant flow is in the  $x$ -direction so  $v_z = 0$ . Moreover, the diffusion in the  $x$ - and  $z$ -directions are neglected.

The continuity equation:

$$\frac{\partial \bar{v}_x}{\partial x} + \frac{\partial \bar{v}_y}{\partial y} = 0 \quad (5.219)$$

The momentum transport:

$$\rho \bar{v}_x \frac{\partial \bar{v}_x}{\partial x} + \rho \bar{v}_y \frac{\partial \bar{v}_x}{\partial y} = -\frac{\partial \bar{p}}{\partial x} + \frac{\partial}{\partial y} \left( \mu \frac{\partial \bar{v}_x}{\partial y} - \rho \overline{v'_x v'_y} \right) \quad (5.220)$$

The heat transport:

$$\rho C_p \bar{v}_x \frac{\partial \bar{T}}{\partial x} + \rho C_p \bar{v}_y \frac{\partial \bar{T}}{\partial y} = \frac{\partial}{\partial y} \left( k \frac{\partial \bar{T}}{\partial y} - \rho C_p \overline{T' v'_y} \right) \quad (5.221)$$

The species concentration transport:

$$\overline{v_x} \frac{\partial \bar{c}}{\partial x} + \overline{v_y} \frac{\partial \bar{c}}{\partial y} = \frac{\partial}{\partial y} \left( D \frac{\partial \bar{c}}{\partial y} - \overline{c'v_y'} \right) \quad (5.222)$$

The Reynolds transport terms (i.e., the terms of the kind  $\overline{v'_x v'_y}$ ,  $\overline{T'v'_y}$  and  $\overline{c'v'_y}$ ) are the mean rates of transport of momentum, heat, and mass across the corresponding CV-surfaces of the balanced element by the turbulent velocity fluctuations. This system of equations can not be solved because these terms are not known. We therefore need additional information regarding the Reynolds transport terms. We may postulate a model for the momentum transport terms, intending to relate the Reynolds transport stresses to the mean flow field variables.

### *The gradient hypothesis*

The turbulent transport processes are often described as diffusive fluxes being proportional to the mean variable gradient of the transported quantities. The turbulent transport terms may then be expressed in a form analogous to their laminar equivalents in accordance with the hypothesis of Boussinesq [17]:

The dominating turbulent fluxes can then be expressed as:

$$\sigma_t = \overline{\rho v'_x v'_y} = -\mu_t \frac{\partial \overline{v_x}}{\partial y} \quad (5.223)$$

$$q_t = \rho C_p \overline{T'v'_y} = -k_t \frac{\partial \overline{T}}{\partial y} \quad (5.224)$$

$$N_t = \overline{c'v'_y} = -D_t \frac{\partial \bar{c}}{\partial y} \quad (5.225)$$

where  $\mu_t$  denotes the turbulent viscosity,  $k_t$  the turbulent conductivity, and  $D_t$  the turbulent diffusivity.

Although the Boussinesq's hypothesis does not determine a complete model for turbulence, its importance lies in the fact that it provides a relationship between the apriori unknown Reynolds transport terms and the mean flow field variables. To close the model it is necessary to specify the turbulent coefficients in terms of known quantities. The molecular and turbulent transport coefficients may be added as a linear sum of independent contributions determining the effective transport coefficients:

The effective fluxes are thus given by:

$$\sigma = -(\mu + \mu_t) \frac{\partial \overline{v_x}}{\partial y} \quad (5.226)$$

$$q = -(k + k_t) \frac{\partial \overline{T}}{\partial y} \quad (5.227)$$

$$N_t = -(D + D_t) \frac{\partial \bar{c}}{\partial y} \quad (5.228)$$

In general, in fully developed turbulent flows the turbulent viscosity, conductivity and diffusivity vary from point to point in the flow field and are many magnitudes greater than the molecular coefficients. The existing turbulence models consist of approximate relations for the  $\mu_t$ -parameter in (5.226). The Prandtl mixing-length model (1.362) represents an early algebraic (zero-equation) model for the turbulent viscosity  $\mu_t$  in turbulent boundary layers.

To determine the corresponding coefficients for heat and mass transfer we need some theoretical prerequisites which were introduced already in Sect. 1.3.4. However, it might be convenient to examine and partly repeat certain relationships before we proceed to the next section.

### *Momentum Transfer*

It has been shown that there exists a continuous change in the physical behavior of the turbulent momentum boundary layer with the distance from the wall. The turbulent boundary layer is normally divided into several regions and sub-layers. It is noted that the most important region for heat and mass transfer is the inner region of the boundary layer, since it constitutes the major part of the resistance to the transfer rates. This inner region determines approximately 10–20 % of the total boundary layer thickness, and the velocity distribution in this region follows simple relationships expressed in the inner variables as defined in Sect. 1.3.4.

The ratio between the local shear stress in the boundary layer defined by (5.226) and the shear stress at the wall given by (1.365), yields:

$$\frac{\sigma}{\sigma_w} = \frac{-\rho(\nu + \nu_t) \frac{d\bar{u}}{dy}}{-\rho(v^*)^2} \quad (5.229)$$

This relation may be rewritten introducing the dimensionless inner variables:

$$\frac{\sigma}{\sigma_w} = \left(1 + \frac{\nu_t}{\nu}\right) \frac{du^+}{dy^+} = \varepsilon^+ \frac{du^+}{dy^+} \quad (5.230)$$

Since the shear in the inner region is assumed constant and equal to the shear stress at the wall (i.e.,  $\sigma \approx \sigma_w \approx \text{constant}$ ), we get:

$$\frac{dy^+}{du^+} = \varepsilon^+ = \left(1 + \frac{\nu_t}{\nu}\right) \quad (5.231)$$

For fully developed turbulent flow  $\frac{\nu_t}{\nu} \gg 1$ , the relation reduces to:

$$\frac{dy^+}{du^+} = \frac{\nu_t}{\nu} \quad (5.232)$$

If we combine this relationship with the Prandtl mixing length expression (1.362) in which the mixing length is approximated by  $l = \kappa y$ , we get the following dimensionless velocity gradient:

$$\frac{du^+}{dy^+} = \frac{1}{\kappa y^+} \quad (5.233)$$

After integration, the velocity distribution in the inner region of the boundary layer appears:

$$u^+ = \frac{1}{\kappa} \ln y^+ + G \quad (5.234)$$

The values of  $\kappa = 0.4$  and  $G = 5.1$  are recommended on the basis of extensive experimental data [140]. This equation is in satisfactory agreement with the experimental data for most parts of the inner region of the boundary layer (i.e., in the region where the Reynolds stress is of considerably greater magnitude than the viscous stress). Near the wall where the molecular viscosity effects predominate is called the viscous sub-layer and in that thin region the velocity profile is given by  $u^+ = y^+$ . A transition zone can be identified between the viscous sub-layer and the turbulent core where both molecular and turbulent transport mechanisms are significant. This layer is called a buffer zone. Numerous parameterizations of the velocity profile in the boundary layer exist on this form. Some of them are discussed by Sherwood [109] and listed by Sideman and Pinczewski [111]. The commonly used relationships were proposed by von Karman [133]. He defined the velocity profile in the form of empirical expressions relating  $u^+$  and  $y^+$  for three separate zones of the inner region.

- Viscous sub-layer,  $0 < y^+ < 5$ :

$$u^+ = y^+ \quad (5.235)$$

- Buffer zone,  $5 < y^+ < 30$ :

$$u^+ = 5.0 \ln y^+ - 3.05 \quad (5.236)$$

- Turbulent core,  $y^+ > 30$ :

$$u^+ = 2.5 \ln y^+ + 5.5 \quad (5.237)$$

These relations are often referred to as *the universal velocity profile* or the *law of the wall*.

### *Analogies Between Mass, Heat and Momentum Transfer Fluxes*

A comparison of the partial differential equations for the conservation of heat, mass and momentum in a turbulent flow field (5.220), (5.221) and (5.222) shows that the equations are mathematically similar provided that the pressure term  $\frac{\partial P}{\partial x}$  in the momentum equation is negligible [111]. If the corresponding boundary conditions are similar too, the normalized solution of these equations will have the same form. However, to solve the heat and mass transfer equations an additional modeling problem has to be overcome. While there are sufficient measurements of the turbulent

velocity field available to validate the different  $\nu_t$  modeling concepts proposed in the literature, experimental difficulties have prevented the development of any direct modeling concepts for determining the turbulent conductivity  $\alpha_t$ , and the turbulent diffusivity  $D_t$  parameters. Nevertheless, alternative semi-empirical modeling approaches emerged based on the hypothesis that it might be possible to calculate the turbulent conductivity and diffusivity coefficients from the turbulent viscosity provided that sufficient parameterizations were derived for  $Pr_t$  and  $Sc_t$ .

The first model suggested for these dimensionless groups is named the Reynolds analogy. Reynolds suggested that in fully developed turbulent flow heat, mass and momentum are transported as a result of the same eddy motion mechanisms, thus both the turbulent Prandtl and Schmidt numbers are assumed equal to unity:

$$Pr_t = 1 \quad Sc_t = 1 \quad (5.238)$$

Provided that this hypothesis holds the heat and mass transfer rates can be estimated from the rate of momentum transport. It is noted that Sideman and Pinczewski [111], among others, have examined this hypothesis in further details and concluded that there are numerous requirements that need to be fulfilled to achieve similarity between the momentum, heat and mass transfer fluxes. On the other hand, there are apparently fewer restrictions necessary to obtain similarity between heat and low-flux mass transfer. This observation has lead to the suggestion that empirical parameterizations developed for mass transfer could be applied to heat transfer studies simply by replacing the Schmidt number ( $Sc_t = \frac{\nu_t}{D_t}$ ) by the Prandtl number ( $Pr_t = \frac{\nu_t}{\alpha_t}$ ) and visa versa. To proceed we need to put up dimensionless relations for the heat and mass transfer fluxes in the turbulent boundary layer using a procedure analogous to the one applied for the momentum flux (5.229) in which the Boussinesq's turbulent viscosity hypothesis is involved.

### Heat Transport

Using Fourier's law, the ratio of the heat flux in the boundary layer (5.227) and the heat flux at the wall can be expressed as:

$$\frac{q}{q_w} = \frac{-(k + k_t) \frac{d\bar{T}}{dy}}{q_w} \quad (5.239)$$

A dimensionless temperature,  $T^+$ , may be defined as:

$$T^+ = \frac{\bar{T} - T_w}{T^*} \quad (5.240)$$

Introducing dimensionless variables, we get:

$$\frac{q}{q_w} = - \frac{(k + k_t) \frac{T^* u^*}{\nu} \frac{dT^+}{dy^+}}{q_w} = \frac{-\rho C_P (\alpha + \alpha_t) \frac{T^* u^*}{\nu} \frac{dT^+}{dy^+}}{q_w} \quad (5.241)$$

In the latter relation the thermal diffusivity parameters,  $\alpha$  and  $\alpha_t$ , are defined by:

$$\alpha = \frac{k}{\rho C_P} \quad \text{and} \quad \alpha_t = \frac{k_t}{\rho C_P} \quad (5.242)$$

For convenience the corresponding Prandtl numbers,  $Pr$  and  $Pr_t$ , can be introduced:

$$\frac{q}{q_w} = \frac{-\rho C_P (\frac{1}{Pr} + \frac{1}{Pr_t} \frac{\nu_t}{\nu}) T^* u^* \frac{dT^+}{dy^+}}{q_w} \quad (5.243)$$

where

$$Pr = \frac{\nu}{\alpha} \quad \text{and} \quad Pr_t = \frac{\nu_t}{\alpha_t} \quad (5.244)$$

With the given sign convention, the heat flux at the wall can be expressed by:

$$q_w = -\rho C_P T^* u^* \quad (5.245)$$

which is merely the defining equation for the temperature scale.

The ratio of the heat fluxes (5.243) can then be expressed by:

$$\frac{q}{q_w} = \frac{-\rho C_P (\frac{1}{Pr} + \frac{1}{Pr_t} \frac{\nu_t}{\nu}) T^* u^* \frac{dT^+}{dy^+}}{-\rho C_P T^* u^*} = (\frac{1}{Pr} + \frac{1}{Pr_t} \frac{\nu_t}{\nu}) \frac{dT^+}{dy^+} \quad (5.246)$$

The dimensionless temperature is given by:

$$T^+ = \frac{\bar{T} - T_w}{T^*} = -(\bar{T} - T_w) \frac{\rho C_P u^*}{q_w} = -(\bar{T} - T_w) \frac{C_P \sigma_w}{q_w u^*} \quad (5.247)$$

### *Species Mole (Mass) Transport*

Using Ficks law, the ratio of the species mole (mass) flux in the boundary layer (5.227) and the species mole (mass) flux at the wall can be expressed as:

$$\frac{N}{N_w} = -\frac{(D + D_t) \frac{d\bar{c}}{dy}}{N_w} \quad (5.248)$$

A dimensionless mole (mass) concentration,  $c^+$ , may be defined as:

$$c^+ = \frac{\bar{c} - c_w}{c^*} \quad (5.249)$$

Introducing the dimensionless variables, we get:

$$\frac{N}{N_w} = \frac{-(D + D_t) \frac{c^* u^*}{\nu} \frac{dc^+}{dy^+}}{N_w} \quad (5.250)$$

We may reformulate the relation by introducing the Schmidt numbers,  $Sc$  and  $Sc_t$ :

$$\frac{N}{N_w} = \frac{-(\frac{1}{Sc} + \frac{1}{Sc_t} \frac{\nu_t}{\nu}) c^* u^* \frac{dc^+}{dy^+}}{N_w} \quad (5.251)$$

where

$$Sc = \frac{\nu}{D} \quad \text{and} \quad Sc_t = \frac{\nu_t}{D_t} \quad (5.252)$$

With the given sign convention, the species mole (mass) flux at the wall can be defined as:

$$N_w = -c^* u^* \quad (5.253)$$

which is merely the definition equation for the concentration scale.

The ratio between the species mole (mass) fluxes can then be expressed:

$$\frac{N}{N_w} = \left( \frac{1}{Sc} + \frac{1}{Sc_t} \frac{\nu_t}{\nu} \right) \frac{dc^+}{dy^+} \quad (5.254)$$

The dimensionless concentration is given by:

$$c^+ = \frac{\bar{c} - c_w}{c^*} = -(\bar{c} - c_w) \frac{u^*}{N_w} = -(\bar{c} - c_w) \frac{\sigma_w}{\rho N_w u^*} \quad (5.255)$$

The momentum, heat and species concentration equations (5.230), (5.246) and (5.254) may now be integrated to express the velocity, temperature, and concentration distribution in the turbulent boundary layer:

The velocity profile:

$$u^+ = \int_0^{y^+} \frac{\frac{\sigma_w}{\rho}}{1 + \frac{\nu_t}{\nu}} dy^+ \quad (5.256)$$

The temperature profile:

$$T^+ = \int_0^{y^+} \frac{\frac{q_w}{\rho c_p}}{\frac{1}{Pr} + \frac{1}{Pr_t} \frac{\nu_t}{\nu}} dy^+ \quad (5.257)$$

The concentration profile:

$$c^+ = \int_0^{y^+} \frac{\frac{N_w}{\rho N_w u^*}}{\frac{1}{Sc} + \frac{1}{Sc_t} \frac{\nu_t}{\nu}} dy^+ \quad (5.258)$$

It is noted that the upper boundary of the integrals is taken as  $y = \delta > \delta_T$ , where  $\delta_T$  is the thickness of the thermal boundary layer for the temperature profile, and  $y = \delta > \delta_c$ , where  $\delta_c$  is the thickness of the concentration boundary layer for the concentration profile. Outside the boundary layers the free stream or completely mixed bulk quantities are set to  $T = T_0$  and  $c = c_0$ , respectively.

Therefore, by adopting the Reynolds analogy for turbulent flows (5.238) we get:

$$T_0^+ = (\bar{T}_W - \bar{T}_0) \frac{\rho C_p u^*}{q_W} = \int_0^{\delta^+} \frac{dy^+}{\frac{1}{Pr} + \frac{\nu_t}{\nu}} \quad (5.259)$$

$$c_0^+ = (\bar{c}_W - \bar{c}_0) \frac{u^*}{N_W} = \int_0^{\delta^+} \frac{dy^+}{\frac{1}{Sc} + \frac{\nu_t}{\nu}} \quad (5.260)$$

where  $\delta^+ = \delta u^* / \nu$  as can be derived from  $y^+ = y u^* / \nu$  when  $y = \delta$ .

Combining these two expressions with the definitions of dimensionless temperature (5.247) and concentration (5.255), and then rearranging these relations we obtain the general expressions for the heat and mass transfer coefficients.

The heat transfer coefficient:

$$h = \frac{q_W}{(\bar{T}_W - \bar{T}_0)} = \frac{\rho C_p u^*}{\int_0^{\delta^+} \frac{dy^+}{\frac{1}{Pr} + \frac{\nu_t}{\nu}}} \quad (5.261)$$

The mass transfer coefficient:

$$k_c = \frac{N_W}{(\bar{c}_W - \bar{c}_0)} = \frac{u^+}{\int_0^{\delta^+} \frac{dy^+}{\frac{1}{Sc} + \frac{\nu_t}{\nu}}} \quad (5.262)$$

Introducing the appropriate dimensionless groups:

$$Sh = \frac{k_c l}{D}, \quad Nu = \frac{h l}{k} \quad \text{and} \quad Re = \frac{\bar{u} l}{\nu} \quad (5.263)$$

we can generalize the resulting parameterizations for the heat and mass transfer coefficients as given by (5.264) and (5.266) below.

The dimensionless heat transfer coefficient yields [109, 111]:

$$Nu = \frac{\sqrt{\frac{f_F}{2}} Re Pr}{\int_0^{\delta} \frac{dy^+}{\frac{1}{Pr} + \frac{\nu_t}{\nu}}} \quad (5.264)$$

in which the friction velocity (1.365) is expressed in terms of the Fanning friction factor (3.486):

$$u^* = \sqrt{\frac{-\sigma_w}{\rho}} = \sqrt{\frac{f_F}{2}} \bar{u} \quad (5.265)$$

The dimensionless mass transfer coefficient yields [109, 111]:

$$Sh = \frac{\sqrt{\frac{f_F}{2}} Re Sc}{\int_0^\delta \frac{dy^+}{\frac{1}{Sc} + \frac{\nu_t}{\nu}}} \quad (5.266)$$

The introduction of different parameterizations for the turbulent viscosity parameter leads to different modifications of the correlations for the dimensionless numbers. By setting the viscous Prandtl and Schmidt number equal to unity and noting that the integral term in the denominator is simply the velocity  $u^+$  (5.256) that can also be expressed by  $u^+ = \frac{\bar{u}}{u^*} = \sqrt{\frac{2}{f_F}}$ , we get [109, 111]:

$$Sh = Nu = \frac{f_F}{2} Re \quad (5.267)$$

The latter relation may also be expressed in the form ([110], p. 163; [53], p. 364):

$$St_m = St_h = \frac{f_F}{2} \quad (5.268)$$

which is by many authors referred to as *the Reynolds analogy*.

This relationship is based on the assumption that the Prandtl and Schmidt numbers (i.e. for laminar flow) are equal to unity. The given relation has been compared with experimental data and found to be appropriate for most common gases, but not for liquids [110]. For many common gasses  $D \approx \alpha \approx \nu$ , confirming the assumption that  $Pr$  and  $Sc$  are equal to unity [27] (p. 510). However, for liquids these numbers may be significantly different. The need to extend the Reynolds analogy enabling a reliable description of liquid systems lead to the Chilton-Colburn relation [20], which was mentioned deriving the transfer coefficients for laminar flow in the previous section:

$$Sh = \frac{f_F}{2} Re Sc^{1/3} \quad (5.269)$$

and

$$Nu = \frac{f_F}{2} Re Pr^{1/3} \quad (5.270)$$

For Prandtl numbers other than unity, the integrals in (5.264) and (5.266) are split into parts depending upon the number of regions needed to appropriately reproduce the law of the wall. The simplest extension of the basic model is to split the integral into two parts, thus the expressions for  $Nu$  and  $Sh$  yield [109, 111]:

$$Nu = \frac{\sqrt{\frac{f_F}{2}} Re Pr}{\int_0^{y_1^+} \frac{dy_1^+}{\frac{1}{Pr} + \frac{\nu}{v}} + \int_{y_1^+}^{\delta^+} \frac{dy_1^+}{\frac{\nu}{v}}} \quad (5.271)$$

and

$$Sh = \frac{\sqrt{\frac{f_F}{2}} Re Sc}{\int_0^{y_1^+} \frac{dy_1^+}{\frac{1}{Sc} + \frac{\nu}{v}} + \int_{y_1^+}^{\delta^+} \frac{dy_1^+}{\frac{\nu}{v}}} \quad (5.272)$$

The analogy calculations with the turbulent Prandtl and Schmidt numbers other than unity are based on various empirical relations for these dimensionless parameters. However, comparisons with experimental data show that the parameter values of  $Sc = Pr = 1$  are good first approximations for most practical applications. No significant improvements have been obtained by the extended formulations.

Reviews of several extensions of the analogy theory are given in the reports by Sherwood [109] and Sideman and Pinczewski [111].

### 5.2.5.11 Heat and Mass Transfer to the Surface of a Sphere

The mass transfer correlation determining the mass transfer to the surface of a sphere is commonly referred to as the Frössling equation [45]:

$$Sh = 2 + 0.6Re^{1/2}Sc^{1/3} \quad (5.273)$$

Based on Frössling's development, Ranz and Marshall [102] came to the well established conclusion that the heat transfer correlation can be expressed in an analogous manner:

$$Nu = 2 + 0.6Re^{1/2}Pr^{1/3} \quad (5.274)$$

If we study the heat transfer from the surface of a sphere with  $r = R$ , that is immersed in a stagnant fluid we have a process of steady conduction from the surface of the sphere ( $r = R$ ) through the fluid, radially outward to  $r = \infty$ . The radial conductive flux is:

$$q_r = -k \frac{dT}{dr} \quad (5.275)$$

When we have obtained steady state, the rate of heat transfer (flux times area) through the surrounding fluid is constant with respect to the radial position:

$$4\pi r^2 q_r = -4\pi k r^2 \frac{dT}{dr} = \text{Constant} \quad (5.276)$$

With the following boundary conditions:

$$T = T_R \quad r = R \quad (5.277)$$

$$T = T_0 \quad r = \infty \quad (5.278)$$

The solution to this problem is the temperature profile:

$$T = T_0 + (T_R - T_0) \frac{R}{r} \quad (5.279)$$

By inserting this temperature profile into the flux expression (5.275), we obtain the steady heat flux at the surface  $r=R$ :

$$q_R = k \frac{T_R - T_0}{R} \quad (5.280)$$

It is recollected that in according to Newton's law of cooling (5.105) the corresponding definition of the heat transfer coefficient can be expressed as:

$$q_R = h(T_R - T_0) \quad (5.281)$$

By comparing the given conductive heat flux relation with the corresponding definition of the heat transfer coefficient, it is customary to define the heat transfer coefficient by:

$$h = \frac{k}{R} \quad (5.282)$$

This  $h$  is the convective heat transfer coefficient for pure conduction (assuming no slip at the surface).

The dimensionless heat transfer coefficient, named the Nusselt number is defined by  $Nu = hd_p/k$ , and by combining this with (5.282) we get:

$$Nu = \frac{hd_p}{k} = \frac{2hR}{k} = 2 \quad (5.283)$$

This is the appropriate correlation to use when there is heat or mass (i.e., substitute  $Nu$  by  $Sh$ ) transfer from a sphere immersed in a stagnant film is studied,  $Nu = 2$ . The second term in (5.274) accounts for convective mechanisms, and the relation is derived from the solution of the boundary layer equations. For higher Reynolds numbers the Nusselt number is set equal to the relation resulting from the boundary layer analysis of a flat plate:

$$Nu = 0.6Re^{1/2}Pr^{1/3} \quad (5.284)$$

Bird et al. [13] (p. 647), Hines and Maddox [52] (Chap. 6.7), Cussler [27], Middleman [87] and Incropera and DeWitt [53] (p. 415), among others, presents tabulated mass transfer correlations for various problems, including laminar/turbulent flow, single solid spheres and packed beds.

### 5.2.6 Heat Transfer by Radiation

In this section a brief introduction to the fundamental concepts of thermal radiation modeling is given. The main purpose of this survey is to elucidate the basic assumptions involved deriving the conventional engineering model of thermal radiation fluxes. To this end the thermal radiation flux is determined in terms of a heat transfer coefficient. Explanations of radiation physics and more detailed descriptions of the concepts of thermal radiation can be found in the books by Long [78], Arpaci et al. [5], Hagen [50], Incropera and DeWitt [53], Siegel and Howel [112], Eckert and Drake [39], among many others.

#### 5.2.6.1 Basic Definitions and Elementary Concepts of Thermal Radiation

Radiative heat transfer or thermal radiation is a distinctly separate mechanisms from conduction and convection for the transport of heat. Thermal radiation is associated with the rate at which energy is emitted by the material as a result of its finite temperature. The mechanism of emission is related to energy released as a result of oscillations or transitions of the many electrons that constitute the material. These oscillations are, in turn, supported by the internal energy for this reason the temperature drops. The emission of thermal radiation is thus associated with thermally excited conditions within the matter.

Since radiation originates due to emission by matter its subsequent transport does not require the presence of any matter. Unlike convection and conduction, heat can thus be transferred by thermal radiation through vacuum. One theory views radiation as the propagation of electro-magnetic waves. Alternatively, radiation may be viewed as the propagation of a collection of particles termed photons or quanta. Planck [96] developed the quantum mechanics which can explain radiation in terms of particles (photon) traveling with the speed of light. The energy associated with each photon is given by:

$$E = h\nu = \frac{hc}{\lambda} \quad (5.285)$$

where  $h = 6.6262 \times 10^{-34}$  (Js) is the Planck constant.

Radiation also possesses the standard wave properties of frequency  $\nu$  and wavelength  $\lambda$ . For radiation propagating in a particular medium, the two properties are related by:

$$\lambda = \frac{c}{\nu} \quad (5.286)$$

where  $c$  is the speed of light in the medium. For propagation in a vacuum,  $c_0 = 2.998 \times 10^8$  (m/s). The unit of wavelength is normally given in micrometer ( $\mu\text{m}$ ).

All states of matter (solids, liquids, and gases) emit thermal radiation. For gases and for semi-transparent solids, such as glass and salt crystals at elevated temperatures, emission is a volumetric phenomenon. That is, radiation emerging from a

finite volume of matter is the integrated effect of local emission throughout the volume. In most solids and liquids, radiation emitted from interior molecules is strongly absorbed by adjoining molecules. Accordingly, radiation that is emitted from a solid or a liquid originates from molecules that are within a distance of approximately  $1\text{ }\mu\text{m}$  from the exposed surface. It is for this reason that emission from a solid or a liquid into an adjoining gas or a vacuum is viewed as a surface phenomenon.

Consider a heated enclosure with surface  $A$  and volume  $V$  filled with radiating material. If  $\mathbf{q}_A dA$  is defined as the radiant surface energy flux arriving at  $dA$  from a surface element  $dA_S$ , and the volumetric energy flux  $\mathbf{q}_V dV$  arrives at  $dA$  from a volume element  $dV$ , then the radiative energy flux from the entire enclosure arriving at  $dA$  is:

$$\mathbf{q}^{\text{rad}} dA = \int_{A_S} \mathbf{q}_{A_S} dA_S + \int_V \mathbf{q}_V dV \quad (5.287)$$

Radiation thus leads to energy balances in the form of integral equations. When radiation is combined with advection and conduction, the combination of integral and differential operators leads to integrodifferential equations which are more cumbersome to solve than partial differential equations (PDEs). The energy in thermal radiation has in general a spectral distribution, as the radiation varies with the wavelength, and a directional distribution as the radiation also varies with angle. Actually, thermal radiation is the name given to electromagnetic radiation in the range of wavelengths  $0.1 < \lambda < 100\text{ }\mu\text{m}$ . These spectral and directional dependencies severely complicates rigorous radiation analysis. Before further details of the theory are considered an informative sketch of the general radiation flux modeling framework is required giving an introductory overview linking the conceptual fragments which constitute the overall theory. In most cases we will preferably focus on radiation from solid surfaces. Basically, as already mentioned, a material will emit radiation as a direct result of its temperature. This energy flux or emissive power is denoted by  $E$ . Also, radiation emitted from other objects can fall into a surface. This energy flux is termed irradiation and denoted by  $G$ . The irradiation generally interacts with a semitransparent medium and portions of this radiation are reflected, absorbed, and transmitted. The properties that determine the fractions of the irradiation that are distributed in each of these rays are called reflectivity, absorptivity and transmissivity, respectively. The total radiation leaving a surface is the sum of the reflected and emitted components and this is named radiosity indicated by the symbol  $J$ . The radiative behavior and properties of ideal (blackbody) and opaque materials are both important for the determination of the radiant flux from a real material. A property called emissivity is defined as the ratio of the radiation emitted by the real surface to the radiation emitted by a blackbody at the same temperature.

To get an idea about the spectral and directional complexity of the rigorous modeling of radiant heat transfer the variables that must be specified for the radiative properties are introduced. A functional notation is used to give explicitly the variables upon which a quantity depends. The most fundamental variables includes dependencies on wavelength, direction, and surface temperature. A total quantity does not have a spectral dependency. A hemispherical spectral variable does not have a directional

dependency. A hemispherical total quantity has only a temperature dependency. In the following radiation is treated as an electromagnetic phenomenon. The radiation emitted in any direction is normally defined in terms of a quantity called the intensity of radiation. There are two types of intensity, a spectral intensity which refers to radiation in an interval  $d\lambda$  around a single wavelength  $\lambda$ , and the total intensity which refers to the combined radiation including all wavelengths.

The *spectral intensity* is defined as the energy per unit area normal to the direction of propagation, per unit solid angle about the direction, per metre of wavelength. The solid angle is a 3D angle measured in steradian, as explained in Sect. 2.4.2. For convenience the defining arguments are briefly summarized this time with emphasis on applications to radiation heat transfer. Consider emission from a differential element of area  $dA$  into a hypothetical hemisphere centered at a point on  $dA$ . The emission in a particular direction from an element of area  $dA$  is specified in terms of the zenith and azimuthal angles,  $\theta$  and  $\phi$ , respectively, of a spherical coordinate system Fig. 5.11. A differential surface in space  $dA_S$ , through which this radiation passes, subtends a solid angle  $d\Omega$  when viewed from a point on  $dA$ . From Sect. 2.4.2.3 we recall that the differential solid angle  $d\Omega$  is defined by a region between the rays of a sphere and is measured as the ratio of the element of area  $dA_S$  on the sphere to the square of the sphere's radius (see Figs. 2.5 and 2.6 in which  $dA$  denotes any surface element):

$$d\Omega = \frac{dA_S}{r^2} = \frac{r \sin \theta r d\theta d\phi}{r^2} = \sin \theta d\theta d\phi \quad (5.288)$$

The area  $dA_S$  is normal to the  $(\theta, \phi)$  direction and may be represented by:

$$dA_S = r^2 \sin \theta d\theta d\phi \quad (5.289)$$

for a spherical surface.

The rate at which emission from  $dA$  passes through  $dA_S$  can be expressed in terms of the spectral intensity  $I_{\lambda,e}$  of the emitted radiation.  $I_{\lambda,e}$  denotes the rate at which radiant energy is emitted at the wavelength  $\lambda$  in the  $(\theta, \phi)$  direction, per unit area of the emitting surface normal to this direction, per unit solid angle about this direction, and per unit wavelength interval  $d\lambda$  about  $\lambda$ . The area used to define  $I_{\lambda,e}$  is the component of  $dA$  perpendicular to the direction of the radiation,  $dA_p = dA \cos \theta$ , which denotes the projected area of  $dA$ . The spectral intensity is defined by:

$$I_{\lambda,e}(\lambda, \theta, \phi) = \frac{d\dot{Q}^{\text{rad}}}{dA \cos \theta d\Omega d\lambda} \quad (\text{W/m}^2 \text{ sr } \mu\text{m}) \quad (5.290)$$

in which  $d\dot{Q}_\lambda = (d\dot{Q}^{\text{rad}}/d\lambda)$  is the rate at which radiation of wavelength  $\lambda$  leaves  $dA$  and passes through  $dA_S$ .

The *spectral heat flux* associated with emission into any finite solid angle or any finite wavelength interval may be determined by integration over the hypothetical hemisphere above  $dA$ :

$$q_\lambda(\lambda) = \int_0^\infty \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi \quad (\text{W/m}^2 \mu\text{m}) \quad (5.291)$$

The *total heat flux* associated with emission in all directions and at all wavelengths is then:

$$q^{\text{rad}} = \int_0^\infty q_\lambda(\lambda) d\lambda = \int_0^\infty \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi d\lambda \quad (\text{W/m}^2) \quad (5.292)$$

The concept of *emissive power* is used to quantify the amount of radiation emitted per unit surface area. The hemispherical spectral emissive power  $E_\lambda$  is defined as the rate at which radiation of wavelength  $\lambda$  is emitted in all directions from a surface per unit wavelength  $d\lambda$  about  $\lambda$  and per unit surface area. It is thus related to the spectral intensity of the emitted radiation by:

$$E_\lambda(\lambda) = \int_0^\infty \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi = q_\lambda(\lambda) \quad (\text{W/m}^2 \mu\text{m}) \quad (5.293)$$

It is noted that  $E_\lambda(\lambda)$  is a flux based on the actual surface area, whereas  $I_{\lambda,e}$  is based on the projected area.

The *total hemispherical emissive power*  $E$  is the rate at which radiation is emitted per unit area at all possible wavelengths and directions:

$$E = \int_0^\infty E_\lambda(\lambda) d\lambda = \int_0^\infty \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi d\lambda \quad (\text{W/m}^2) \quad (5.294)$$

A diffuse emitter denotes a special case of a surface for which the intensity of the emitted radiation is independent of direction,  $I_{\lambda,e}(\lambda, \theta, \phi) \approx I_{\lambda,e}(\lambda)$ . In this case

$$E_\lambda(\lambda) = I_{\lambda,e}(\lambda) \int_0^\infty \int_0^{2\pi} \cos \theta \sin \theta d\theta d\phi \quad (5.295)$$

and

$$E = \int_0^\infty E_\lambda(\lambda) d\lambda = \pi I_e \quad (5.296)$$

The given concepts also apply to *incident radiation*. Such radiation originates from emission and reflection occurring at other surfaces and have spectral and directional distributions determined by the spectral intensity  $I_{\lambda,i}(\lambda, \theta, \phi)$ .

The *spectral irradiation* which encompasses radiation of wavelength  $\lambda$  incident from all directions is defined by:

$$G_{\lambda}(\lambda) = \int_0^{\infty} \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,i}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi d\lambda \quad (\text{W/m}^2 \mu\text{m}) \quad (5.297)$$

The *total irradiation*  $G$  represents the rate at which radiation is incident per unit area from all directions and wavelengths:

$$G = \int_0^{\infty} G_{\lambda}(\lambda) d\lambda = \int_0^{\infty} \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,i}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi d\lambda \quad (\text{W/m}^2) \quad (5.298)$$

In the particular case in which the incident radiation is diffuse,  $I_{\lambda,i}$  is independent of  $\theta$  and  $\phi$ , thus:

$$G_{\lambda}(\lambda) = \pi I_{\lambda,i} \quad (5.299)$$

and

$$G = \pi I_i \quad (5.300)$$

The radiative flux termed *radiosity* accounts for the net radiant energy leaving a surface. The spectral radiosity  $J_{\lambda}$  represents the rate at which radiation of wavelength  $\lambda$  leaves a unit area of the surface, per unit wavelength interval  $d\lambda$  about  $\lambda$ .  $J_{\lambda}$  accounts for radiation leaving in all directions and is thus related to the intensity associated with emission and reflection  $I_{\lambda,e+r}(\lambda, \theta, \phi)$ . Therefore,

$$J_{\lambda}(\lambda) = \int_0^{\infty} \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e+r}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi d\lambda \quad (\text{W/m}^2 \mu\text{m}) \quad (5.301)$$

The total radiosity  $J$  is:

$$J = \int_0^{\infty} J_{\lambda}(\lambda) d\lambda = \int_0^{\infty} \int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e+r}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi d\lambda \quad (\text{W/m}^2) \quad (5.302)$$

In the particular case that the surface is both a diffuse reflector and a diffuse emitter,  $I_{\lambda,\theta,\phi}$  is independent of  $\theta$  and  $\phi$ , hence:

$$J_{\lambda}(\lambda) = \pi I_{\lambda,e+r} \quad (5.303)$$

and

$$J = \pi I_{e+r} \quad (5.304)$$

The concept of *blackbody* is determining the basis for describing the radiation properties of real surfaces. The black body denotes an ideal radiative surface which absorb all incident radiation, being a diffuse emitter and emit a maximum amount of energy as thermal radiation for a given wavelength and temperature. The black body can be considered as a perfect absorber and emitter.

The spectral thermal radiative power  $E_{\lambda,b}$  emitted by a blackbody with wavelength  $\lambda$  can be related to the spectral radiation intensity  $I_{\lambda,b}$  as derived by Planck [96] from considerations of quantum statistical thermodynamics. The relation is given by:

$$I_{\lambda,b}(\lambda, T) = \frac{2hc_0^2}{\lambda^5 [\exp(hc_0/\lambda kT) - 1]} \quad (\text{W/m}^2 \text{ sr } \mu\text{m}) \quad (5.305)$$

where  $T$  is the absolute temperature,  $h$  is Plank's constant,  $c_0$  is the velocity of electromagnetic radiation (i.e., speed of light in vacuum), and  $k$  is the Boltzmann constant. Hence it follows that:

$$E_{\lambda,b}(\lambda, T) = \pi I_{\lambda,b}(\lambda, T) = \frac{2\pi hc_0^2}{\lambda^5 [\exp(hc_0/\lambda kT) - 1]} \quad (\text{W/m}^2 \mu\text{m}) \quad (5.306)$$

The total emissive power emitted by a black body is obtained by integration over all wavelengths:

$$E_b = \int_0^{\infty} \pi I_{\lambda,b} d\lambda \quad (5.307)$$

The solution to this integral is called *the Stefan-Boltzmann law*:

$$E_b = \sigma \times T^4 \quad (\text{W/m}^2) \quad (5.308)$$

$\sigma$  is the Stefan-Boltzmann constant given by:

$$\sigma = \frac{8\pi^5 k^4}{15c^3 h^3} = 5.67 \times 10^{-8} \quad (\text{W/m}^2 \text{ K}^4) \quad (5.309)$$

This relation is often used in engineering calculations.

The blackbody spectral and total intensities are independent of direction so that emission of energy into a direction at  $\theta$  away from the surface normal direction is proportional to  $\cos \theta$ . This is known as *Lambert's cosine law*.

For real surfaces *emissivity* is defined as the ratio of the radiation emitted by the surface to the radiation emitted by a blackbody at the same temperature. So, the emissivity specifies how well a real body radiates energy as compared with a blackbody. The directional spectral emissivity  $\epsilon_{\lambda,\theta}(\lambda, \theta, \phi, T)$  of a surface at temperature  $T$  is

defined as the ratio of the intensity of the radiation emitted at the wavelength  $\lambda$  and the direction of  $\theta$  and  $\phi$  to the intensity of the radiation emitted by a blackbody at the same values of  $T$  and  $\lambda$ :

$$\epsilon_{\lambda,\theta}(\lambda, \theta, \phi, T) = \frac{I_{\lambda,e}(\lambda, \theta, \phi, T)}{I_{\lambda,b}(\lambda, T)} \quad (-) \quad (5.310)$$

In a similar manner, a total, directional emissivity  $\epsilon_\theta$  representing a spectral average of  $\epsilon_{\lambda,\theta}$  is defined by:

$$\epsilon_\theta(\theta, \phi, T) = \frac{I_e(\theta, \phi, T)}{I_b(T)} \quad (-) \quad (5.311)$$

A hemispherical spectral emissivity is a directional average of  $\epsilon_{\lambda,\theta}$  defined by:

$$\epsilon_\lambda(\lambda, T) = \frac{E_\lambda(\lambda, T)}{E_{\lambda,b}(\lambda, T)} = \frac{\int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi, T) \cos \theta \sin \theta d\theta d\phi}{\int_0^{2\pi} \int_0^{\pi/2} I_{\lambda,b}(\lambda, T) \cos \theta \sin \theta d\theta d\phi} \quad (-) \quad (5.312)$$

The *hemispherical total emissivity* represents an average of  $\epsilon_{\lambda,\theta}$  over all directional and wavelengths and is defined by:

$$\epsilon(T) = \frac{E(T)}{E_b(T)} \quad (-) \quad (5.313)$$

In the most general situation the irradiation interacts with a semitransparent medium. For a spectral component of irradiation, portions of this radiation can be reflected, absorbed, and transmitted:

$$G_\lambda = G_{\lambda,\text{ref}} + G_{\lambda,\text{abs}} + G_{\lambda,\text{trans}} \quad (\text{W/m}^2 \mu\text{m}) \quad (5.314)$$

where  $G_{\lambda,\text{ref}}$  is the reflected portion of the spectral irradiation,  $G_{\lambda,\text{abs}}$  is the absorbed portion of the spectral irradiation, and  $G_{\lambda,\text{trans}}$  is the transmitted portion of the spectral irradiation.

In general, the determination of these components is complex and can be strongly influenced by volumetric effects within the medium. However, in many engineering applications the medium is opaque to the incident radiation so that  $G_{\lambda,\text{trans}} \approx 0$  and the absorption and reflection processes are treated as surface phenomena.

The *absorptivity* is a property that determines the fraction of the irradiation that is absorbed by a surface. The directional spectral absorptivity of a surface is defined as the fraction of the spectral intensity incident in the direction of  $\theta$  and  $\phi$  that is absorbed by the surface:

$$\alpha_{\lambda,\theta}(\lambda, \theta, \phi, T) = \frac{I_{\lambda,i,\text{abs}}(\lambda, \theta, \phi, T)}{I_{\lambda,i}(\lambda, \theta, \phi, T)} \quad (-) \quad (5.315)$$

The *hemispherical total absorptivity*  $\alpha$  represents an integrated average over both direction and wavelength:

$$\alpha = \frac{G_{\text{abs}}}{G} = \frac{\int_0^\infty \alpha_\lambda(\lambda) G_\lambda(\lambda) d\lambda}{\int_0^\infty G_\lambda(\lambda) d\lambda} \quad (-) \quad (5.316)$$

$\alpha_\lambda(\lambda)$  is a hemispherical spectral absorptivity:

$$\alpha_\lambda(\lambda) = \frac{G_{\lambda,\text{abs}}(\lambda)}{G_\lambda(\lambda)} = \frac{\int_0^{2\pi} \int_0^{2\pi} \alpha_{\lambda,\theta}(\lambda, \theta, \phi) I_{\lambda,i}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi}{\int_0^{2\pi} \int_0^{2\pi} I_{\lambda,i}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi} \quad (-) \quad (5.317)$$

Similar directional spectral reflectivity and transmissivity quantities can also be defined. These properties are normally given the symbols  $\rho$  and  $\tau$ . However, from the above discussion, it's apparent that the sum of the reflected, absorbed and transmitted components must equal the irradiance, and so we can write:

$$\rho G + \alpha G + \tau G = G \quad (\text{W/m}^2) \quad (5.318)$$

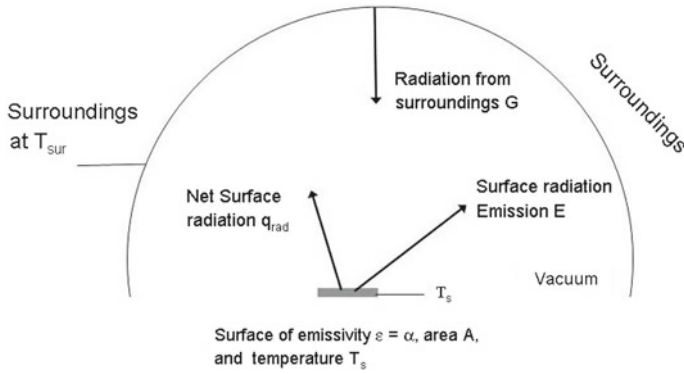

or  $\rho + \alpha + \tau = 1$ .

As a rule of thumb, most gases have a high value of  $\tau$  as they transmit thermal radiation, and quite low values of  $\rho$  and  $\alpha$  as they reflect and absorb small amounts at moderate temperature and pressures. Most solids transmit little thermal radiation but reflect and absorb significant amounts. Since reactor analysis concerns radiation from solid surfaces in most cases, we get  $\rho + \alpha = 1$ . The radiosity  $J$  from a surface is thus given by:

$$J = E + \rho G = E + (1 - \alpha)G \quad (\text{W/m}^2) \quad (5.319)$$

Besides, according to *Kirchhoff's law*, the total hemispherical emissivity of the surface equals the total hemispherical absorptivity. Therefore,  $\epsilon = \alpha$ ,  $\epsilon_\lambda = \alpha_\lambda$ , and  $\epsilon_{\lambda,\theta} = \alpha_{\lambda,\theta}$ .

A *gray surface* may be defined as a surface for which  $\alpha_\lambda$  and  $\epsilon_\lambda$  are independent of  $\lambda$  over the relevant spectral regions of the irradiation and the surface emission.

**Fig. 5.19** Radiation cooling of a heated solid

$$\epsilon(T) = \frac{\epsilon_{\lambda,0}(T) \int_{\lambda_1}^{\lambda_2} E_{\lambda,T}(T) d\lambda}{E_b(T)} = \epsilon_{\lambda,0}(T) \quad (-) \quad (5.320)$$

and

$$\alpha(T) = \frac{\alpha_{\lambda,0}(T) \int_{\lambda_3}^{\lambda_4} G_{\lambda}(T) d\lambda}{G(T)} = \alpha_{\lambda,0}(T) \quad (-) \quad (5.321)$$

### 5.2.6.2 Engineering Modeling of Thermal Radiation Fluxes

In this subsection we focus on the engineering modeling approach determining thermal radiation from plan solid surfaces. In this case the emitter is assumed to be diffuse and only hemispherical total radiation quantities are considered as calculated from the spectral counterparts by integration over all wavelengths and all directions.

Consider a solid that is initially at a higher temperature  $T_s$  than that of its surroundings  $T_{sur}$ , and around it there exist a vacuum, see Fig. 5.19. The presence of the vacuum prevents energy loss from the surface of the solid by conduction or convection. However, experience has shown that the solid will cool and eventually achieve thermal equilibrium with its surroundings. This cooling is associated with a reduction in the internal energy stored by the solid and is a direct consequence of the emission of thermal radiation from the surface. In turn, the surface will receive and absorb radiation originating from the surroundings. But, since  $T_s > T_{sur}$  the net heat transfer rate by radiation  $\mathbf{q}^{rad}$  is from the surface, and the surface will be cooled until  $T_s$  reaches  $T_{sur}$ .

Radiation that is emitted by the surface originates from the thermal energy of matter bounded by the surface. The rate at which energy is released per unit area ( $\text{W/m}^2$ ) is determined by the surface emissive power  $E$ . For a blackbody the emissive power (representing a theoretical maximum rate) is prescribed by the Stefan-Boltzmann

law:

$$E_b(T_s) = \sigma T_s^4 \quad (5.322)$$

where  $T_s$  is the absolute temperature (K) of the surface.

The heat flux emitted by a real surface is of course less than that of a blackbody at the same temperature and is given by:

$$E = \epsilon \sigma T_s^4 \quad (5.323)$$

where  $\epsilon$  the emissivity of the surface. This quantity takes values in the range  $0 \leq \epsilon \leq 1$  and depends strongly on the surface material.

In this instance the irradiation  $G$  may originate from a special source, such as the sun, or from other surfaces to which the surface of interest is exposed. A portion, or all, of the irradiation may be absorbed by the surface, thereby increasing the thermal energy of the material. Since the rate at which radiant energy is absorbed per unit area is evaluated in terms of the surface radiative property termed the absorptivity  $\alpha$ , we get:

$$G_{\text{abs}} = \alpha G \quad (5.324)$$

where  $0 \leq \alpha \leq 1$ . If  $\alpha < 1$ , the surface is opaque and portions of the irradiation are reflected. If the surface is semitransparent, portions of the irradiation may also be transmitted.

A special case that occurs frequently in engineering practice involves radiation exchange between a small surface at  $T_s$  and a much larger, isothermal surface that completely surrounds the smaller one. The surroundings could be a furnace whose temperature  $T_{\text{sur}}$  differs from that of an enclosed surface ( $T_{\text{sur}} - T_s$ ). For such a condition, the irradiation may be approximated by emission from a blackbody at  $T_{\text{sur}}$ , in which case  $G = \sigma T_{\text{sur}}^4$ . If the surface is assumed to be one for which  $\alpha = \epsilon$  (a gray surface), the net rate of radiation heat transfer from the surface, is:

$$\dot{Q}^{\text{rad}} = \epsilon A E_b(T_s) - \alpha G A = \epsilon A \sigma (T_s^4 - T_{\text{sur}}^4) \quad (5.325)$$

This expression provides the difference between thermal energy that is released due to radiation emission and that which is gained due to radiation absorption.

There are many applications for which it is convenient to express the net radiation heat exchange in a form similar to Newton's law of cooling:

$$\langle \dot{Q}^{\text{rad}} \rangle_{A_I} = h^{\text{rad}} A (\langle T_s \rangle_{A_I} - \langle T_{\text{sur}} \rangle_V) \quad (5.326)$$

The radiation heat transfer coefficient  $h_r$  is:

$$h^{\text{rad}} = \epsilon \sigma (\langle T_s \rangle_{A_I} + \langle T_{\text{sur}} \rangle_V) (\langle T_s \rangle_{A_I}^2 + \langle T_{\text{sur}} \rangle_V^2) \quad (5.327)$$

In this case we have linearized the radiation rate equation, making the heat rate proportional to a temperature difference rather than to the difference between two

temperatures to the fourth power. Note, however, that  $h^{\text{rad}}$  depends strongly on temperature, while the temperature dependence of the convection heat transfer coefficient,  $h^{\text{cond,conv}}$  is generally weak.

In reactor simulations where the bulk of the vessel contains a fluid the surface may also simultaneously transfer heat by convection to the adjoining fluid. The total rate of heat transfer from the surface is then given by:

$$\begin{aligned}\dot{Q}^{\text{cond,conv,rad}} &= h^{\text{cond,conv}} A(\langle T_s \rangle_{A_I} - \langle T_{\text{sur}} \rangle_V) + h^{\text{rad}} A(\langle T_s \rangle_{A_I} - \langle T_{\text{sur}} \rangle_V) \\ &= h^{\text{cond,conv}} A(\langle T_s \rangle_{A_I} - \langle T_{\text{sur}} \rangle_V) + \epsilon A \sigma (\langle T_s \rangle_{A_I}^4 - \langle T_{\text{sur}} \rangle_V^4) \quad (5.328)\end{aligned}$$

Note that most monoatomic and diatomic gases, as well as air, are transparent at low temperatures, thus we often assume that the radiation energy exchange among the enclosure surfaces is unaffected by the presence of these gases. At higher temperatures, gases no longer remain transparent and become to some degree opaque. Then they start participating in the energy exchange process by absorbing, and emitting this energy making the modeling problem much more complex since the radiation emerging from a finite volume of matter is an integrated effect of the local emission throughout the volume.

Radiation is relevant to many environmental (solar radiation) and industrial heating, cooling and drying processes. In chemical reaction engineering in particular thermal radiation is especially important for gas systems operating at high temperatures like chemical conversion processes that involve fossil fuel combustion. In addition to the thermal radiation from solid wall surfaces the gas radiation effects might be important describing the heat transport in furnaces of fired steam reformers [38]. Furthermore, the radiation energy emitted by flames in furnaces and combustion chambers depends not only on the gaseous emission, but also on the heated carbon (soot) particles formed within flames [5] (Chaps. 8–10). The radiation modeling and simulation approaches frequently applied in combustion engineering are reviewed by Viskanta and Mengüç [132].

# **Applications**

## Chapter 6

# Chemical Reaction Engineering

Chemical reaction engineering<sup>1</sup> (CRE) emerged as a methodology that quantifies the interplay between transport phenomena and kinetics on a variety of scales and allows formulation of quantitative models for various measures of reactor performance [1]. The ability to establish such quantitative links between measures of reactor performance and input and operational variables is essential in optimizing the operating conditions in manufacturing, for proper reactor design and scale-up, and in correct interpretation of data in research and pilot plant work. A starting point for reaction engineers is the formulation of a reactor model for which the basis is the micro-scale species mass—and enthalpy balances. For practical applications the direct solution of these equations is too costly and simplifications or average representations are usually introduced. The choice of averages (e.g., global reactor volume, cross sectional area or length) to which the balance equations are integrated over (averaged) determines the level of sophistication of the reactor model. It is very common in tubular reactors to have flow predominantly in one spatial direction, say  $z$ . The major gradients then occur in that direction. For many cases, then, the cross-sectional average values of concentration and temperature are used instead of the local values. In this way the one dimensional dispersion model is obtained. If the convective transport is completely dominant over the diffusive transport, the diffusive term may be neglected. The resulting equations are denoted the ideal Plug Flow Reactor (PFR) model. When the entire reactor can be considered to be uniform in both concentration and temperature (i.e., due to very large dispersion coefficients), one may neglect gradients in all spatial directions and integrate the equations globally over all spatial dimensions (assuming convective flows at the boundaries) leading to the ideal reactor model of the Continuous Stirred Tank Reactor (CSTR). The description of a real reactor, with intermediate levels of mixing, may require amplified information about the mixing. For such processes the dispersion models (DM), in which the mixing processes are described through the empirical dispersion parameters, might be useful.

---

<sup>1</sup> Recently a branch of CRE that is mainly focusing on transport phenomena and fluid flow analysis, rather than reaction kinetics, has emerged. By these groups the abbreviation *CRE* is frequently interpreted as *chemical reactor engineering*.

A classification of dispersion models for fixed-bed tubular reactors, for example, is given by Froment and Hofmann [2]. For more complex flow patterns more elaborated and complete models are required where the flow fields are described via the solution of the Navier-Stokes equations. The understanding of the complex flow phenomena involved as well as the solution of these vector equations make the problem much more difficult to analyze spending reasonable costs and efforts. The advanced reactor models are discussed in the subsequent chapters, only a brief introduction to the idealized reactor models are presented in this chapter as these models are principal tools for chemical reaction engineers. In particular, the idealized models are easy to calculate, and they give the extreme values of the conversions between which those realized in a real reactor will occur provided there is no bypassing of reactants in the reactor.

## 6.1 Idealized Reactor Models

Basically, the processes taking place in a chemical reactor are chemical reaction, and mass, heat and momentum transfer phenomena. The modeling and design of reactors are therefore sought from employing the governing equations describing these phenomena [3]: the reaction rate equation, and the species mass, continuity, heat (or temperature) and momentum balance equations.

A fundamental aim in chemical reaction engineering is to be able to size reactors given the rate of reaction as a function of species composition and temperature. For practical applications chemical reaction engineers usually consider two extreme cases, either no mixing occurs in the reactor as the fluid elements move along parallel streamlines with equal velocity in the reactor or the mixing is complete and the fluid motion is complex and not ordered. By these two extremes approximations, the tubular plug flow (PFR) and the continuous stirred tank reactor (CSTR) models can be derived from the governing microscopic transport equations.

### 6.1.1 Plug Flow Reactor Models

To derive the plug flow reactor model for homogeneous systems we consider the single phase cross sectional averaged model formulation as derived in Sect. 1.2.7. The microscopic species mass balance reduces to (1.307) and the corresponding heat or temperature equation is given by (1.308). In chemical reaction engineering the non-ideal flow reactor model consisting of the species mass balance (1.307) and temperature Eq. (1.308) is named the axial dispersion model (ADM). If more than one phase exist, similar balance equations are needed for each of the phases. For two phase flow the cross sectional average model Eqs. (3.505) and (3.506) might be employed, as derived in Sect. 3.4.7. The latter non-ideal flow reactor model is often referred to as the heterogeneous axial dispersion model. Note also that in

multiphase flow models, a distinction is made between the true local velocity, called the interstitial velocity (m/s), and the velocity averaged over the whole cross section, called the superficial velocity ( $\text{m}^3/\text{m}^2 \text{ s}$ ). Under plug flow conditions the convective transport is completely dominant over the diffusive mass transport term. The fluid moves like a plug and the diffusive term can be neglected. The conditions for plug flow are closely satisfied for narrow and long tubular reactors when the viscosity is low. However, this approximation is clearly best for fully developed turbulent flow, for which the velocity profiles are relatively flat. For dynamic conditions, the species mass balance is a PDE with  $z$  and  $t$  as the independent variables. The Eulerian species mass balance (1.307) reduces further to:

$$\frac{\partial}{\partial t}(\rho\omega_s) + \frac{\partial}{\partial z}(\rho v^S \omega_s) = R_s \quad (6.1)$$

Recall that the rate of generation for reaction  $r$  can be expressed independent of species, since this quantity is proportional to the extent of reaction (1.155), thus if only one reaction takes place:  $R_s = \nu_s M_{\omega_s} r_r$ .

Integration over a differential volume element in a tubular reactor gives:

$$\frac{\partial}{\partial t} \int_V \rho_s dv + A \int_z \frac{\partial}{\partial z} (\rho v^S \omega_s) dz = \int_V R_s dv \quad (6.2)$$

or

$$\frac{\partial M_s}{\partial t} + \int_z \frac{\partial \dot{m}_s}{\partial z} dz = \int_V R_s dv \quad (6.3)$$

in which  $M_s = \int_V \rho_s dv$  (kg) and  $\dot{m}_s = \rho v^S \omega_s A$  (kg/s).

For steady-state conditions the species mass balance equation is a first-order ODE with the  $z$ -coordinate as the only independent variable. The Eulerian species mass balance (6.1) becomes:

$$\frac{d}{dz}(\rho v^S \omega_s) = R_s \quad (6.4)$$

Multiplying the LHS of the species mass balance with the cross sectional area ratio  $A/A$ , gives:

$$\frac{d\dot{m}_s}{dV} = R_s \quad (6.5)$$

The standard plug flow model is written in terms of molar concentrations [4, 5], hence both sides of the relation above are divided by the molecular weight of species  $s$ ,  $M_{\omega_s}$ . The mole balance yields:

$$\frac{dF_s}{dV} = r_s \quad (6.6)$$

where  $F_s = \rho_s v^S A / M_{\omega_s}$  (mol/s). This relation is named the *plug flow reactor* model.

The 1D total mass balance or continuity states that:

$$\frac{d}{dz}(\rho v^S) = 0 \quad (6.7)$$

This relation can be solved for the superficial velocity, provided that the density is known from a appropriate EOS. For gas mixtures the ideal gas law is often used, thus the changes in composition is taken into account through the average molecular mass of the mixture.<sup>2</sup> Moreover, the continuity equation can be integrated from the inlet  $z = 0$  to any level  $z = z$ , to show that the mass flux is constant in the tube:

$$(\rho v^S)|_z = (\rho v^S)|_{\text{in}} = \text{Constant} \quad [\text{kg/m}^2 \text{ s}]. \quad (6.8)$$

In particular, this integral relationship is frequently used to simplify the models, calculating the convective/advective flux terms from the known inlet values.

The plug flow model heat or temperature equation is deduced from the cross section averaged temperature equation (1.305). In many tubular reactor processes the heat conduction term in the  $z$ -direction is much smaller than the heat transport by convection. For such cases the conductive transport term can be neglected and the temperature equation reduces to:

$$\rho C_p \frac{\partial T}{\partial t} + \rho C_p v^S \frac{\partial T}{\partial z} = (-\Delta H_{r,s}) R_s / M_{\omega_s} + \frac{4U}{d_r} (T_{\text{sur}} - T) \quad (6.9)$$

For steady-state conditions the temperature equation becomes, after adopting the integrated continuity (6.8) and multiplying the resulting relation with the cross section area  $A = \pi d_r^2/4$ ,

$$\dot{m} C_p \frac{dT}{dz} = (-\Delta H_{r,s}) A R_s / M_{\omega_s} + \pi d_r U (T_{\text{sur}} - T) \quad (6.10)$$

where  $\dot{m} = \rho v^S A = \rho_{\text{in}} v_{\text{in}}^S A$  (kg/s). This relation is the heat balance for a single phase tubular reactor operating under plug flow conditions. This temperature equation is coupled with the species mass balances by the reaction term and through the mixture heat capacity term on the LHS.

The principal difference between reactor design calculations involving homogeneous reactions and those involving fluid-solid heterogeneous reactions is that for the latter, the reaction takes place on the surface of a catalyst. For the heterogeneous processes the reaction rate is normally based on mass of solid catalyst,  $W$ , rather than on reactor volume,  $V$ . For a fluid-solid heterogeneous process, the rate of reaction of a species  $s$  is defined as:

$$r'_s = \text{mol } s \text{ produced/s kg(catalyst)} \quad (6.11)$$

---

<sup>2</sup> In Chap. 1 it was shown that when the total mole balance is used instead, the reaction term does not always vanish on the RHS because the number of moles may change in a chemical process. This total molar balance can be obtained starting out from the species mass balance (6.4), after dividing by the molecular mass for each species to obtain a species mole balance and finally sum these equations for all species in the mixture.

The mass of solid catalyst is used because the amount of catalyst is what is important to the rate of product formation. For a packed tubular reactor the governing plug flow balance equations are [5]:

$$\frac{d}{dz}(\rho v^S \omega_s) = \rho_B R'_s, \quad (6.12)$$

$$\dot{m} C_p \frac{dT}{dz} = (-\Delta H_{r,s}) A \rho_B R_s / M_{\omega_s} + \pi d_r U (T_{\text{sur}} - T), \quad (6.13)$$

$$\frac{dp_t}{dz} = f \frac{\rho_g (v^s)^2}{d_p} \quad (6.14)$$

The latter equation is used to calculate the pressure drop through the bed and is named the *Ergun equation* [6]. The  $\rho_B$  is the catalyst bulk density ( $\text{kg}/\text{m}^3$ ), and  $f$  is a friction factor (–) for the packing. Ergun proposed the following parameterization for the friction factor:

$$f = \frac{1 - \varepsilon}{\varepsilon^3} \left[ 1.75 + \frac{150(1 - \varepsilon)}{Re_p} \right] \quad (6.15)$$

The following initial conditions are often used: at  $z = 0$ ,  $\rho_s = \rho_{s,0}$ ,  $T = T_0$ ,  $p_t = p_{t,0}$ . In this model  $d_p$  is the equivalent particle diameter.

### 6.1.2 Batch and Continuous Stirred Tank Reactors

Considering a well-mixed vessel, one may average the governing microscopic equations over all the spatial dimensions. For convenience, this operation is performed by further integrating the cross sectional averaged axial dispersion model equations over the remaining  $z$ -dimension. Moreover, due to the assumption of complete uniformity within the reactor, the diffusive transport terms vanish after integration of the balance equations because only convection/advection is considered at the inlet and outlet boundaries. Nevertheless, one should keep in mind that the uniformity is actually created by the large level of mixing (large dispersion terms in the bulk of the reactor volume).

The reactor models considering *complete mixing* may be subdivided into batch and continuous types. In the continuous stirred tank reactor (CSTR) models, an entering fluid is assumed to be instantaneously mixed with the existing contents of the reactor so that it loses its identity. This type of reactor operates at uniform concentration and temperature levels. For this reason the species mass balances and the temperature equation may be written for the entire reactor volume, not only over a differential volume element. Under steady-state conditions, the species mass and heat balances reduce to algebraic equations.

For a CSTR which is completely mixed, we start from the averaged species mass (1.307) and heat (1.308) balance equations. No diffusive terms are retained

as the reactor volume is assumed to be uniform in composition and temperature, as explained above. The resulting species mass balance yields:

$$\frac{\partial}{\partial t}(\rho\omega_s) + \frac{\partial}{\partial z}(\rho v^s \omega_s) = R_s \quad (6.16)$$

After global integration in  $z$  from the inlet to the outlet of the reactor and multiplying the resulting relation by the cross section area  $A$ , we get:

$$\frac{\partial}{\partial t}(\rho\omega_s V) + \int_{\dot{m}_s(z_{\text{in}})}^{\dot{m}_s(z_{\text{out}})} \frac{\partial \dot{m}_s}{\partial z} dz = R_s V \quad (6.17)$$

Let  $\dot{m}_s|_{\text{in}}$  and  $\dot{m}_s|_{\text{out}}$  represent, respectively, the inlet and outlet mass flow rates of species  $s$ , the following relation can then be obtained by use of Green's theorem:

$$\frac{dM_s}{dt} = \dot{m}_s|_{\text{in}} - \dot{m}_s|_{\text{out}} + R_s V \quad (6.18)$$

Under steady-state conditions, the simplified species mass balance reduces further to:

$$\dot{m}_s|_{\text{in}} - \dot{m}_s|_{\text{out}} + R_s V = 0 \quad (6.19)$$

The reactor model is preferably formulated in terms of mole numbers, so we may divide the relation by the molecular weight of the species  $s$ . The result is the algebraic mole balance:

$$F_s|_{\text{out}} - F_s|_{\text{in}} = R_s V \quad (6.20)$$

This mole balance is named the *continuous stirred tank reactor (CSTR)* model.

Integrating the temperature equation (1.308) over the entire reactor volume, we obtain:

$$MC_p \frac{\partial T}{\partial t} + \rho C_p v^s A \int \frac{\partial T}{\partial z} dz = V(-\Delta H_{r,s})R_s/M_{\omega_s} + \int \pi d_r U(T_{\text{sur}} - T) dz \quad (6.21)$$

in which  $M = \rho V$  (kg).

For steady-state conditions, using the integrated continuity (6.8) and assuming that the heat transfer term is not a function of  $z$ , the temperature equation can be modified to:

$$C_p(\rho v^s)|_{\text{in}} A \int \frac{\partial T}{\partial z} dz = V(-\Delta H_{r,s})R_s/M_{\omega_s} + A_h U(T_{\text{sur}} - T) \quad (6.22)$$

By use of a fundamental theorem the relation reduces to:

$$C_p \dot{m}_{\text{in}}(T_{\text{out}} - T_{\text{in}}) = V(-\Delta H_{r,s})R_s/M_{\omega_s} + A_h U(T_{\text{sur}} - T) \quad (6.23)$$

in which the heat exchange surface of the reactor is denoted by  $A_h = \pi d_r L$ . This equation can be used calculating the temperature when the CSTR model is adopted.

In *batch reactors* the spatially uniform composition and temperature variables may vary with time, however, so first-order ODEs are obtained, with time as the only independent variable. In a batch reactor no fluid is entering or leaving the reactor except at the time of loading or unloading, so the species mass balance (1.307) and the temperature equation (1.308), with no transport terms, can be integrated to yield:

$$\frac{d(\rho_s V)}{dt} = R_s V \quad (6.24)$$

or

$$\frac{dM_s}{dt} = R_s V \quad (6.25)$$

The classical batch reactor model is preferably formulated in terms of mole numbers,  $N_s$  (*mol*), so we may divide the relation by the molecular weight of the species  $s$ ,  $M_{\omega_s}$ . The resulting mole balance for the batch reactor yields:

$$\frac{dN_s}{dt} = r_s V \quad (6.26)$$

The batch reactor temperature equation is given by:

$$\dot{m} C_p \frac{dT}{dt} = (-\Delta H_{r,s}) V R_s / M_{\omega_s} + (\pi d_r L) U (T_{\text{sur}} - T). \quad (6.27)$$

## 6.2 Simplified Reactor Models

In particular cases simplified reactor models can be obtained neglecting the insignificant terms in the governing microscopic equations (without averaging in space) [7]. For axisymmetrical tubular reactors, the species mass and heat balances are written in cylindrical coordinates. Himmelblau and Bischoff [7] give a list of simplified models that might be used to describe tubular reactors with steady-state turbulent flow. A representative model, with radially variable velocity profile, and axial-and radial dispersion coefficients, is given below:

$$v_z(r) \frac{\partial \rho_s}{\partial z} = \frac{\partial}{\partial z} (\rho D_{\text{eff},z}(r) \frac{\partial \omega_s}{\partial z}) + \frac{1}{r} \left[ \frac{\partial}{\partial r} (r \rho D_{\text{eff},r}(r) \frac{\partial \omega_s}{\partial r}) \right] + R_s \quad (6.28)$$

$$\rho C_p v_z(r) \frac{\partial T}{\partial z} = \frac{\partial}{\partial z} (k_{\text{eff},z}(r) \frac{\partial T}{\partial z}) + \frac{1}{r} \left[ \frac{\partial}{\partial r} (r k_{\text{eff},r}(r) \frac{\partial T}{\partial r}) \right] + R_s / M_{\omega_s} (-\Delta H_{r,s}) \quad (6.29)$$

with boundary conditions:

$$\begin{aligned}
 v_z(r)\rho_{s,\text{in}} &= v_z(r)\rho_s(0, r) - \rho(0, r)D_{\text{eff},z}(r)\frac{\partial\omega_s(0, r)}{\partial z}, \\
 \frac{\partial\omega_s(L, r)}{\partial z} &= 0, \\
 \frac{\partial\omega_s(z, 0)}{\partial r} &= 0, \\
 \frac{\partial\omega_s(z, R_r)}{\partial r} &= 0
 \end{aligned} \tag{6.30}$$

and

$$\begin{aligned}
 \rho_{\text{in}}C_{p,\text{in}}v_z(r)T_{\text{in}} &= \rho(0, r)C_p(0, r)v_z(r)T(0, r) - k_{\text{eff},z}(r)\frac{\partial T(0, r)}{\partial z}, \\
 \frac{\partial T(L, r)}{\partial z} &= 0, \\
 \frac{\partial T(z, 0)}{\partial r} &= 0, \\
 \frac{\partial T(z, R_r)}{\partial r} &= -\frac{U}{k_r}\left(T(z, R_r) - T_{\text{wall}}\right)
 \end{aligned} \tag{6.31}$$

For turbulent flow in pipes the velocity profile can be calculated from the empirical power law design formula (1.360). Similar balance equations with purely molecular diffusivities can be used for a fully developed laminar flow in tubular reactors. The velocity profile is then parabolic, so the Hagen Poiseuille law (1.359) might suffice. It is important to note that the difference between the cross section averaged 1D axial dispersion model equations (discussed in the previous section) and the simplified 2D model equations (presented above) is that the latter is valid locally at each point within the reactor, whereas the averaged one simply gives a cross sectional average description of the axial composition and temperature profiles.

### 6.3 Chemical Reaction Equilibrium Calculations

The second law of thermodynamics is the basis for any equilibrium calculation. One way to state the second law is that all real processes occur spontaneously in the direction that increases the entropy of the universe<sup>3</sup> (system plus surroundings).

---

<sup>3</sup> In classical thermodynamics a simple system is defined as a system that is macroscopically homogeneous, isotropic, and uncharged, that are large enough so that surface effects can be neglected, and that are not acted on by electric, magnetic, or gravitational fields [8]. A thermal reservoir is defined as a reversible heat source that is so large that any heat transfer of interest does not alter

A spontaneous change occurs naturally (by itself) under specified conditions, without an ongoing input of energy from outside the system. In particular, a chemical reaction proceeding toward equilibrium is an example of a spontaneous change. For a thermodynamically reversible adiabatic process a quantitative statement of the second law can be formulated as [9]:

$$d\hat{S}_{\text{univ}} = d\hat{S}_{\text{sys}} + d\hat{S}_{\text{surr}} \geq 0 \quad (6.32)$$

Using this formulation two separate measurements of  $d\hat{S}_{\text{sys}}$  and  $d\hat{S}_{\text{surr}}$  are required to predict whether a reaction will be spontaneous at a particular temperature. Therefore, it is considered more convenient to have one criterion for spontaneity with reference to changes in the system only, which can be used to define an equilibrium state, without explicitly considering the environment. The Gibbs free energy ( $\hat{G}$ ) and the Helmholtz free energy<sup>4</sup> ( $\hat{F}$ ) functions have both been introduced especially, among other things, to provide such criteria for spontaneity as requested. Generally, the free energy change is a measure of the spontaneity of a process and of the useful energy available from the process. Moreover, the use of the Gibbs function is more common than the Helmholtz function because of the experimental convenience of specifying the  $T$  and  $p$  constraints (as compared with the alternative  $T$  and  $V$  constraints). Henceforth we continue to use the Gibbs function ( $\hat{G}$ ) exclusively, but the concepts might be recast into equivalent forms when appropriate to a particular situation [8].

By elementary theory we can show that the Gibbs function is defined in such a way that the free energy change criterion we are searching for (i.e.,  $d\hat{G}|_{T,p} = 0$ ) may be deduced from the second law of thermodynamics on the condition that  $T$  and  $p$  are constants. However, only a superficial summary of the fundamental theory is provided as the underlying ideas is quite involved. For a thermodynamically reversible adiabatic process ( $T_{\text{sys}} = T_{\text{surr}}$ ) at constant pressure, the change in entropy of the surroundings can be expressed as [9]:

$$d\hat{S}_{\text{surr}} = -\frac{d\hat{H}_{\text{sys}}}{T_{\text{sys}}} \quad (6.33)$$

Substituting for  $d\hat{S}_{\text{surr}}$  in (6.32) gives a relationship that lets us focus solely on the system:

---

(Footnote 3 continued)

the temperature of the thermal reservoir. Such a thermal reservoir is a system enclosed by rigid impermeable walls and characterized by relaxation times sufficiently short so that all processes of interest therein are essentially quasi-static. Given two or more simple systems, they may be considered as constituting a single composite system. The composite system is termed closed if it is surrounded by a wall that is restrictive with respect to the total energy, the total volume, and the total mole numbers of each species of the composite system. In the present outline the universe is considered a composite system, the system represents a simple subsystem and the surroundings a thermal reservoir.

<sup>4</sup> The Helmholtz free energy is sometimes denoted by  $\hat{A}$  ( $J$ ).

$$d\hat{S}_{\text{univ}} = d\hat{S}_{\text{sys}} - \frac{d\hat{H}_{\text{sys}}}{T_{\text{sys}}} \geq 0 \quad (6.34)$$

Multiplying both sides by  $(-T_{\text{sys}})$  gives:

$$-T_{\text{sys}}d\hat{S}_{\text{univ}} = -T_{\text{sys}}d\hat{S}_{\text{sys}} + d\hat{H}_{\text{sys}} \quad (6.35)$$

From the Gibbs equation,  $\hat{G} = \hat{H} - T\hat{S}$ , the change in the free energy of the system ( $d\hat{G}_{\text{sys}}$ ) at constant temperature and pressure is given by:

$$d\hat{G}_{\text{sys}} = d\hat{H}_{\text{sys}} - T_{\text{sys}}d\hat{S}_{\text{sys}} \quad (6.36)$$

Combining this equation with the previous one, the result is:

$$-T_{\text{sys}}d\hat{S}_{\text{univ}} = -T_{\text{sys}}d\hat{S}_{\text{sys}} + d\hat{H}_{\text{sys}} = d\hat{G}_{\text{sys}} \quad (6.37)$$

In accordance with the second law interpretation, the sign of  $d\hat{G}_{\text{sys}}$  dictates whether a reaction is spontaneous or not. We reiterate that the second law states that if  $d\hat{S}_{\text{univ}} > 0$  the process is spontaneous, else if  $d\hat{S}_{\text{univ}} < 0$  the process is non-spontaneous, and if  $d\hat{S}_{\text{univ}} = 0$  the process is at equilibrium. Because  $d\hat{G}_{\text{sys}} = -T_{\text{sys}}d\hat{S}_{\text{univ}}$ , we can easily conclude that if  $d\hat{G}_{\text{sys}} < 0$  the process is spontaneous, else if  $d\hat{G}_{\text{sys}} > 0$  the process is non-spontaneous, and if  $d\hat{G}_{\text{sys}} = 0$  the process is at equilibrium.

Before we proceed with the conventional theory of chemical reaction equilibrium calculations, a few words might be required explaining the postulate given above that equivalent forms of the second law of thermodynamics can be preferable when appropriate to a particular situation. Firstly, the reason why the particular  $\hat{G}(T, p, \mathbf{n})$  and  $\hat{F}(T, V, \mathbf{n})$  functions have been introduced to enable convenient equilibrium calculations, and no other state functions, must be seen in connection with historical requirements. The pioneers in classical thermodynamics experienced that in practice many chemical processes occur either in open vessels exposed to the atmosphere at constant temperature and pressure or in closed rigid vessels with diathermal walls at constant temperature and volume. In the latter case the ambient atmosphere acts as a thermal reservoir. The Gibbs energy function is thus conveniently defined in such a way that we can make use of the physical system property that at constant  $T$  and  $p$ , the system tends to move toward a state of minimum Gibbs energy for which  $d\hat{G}|_{T,p} = 0$ . It is emphasized that this system property represents a reformulation of the second law of thermodynamics which holds only when  $T$  and  $p$  are constants. In a similar manner, the Helmholtz energy function ( $\hat{F}$ ) is conveniently defined in such a way that we can make use of the physical system property that at constant temperature and volume, the system tends to move toward a state of minimum Helmholtz energy. Therefore, an alternative condition for chemical reaction equilibrium at constant  $T$  and  $V$  can be expressed as  $d\hat{F}|_{T,V} = 0$ . Again, it is emphasized that this system property represents a reformulation of the second law of thermodynamics which holds only when

$T$  and  $V$  are constants. Secondly, so far we have mentioned that the second law of thermodynamics provides several state functions governing the direction of natural processes. The particular state function appropriate to a given situation is governed by the choice of thermodynamic variables. In classical thermodynamics the most important state functions applied to equilibrium calculations are thus the entropy function, the Helmholtz function, and the Gibbs function. For each such state function, there is a statement of the second law of thermodynamics that include both the criterion for a natural process to occur and for the equilibrium state. Thirdly, Callen [8] proved the equivalence of alternative formulations of the conditions of chemical equilibrium. Each of these alternative formulations can be convenient for particular problems. We recollect that the principle of maximum entropy is the conventional statement of the second law of thermodynamics. Callen postulated that this law may be generalized and expressed as an *extremum principle*. Moreover, he stated that the same extremum principle can be reformulated in several equivalent mathematical forms. In particular, the equivalence of the maximum entropy representation and the minimum energy representation has been examined. The reformulations of the novel extremum principle are written in terms of Legendre transformed energy and entropy functions representations. The Helmholtz and the Gibbs energies represent two such thermodynamic potentials which correspond to two particular Legendre transforms of the energy. In Chap. 2 it is explained that multiple equivalent formulations have been used in classical mechanics (i.e., the Newtonian, Lagrangian, and Hamiltonian mechanics) because certain problems are much more tractable in a Lagrangian formalism than in a Newtonian formalism, or visa versa. Another postulate of Callen [8] is that for particular problem formulations one of the equivalent representations of the equilibrium condition in thermodynamics may also be simpler to use than the conventional Gibbs energy condition. The main point now is that we may utilize these novel ideas enabling more efficient reactor simulations. In fluid dynamics chemical reaction equilibrium calculations are neither naturally occurring at uniform and constant  $T$  and  $p$  nor at uniform and constant  $T$  and  $V$  because a material control volume is not defined at particular  $T$ ,  $p$  or  $V$ . However, it is not trivial to design a more optimal state function for the control volume representation that will make future reactor simulations less computational demanding. Meanwhile we still make use of the conventional theory, thus the chemical reaction equilibrium composition is usually found by minimizing the Gibbs energy constrained by the material balance. In this standard problem definition the values for the element-abundance vector  $\mathbf{b}$ , temperature  $T$ , pressure  $p$ , and the appropriate free energy data are thus assumed to be known. When designing numerical algorithms for calculating the unknown equilibrium composition of a mixture, it is customary to distinguish between two equivalent representations of the minimizing problem [10]:

1. The *stoichiometric formulation*, in which the constraints are incorporated through stoichiometric reaction equations. These procedures are sometimes referred to as the classical equilibrium constant methods because the equilibrium constant and the extent of reaction are the primary quantities.

2. The *non-stoichiometric formulation*, in which the stoichiometric equations are not used, instead the material balance constraints are treated by means of Lagrange multipliers. In these direct free energy minimization methods the problem is usually expressed as minimizing  $G$ , for fixed  $T$  and  $p$ , subject to the material balance constraint.

### 6.3.1 Stoichiometric Formulation

Generally the reaction equilibrium problem may be written:

$$\begin{aligned} \min \hat{G}(\mathbf{n}) &= \sum_{i=1}^q n_i \mu_i, \\ \text{subject to } \mathcal{A}\mathbf{n} &= \mathbf{b} \\ \text{and } n_i &\geq 0 \end{aligned} \quad (6.38)$$

In these equations  $\hat{G}(\mathbf{n})$  is the Gibbs energy function for the mixture and  $\mathbf{n} \in \mathcal{R}^q$  is a column vector (sometimes called the species-abundance vector) containing the unknown variables representing the number of moles of each of the  $q$  species (molecules) in the mixture.  $\mathcal{A} \in \mathcal{R}^{m \times q}$  is the predefined formula matrix. This coefficient matrix defines how the  $m$  elements in the mixture are distributed within the  $q$  species (molecules) that can exist in the system.  $m$  is the total number of elements in the mixture.  $\mathbf{b} \in \mathcal{R}^m$  is a column vector (sometimes called the element-abundance vector) containing the known values for the total amount of the different elements in the mixture.

In this formulation the solution task consist in identifying the species composition vector  $\mathbf{n}_{\text{eq}}$  that minimizes  $\hat{G}$ , for fixed  $T$  and  $p$ . The governing equations to be solved in the equilibrium calculations can be derived from the total differential of the state function. Assuming  $\hat{G} = \hat{G}(T, p, \mathbf{n})$ , the total differential of the Gibbs function can be expressed like:

$$d\hat{G} = \left( \frac{\partial \hat{G}}{\partial p} \right)_{T, \mathbf{n}} dp + \left( \frac{\partial \hat{G}}{\partial T} \right)_{p, \mathbf{n}} dT + \sum_i^q \left( \frac{\partial \hat{G}}{\partial n_i} \right)_{T, p, n_{j, j \neq i}} dn_i, \quad i = 1, 2, \dots, q \quad (6.39)$$

At equilibrium we require that  $d\hat{G}|_{T, p} = 0$ , hence the above differential reduces to:

$$d\hat{G} = \sum_i^q \left( \frac{\partial \hat{G}}{\partial n_i} \right)_{T, p, n_{j, j \neq i}} dn_i = 0, \quad i = 1, 2, \dots, q \quad (6.40)$$

However, the number of unknowns and thus the mathematical problem to be solved is still quite large even for systems in which only a few reactions occur. To reduce

the number of unknown variables, it is convenient to introduce the extent of reaction quantity. For a specific stoichiometric equation defining a particular reaction, the extent of reaction is defined by:

$$\xi = \frac{n_i - n_{i,0}}{\nu_i} \quad (6.41)$$

By definition the stoichiometric coefficient is positive for a product and negative for a reactant.

For a system with  $r$  reactions a matrix notation may be more appropriate, hence the  $r$  stoichiometric equations and the species-abundance vector  $\mathbf{n}$  are related through the extent of reaction  $\boldsymbol{\xi}$  by:

$$\mathbf{n} = \mathbf{n}_0 + \sum_{j=1}^r \boldsymbol{\nu}_j \xi_j. \quad (6.42)$$

where  $\mathbf{n}_0$  represents any particular solution with an initial composition,  $\boldsymbol{\nu}_j$  is a stoichiometric vector, and  $\xi_j$  is the extent of reaction for reaction  $j$ . This relation is merely the definition equation for the extent of reaction  $\xi_j$ .

We may then re-define the Gibbs free energy function in terms of  $\boldsymbol{\xi}$  instead of  $\mathbf{n}$ . Hence, the modified state function definition yields:

$$\hat{G} = \hat{G}(T, p, \boldsymbol{\xi}) \quad (6.43)$$

In this case the solution task is to minimize  $\hat{G}$ , for fixed  $T$  and  $p$ , in terms of the extent of reaction  $\xi_j$  for the  $r$  reactions.

The total differential of the modified Gibbs energy function  $\hat{G} = \hat{G}(T, p, \boldsymbol{\xi})$  is examined to elucidate the necessary conditions for obtaining a minimum in the free energy function:

$$d\hat{G} = \left( \frac{\partial \hat{G}}{\partial p} \right)_{T, \boldsymbol{\xi}} dp + \left( \frac{\partial \hat{G}}{\partial T} \right)_{p, \boldsymbol{\xi}} dT + \sum_j^r \left( \frac{\partial \hat{G}}{\partial \xi_j} \right)_{T, p, \xi_k, k \neq j} d\xi_j, \quad j = 1, 2, \dots, r \quad (6.44)$$

By chain rule differentiation, the last term on the RHS of this relation can be re-written in terms of mole numbers:

$$d\hat{G} = \left( \frac{\partial \hat{G}}{\partial p} \right)_{T, \boldsymbol{\xi}} dp + \left( \frac{\partial \hat{G}}{\partial T} \right)_{p, \boldsymbol{\xi}} dT + \sum_j^r \sum_{i=1}^q \left( \frac{\partial \hat{G}}{\partial n_i} \right)_{T, p, n_k, k \neq i} \left( \frac{\partial n_i}{\partial \xi_j} \right)_{\xi_k, k \neq j} d\xi_j \quad (6.45)$$

The last term derived on the RHS can be further simplified by recognizing that:

$$\left(\frac{\partial \hat{G}}{\partial n_i}\right)_{T,p,n_{k,k \neq i}} = \mu_i \quad (6.46)$$

and

$$\left(\frac{\partial n_i}{\partial \xi_j}\right)_{\xi_{k,k \neq j}} = \nu_{ij} \quad (6.47)$$

At equilibrium, we again require that  $d\hat{G}_{T,p} = 0$ , hence (6.45) reduces to:

$$d\hat{G}_{T,p} = \sum_{j=1}^r \sum_{i=1}^q \nu_{ij} \mu_i d\xi_j = 0 \quad (6.48)$$

where  $\nu_{ij}$  is the stoichiometric coefficient of species  $i$  in reaction  $j$ .

From the relations (6.44)–(6.48) it is concluded that the necessary conditions for a minimum value of  $\hat{G}$  are:

$$\begin{aligned} \left(\frac{\partial \hat{G}}{\partial \xi_j}\right)_{T,p,\xi_{k,k \neq j}} &= \sum_{i=1}^q \left(\frac{\partial \hat{G}}{\partial n_i}\right)_{T,p,n_{k,k \neq i}} \left(\frac{\partial n_i}{\partial \xi_j}\right)_{\xi_{k,k \neq j}} \\ &= \sum_{i=1}^q \mu_i \nu_{ij} = 0, \quad j = 1, 2, \dots, r \end{aligned} \quad (6.49)$$

In this method the chemical equilibrium state is defined by the chemical equilibrium constant [11]. The chemical equilibrium constants can be derived from (6.49) provided that appropriate expressions are introduced for the chemical potential. A change in chemical potential for an isothermal process is related to a change in the fugacity of the species<sup>5</sup> [12]:

$$d\mu_i|_T = RT d \ln \hat{f}_i|_T \quad (6.50)$$

where  $\hat{f}_i$  is the fugacity of species  $i$  in the mixture.

If we integrate, at constant temperature, the given relation between the standard state and some arbitrary state, we obtain [12]:

$$\mu_i = \mu_i^0 + RT \ln \left( \frac{\hat{f}_i}{f_i^0} \right) \quad (6.51)$$

---

<sup>5</sup> The American chemist G. N. Lewis (1875–1946) introduced the fugacity function (Latin *fugare*, to fly) as a measure of the pressure adjusted for the lack of ideality [9]. For an ideal gas the fugacity is equal to the pressure. For a non-ideal gas we normally define the standard state to correspond to unit fugacity,  $f_i^0 = 1$  (bar).

The fugacity of species  $i$  in the mixture  $\hat{f}_i$  can be defined in terms of the pure species fugacity  $f_i^{\text{pure}}$  through an activity coefficient  $\gamma_i$  or a fugacity coefficient  $\phi_i$  as will be explained shortly.

The ratio of the fugacities represents the activity,  $a_i = \hat{f}_i/f_i^0$ , hence we can re-write the above relation like:

$$\mu_i = \mu_i^0 + RT \ln(a_i) \quad (6.52)$$

Considering a single model reaction like:

Based on this reaction we can derive an expression for the rate of change of the chemical potential:

$$\Delta\mu_R = \Delta\mu_R^0 + RT \ln\left(\frac{a_C^c a_D^d}{a_A^a a_B^b}\right) \quad (6.53)$$

The criterion for chemical reaction equilibrium is thus that the energy difference between reactants and products is zero,  $\Delta\mu_R = 0$ . Hence, we can define the equilibrium constant for the model reaction by:

$$-\frac{\Delta\mu_R^0}{RT} = \ln\left(\frac{a_C^c a_D^d}{a_A^a a_B^b}\right)_{eq} = \ln K_{eq} \quad (6.54)$$

The relationship between the equilibrium constant and the change in the chemical potential for the reaction is sometimes called the van't Hoff equation [11].

An explicit expression for the chemical equilibrium constant is thus given by:

$$K_{eq} = \exp\left(-\frac{\Delta\mu_R^0}{RT}\right) \quad (6.55)$$

where  $\Delta\mu_R^0$  is the standard free energy change for the reaction at a given temperature  $T$  and a defined reference state.

This concept can be generalized and applied to a multicomponent mixture in which multiple reactions are taking place. In this case  $\Delta\mu_{R,j}^0$  is systematically expressed in terms of the reference chemical potentials by inserting (6.51) into (6.49). The result is:

$$\sum_{i=1}^q \left[ \nu_{ij} \mu_i^0 + \nu_{ij} RT \ln\left(\frac{\hat{f}_i}{f_i^0}\right) \right] = 0 \quad (6.56)$$

The measure of the change in chemical potential associated with reaction  $j$  is defined by  $\Delta G_{R,j}^0 = \Delta\mu_j^0 = \sum_{i=1}^q \nu_{ij} \mu_i^0$ . It is emphasized that this quantity is calculated from the stoichiometric coefficients of the reaction and not from the number of moles of the different species transformed by the reaction. Nevertheless, the  $\Delta G_{R,j}^0$  is frequently

referred to as the standard Gibbs energy change for reaction  $j$ . The above relation can be re-written as:

$$\frac{\Delta G_{R,j}^0}{RT} = \frac{1}{RT} \sum_{i=1}^q \nu_{ij} \mu_i^0 = - \sum_{i=1}^q \nu_{ij} \ln \left( \frac{\hat{f}_i}{f_i^0} \right) = - \ln K_{eq,j} \quad (6.57)$$

In order to relate  $K_{eq,j}$  to the activities we rearrange the relation to obtain:

$$\ln K_{eq,j} = \sum_{i=1}^q \nu_{ij} \ln (a_i) = \ln (a_i)^{\sum_{i=1}^q \nu_{ij}} = \ln \prod_{i=1}^q a_i^{\nu_{ij}} \quad (6.58)$$

Hence, a non-linear equation for  $K_{eq,j}$  can easily be obtained:

$$K_{eq,j} = \prod_{i=1}^q a_i^{\nu_{ij}} \quad (6.59)$$

For most *liquid mixtures* the fugacity is not a strong function of pressure thus the fugacity ratio is approximately  $f_i^{\text{pure}}/f_i^0 \sim 1$ , thus for liquids the activity can be approximated as:

$$a_i = \frac{\gamma_i x_i f_i^{\text{pure}}}{f_i^0} \approx \gamma_i x_i \quad (6.60)$$

The corresponding equilibrium constant yields:

$$K_{eq,j} = \prod_{i=1}^q (\gamma_i x_i)^{\nu_{ij}} \quad (6.61)$$

The calculation of the equilibrium composition for a reactive liquid mixture requires specific excess models for the activity coefficient of every species [12]. Note that for ideal solutions the activity coefficient has a value of unity,  $\gamma_i = 1$ .

For *gas mixtures*<sup>6</sup> the fugacity of species  $i$  in the mixture  $\hat{f}_i$  is conventionally written:

$$\hat{f}_i = y_i f_i^{\text{pure}} = y_i \frac{f_i^{\text{pure}}}{p} p = y_i \phi_i p \quad (6.62)$$

The fugacity coefficient is defined as  $\phi_i = f_i^{\text{pure}}/p = \hat{f}_i/p_i$ , and is calculated from an appropriate EOS.

The corresponding equilibrium coefficient for reaction  $j$  in the mixture yields:

$$K_{eq,j} = \prod_{i=1}^q \left( \frac{\hat{f}_i}{f_i^*} \right)^{\nu_{ij}} = \prod_{i=1}^q \left( \frac{y_i \phi_i p}{f_i^*} \right)^{\nu_{ij}} = \prod_{i=1}^q \left( \frac{y_i \phi_i p}{p^*} \right)^{\nu_{ij}} \quad (6.63)$$

<sup>6</sup> This approach can also be adopted for liquid mixtures provided that an appropriate EOS is available.

in which  $f_i^* = p^* = 1$  (bar).  $p^*$  is the pressure at the reference state (ideal gas). For gases the standard state for  $\Delta G_{R,j}^0$  is thus 1 (bar).

This model represents the most frequently used description of chemical reaction equilibrium and should be familiar to most chemical engineering students. However, for multicomponent mixtures in which multiple reactions may take place, this type of non-linear problems may be cumbersome to solve numerically. One important obstacle is that the non-linear equilibrium constant definitions may give rise to multiple solutions, hence we have to identify which of them are the physical solutions. The stoichiometric formulation might thus be inconvenient for mixtures containing just a few species for which only a few reactions are taking place.

### 6.3.2 Non-stoichiometric Formulation

In this case the chemical reaction equilibrium problem is expressed so that we are minimizing the free energy directly as formally defined by the fundamental statement (6.38). In mathematical terms (6.38) represents a constrained optimization problem. This type of problems is usually solved by the use of Lagrange multipliers.

A Lagrangian function for the equilibrium problem can be defined as<sup>7</sup>:

$$L(\lambda, \mathbf{n}) \equiv \hat{G}(\mathbf{n}) - \lambda^T (\mathcal{A}\mathbf{n} - \mathbf{b}) \quad (6.64)$$

In this framework the minimization problem is expressed as:

$$\min L(\lambda, \mathbf{n}) \quad (6.65)$$

where  $\lambda \in \mathcal{R}^m$  is a column vector of the Lagrange multipliers.

The Lagrangian function has a minimum when  $\nabla L = 0$ , in which the  $\nabla L$  operator is defined by a column vector consisting of the two elements:

$$\begin{aligned} \frac{\partial L}{\partial \mathbf{n}} &= \frac{\partial \hat{G}}{\partial \mathbf{n}} - \mathcal{A}^T \lambda = \boldsymbol{\mu} - \mathcal{A}^T \lambda = \mathbf{0} \\ \frac{\partial L}{\partial \lambda} &= \frac{\partial \hat{G}}{\partial \lambda} - (\mathcal{A}\mathbf{n} - \mathbf{b}) = -(\mathcal{A}\mathbf{n} - \mathbf{b}) = \mathbf{0} \end{aligned} \quad (6.66)$$

Notice that  $\partial \hat{G} / \partial \mathbf{n}$  equals the chemical potential vector  $\boldsymbol{\mu}$ , and  $\partial \hat{G} / \partial \lambda = 0$ .

The solution of these equations may be obtained by use of the iterative Newton method. The Newton method can be derived from a second order Taylor expansion, which for the given Lagrangian ( $L$ ) gives:

$$\nabla L^{(k)} + \nabla^2 L^{(k)} \delta \mathbf{y}^{(k+1)} = \mathbf{0} \quad (6.67)$$

<sup>7</sup> The elements of Lagrangian mechanics are explained in Chap. 2.

or more conveniently:

$$\nabla^2 L^{(k)} \delta \mathbf{y}^{(k+1)} = -\nabla L^{(k)} \quad (6.68)$$

where  $\delta \mathbf{y} = (\delta \mathbf{n}, \delta \boldsymbol{\lambda})^T$  is a column vector containing the difference in the composition and Lagrange multiplier estimates for the iteration number  $k + 1$  and  $k$ .

The gradient and Laplace operators in (6.68) are applied to the Lagrangian (6.64). The gradient of the Lagrangian is defined by (6.66), whereas the Laplace operator applied to the Lagrangian is simply the divergence of the gradient of the Lagrangian. Hence, (6.68) can be re-written as:

$$\left[ \frac{\partial}{\partial \mathbf{n}^T} (\boldsymbol{\mu} - \mathcal{A}^T \boldsymbol{\lambda}) \quad \frac{\partial}{\partial \boldsymbol{\lambda}^T} (\boldsymbol{\mu} - \mathcal{A}^T \boldsymbol{\lambda}) \right]^{(k)} \begin{bmatrix} \delta \mathbf{n} \\ \delta \boldsymbol{\lambda} \end{bmatrix}^{(k+1)} = \begin{bmatrix} \mathcal{A}^T \boldsymbol{\lambda} - \boldsymbol{\mu} \\ \mathcal{A} \mathbf{n} - \mathbf{b} \end{bmatrix}^{(k)} \quad (6.69)$$

After performing the differentiation in the first parenthesis, the Newton method can be expressed as:

$$\begin{bmatrix} \mathcal{H} & -\mathcal{A}^T \\ -\mathcal{A} & \mathbf{0} \end{bmatrix}^{(k)} \begin{bmatrix} \delta \mathbf{n} \\ \delta \boldsymbol{\lambda} \end{bmatrix}^{(k+1)} = \begin{bmatrix} \mathcal{A}^T \boldsymbol{\lambda} - \boldsymbol{\mu} \\ \mathcal{A} \mathbf{n} - \mathbf{b} \end{bmatrix}^{(k)} \quad (6.70)$$

where  $\mathcal{H}$  is the Hessian matrix of  $G$ ,  $\mathcal{H} = \partial^2 G / \partial \mathbf{n} \partial \mathbf{n}^T = \partial \boldsymbol{\mu} / \partial \mathbf{n}^T$ . The Hessian matrix may be found by analytical differentiation or by a finite differences approximation of the derivative.

The matrix operations may be further simplified, as can be illustrated writing down the problem as two algebraic equations that need to be solved simultaneously:

$$\begin{aligned} \mathcal{H}^{(k)} \delta \mathbf{n}^{(k+1)} - \mathcal{A}^T \delta \boldsymbol{\lambda}^{(k+1)} &= \mathcal{A}^T \boldsymbol{\lambda}^{(k)} - \boldsymbol{\mu}^{(k)} \\ \mathcal{A}^T \delta \mathbf{n}^{(k+1)} &= \mathbf{b} - \mathcal{A} \mathbf{n}^{(k)} \end{aligned} \quad (6.71)$$

Moreover, since  $\delta \boldsymbol{\lambda}^{(k+1)} = (\boldsymbol{\lambda}^{(k+1)} - \boldsymbol{\lambda}^{(k)})$ , the equations reduce to:

$$\begin{aligned} \mathcal{H}^{(k)} \delta \mathbf{n}^{(k+1)} - \mathcal{A}^T \boldsymbol{\lambda}^{(k+1)} &= \mathcal{A}^T \boldsymbol{\lambda}^{(k)} - \mathcal{A}^T \boldsymbol{\lambda}^{(k)} - \boldsymbol{\mu}^{(k)} = -\boldsymbol{\mu}^{(k)} \\ \mathcal{A}^T \delta \mathbf{n}^{(k+1)} &= \mathbf{b} - \mathcal{A} \mathbf{n}^{(k)} \end{aligned} \quad (6.72)$$

The resulting iterative method formulation is called the Newton-Lagrange scheme:

$$\begin{bmatrix} \mathcal{H} & -\mathcal{A}^T \\ -\mathcal{A} & \mathbf{0} \end{bmatrix}^{(k)} \begin{bmatrix} \delta \mathbf{n} \\ \boldsymbol{\lambda} \end{bmatrix}^{(k+1)} = \begin{bmatrix} -\boldsymbol{\mu} \\ \mathcal{A} \mathbf{n} - \mathbf{b} \end{bmatrix}^{(k)} \quad (6.73)$$

Computational aspects of the solution of the chemical reaction equilibrium model formulation are discussed by Michelsen and Mollerup [13]. In particular, the numerical stability properties reflected by the given equation system formulation might not

be optimal thus manipulations of the equation system have been suggested in order to achieve an efficient implementation of Newton's method.

The *Rand method*, for example, is frequently used for the determining the equilibrium composition of complex mixtures. White et al. [14], working at Rand Corporation, proposed an efficient and stable algorithm for computing compositions at equilibrium using Newton's method to minimize the Gibbs free energy of an ideal gas mixture. Shortly after, the Rand algorithm was extended to include pure solid phases and one or more mixed liquid or solid phases. About three decades later the classical Rand method was generalized to explicitly account for non-ideal behavior by Grainer [15]. Readers not familiar with the theory for constrained optimization can find a short introduction therein. A more extensive discussion of practical methods of optimization can be found in the book of Fletcher [16].

An important feature of the non-stoichiometric formulation is that no information about the reaction stoichiometry is required. However, the species that the mixture is composed of must be specified. Note also that this type of chemical reaction equilibrium calculations is sometimes referred to as a *Gibbs reactor* simulation.

## Chapter 7

# Agitation and Fluid Mixing Technology

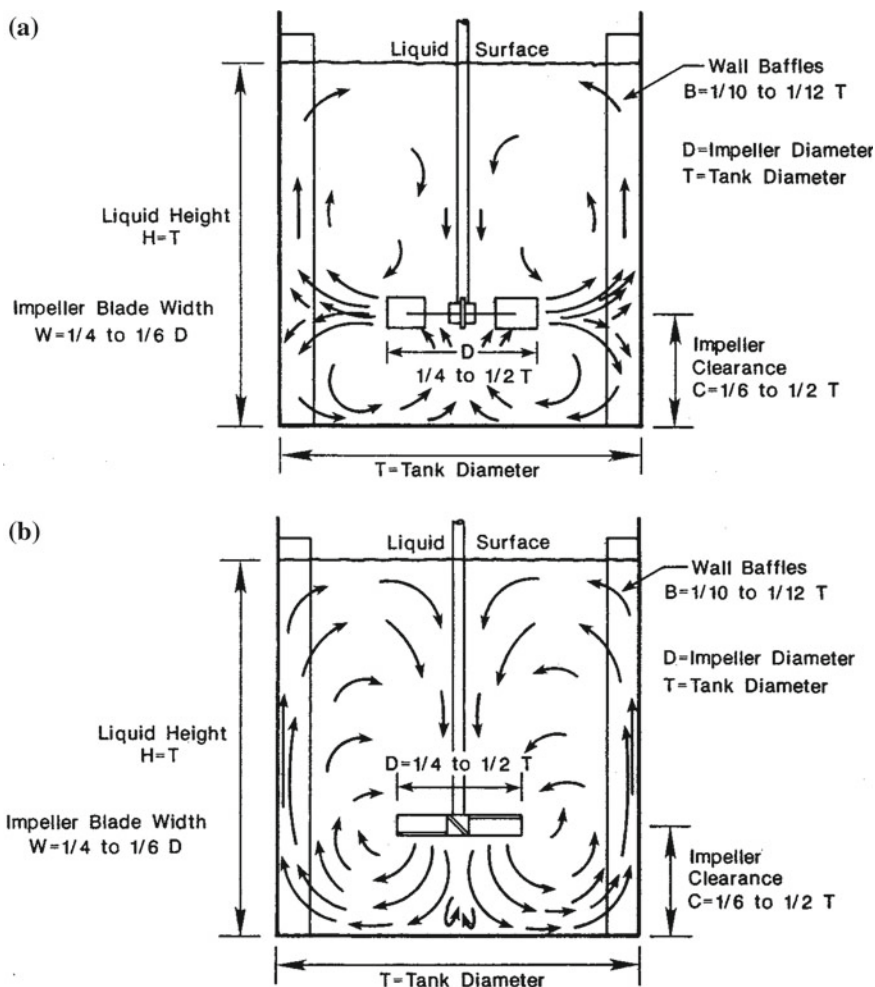

Many industrial processes rely on effective agitation and mixing of fluids. The application of agitators cover the areas of mining, hydrometallurgy, biology, petroleum, food, pulp and paper, pharmaceutical and chemical process industry. In particular, in these industries we find typical chemical reaction engineering processes like fermentation, waste water treatment, hydrogenation, polymerization, crystallization, flue gas desulfurization, etc [21, 65]. Generally, *agitation* refers to forcing a fluid by mechanical means to flow in a vessel. *Mixing* usually implies the taking of two or more separate phases, or two fluids, and causing them to be randomly distributed through one another. There are a number of purposes for agitating fluids, the intention may for example be to optimize blending of two miscible liquids, dissolving solids in liquids, dispersing a gas in a liquid as fine bubbles, suspending fine solid particles in a liquid, and agitation of a liquid to increase heat transfer between the fluid and a coil or jacket in the vessel wall. Fluid mixing may also be important in reactors to ensure optimal operation conditions for some chemical systems requiring uniform temperature and species concentrations within the reactor volume. Fluid mixing and blending<sup>1</sup> devices may thus be important units both for reactive and non-reactive processes. There are many ways to obtain mixing in a vessel. This chapter focuses on the turbulent impeller type of mixers, as they are frequently applied in the chemical process industries.

### 7.1 Tank Geometry and Impeller Design

There is not only one optimal or unique tank design for each kind of process, since several designs may satisfy the process specifications [65]. In order to simplify design and minimize costs, standard reactor designs are usually considered sufficient for most processes. Based on experience, it has been found that for turbulent mixing

---

<sup>1</sup> In English literature the term *blending* are most commonly used describing mixing of miscible liquids, whereas the term *mixing* is used describing mixing of immiscible liquids, powders, etc [53].

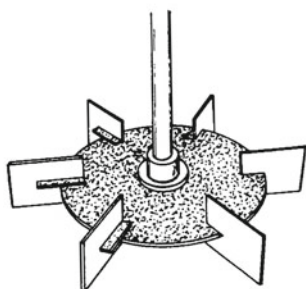

**Fig. 7.1** Turbulent flow impellers. **a** The flow pattern produced by a radial impeller in a the standard tank geometry. **b** The flow pattern produced by an axial impeller in a standard tank geometry Tatterson [87]. By permission from Tatterson (personal communications 2006)

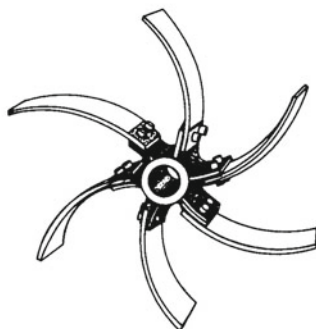

using low viscosity fluids, the standard geometry shown in Fig. 7.1 can be used. The standard tank is characterized by the diameter,  $T$ , liquid height  $H$ , impeller diameter  $D$ , impeller blade width  $W$ , clearance of impeller from the tank bottom  $C$  and the baffle width  $B$ . The standard tank is defined with four baffles placed  $90^\circ$  apart.

However, the standard tank does not reflect an optimized geometry for all processes performed in stirred tanks. The determination of an optimal geometry for a given process is very difficult, hence the standard geometry has been viewed as a reference geometry and as a point of departure for novel studies. For turbulent mixing, a liquid height to tank diameter ratio ( $H/T$ ) equal to 1 is often used as a

base to describe the effect of geometry. No such standard tank geometry similar to the one used in turbulent mixing has been used for laminar mixing of high viscosity fluids.

Two different types of impellers for turbulent flow exist, radial impellers and axial impeller, as sketched in Fig. 7.2. The radial impellers project the fluid radially out from the blade towards the tank wall. The flow splits at the tank wall, and approximately 50 % of the fluid circulates towards the surface while the rest to the bottom, creating two regions of low mean velocity. The flow exiting the impeller blade forms a sharp velocity gradient with a strong peak at the impeller blade horizontal center line. Examples of radial flow impellers are disk style flat blade turbines (Rushton

impellers) and curved blade turbines. Turbines that resemble multi-bladed paddle agitators with shorter blades are used at high speeds for liquids with a very wide range of viscosities. Normally, the turbines have four or six blades. Various types of paddle agitators are often used at low speeds between about 20 and 200 rpm. At low speeds mild agitation is obtained in an unbaffled vessel. At higher speeds baffles are used, since without baffles, the liquid is simply swirled around with little actual mixing. An anchor or gate paddle is often used with viscous liquids where deposits on walls can occur and to improve heat transfer to the wall. The axial impeller discharges fluid mainly axially, parallel to the impeller shaft. The fluid is pumped through the impeller, normally towards the bottom of the tank. Since the flow make a turn at the bottom, the velocity vectors fan out radially at approximately  $D/2$  beneath the impeller. Then, the flow moves along the bottom and rises near the tank wall. Analyzing the flow pattern, one can see that a back-flow eddy region is formed directly under the impeller. Upon examining the flow around the axial impeller one can also observe that a large contribution to the inlet flow enters radially at the tip of the impeller blade. This pattern is shown in Fig. 7.1.

Examples of axial impellers are marine propeller and pitched blade turbine, shown in Fig. 7.2. A three bladed marine type propeller is similar to the propeller blade used in driving boats. The propeller can be a side entering type in a tank or be clamped on the side of an open vessel in an off-center position. Axial flow impellers are used in blending and mixing of miscible liquids. In turbulent mixing unwanted phenomena such as solid body rotation and central surface vortices may occur. In solid body rotation the fluid rotates as if it was a solid mass, and as a result little mixing takes place. At high impeller rotational speeds the centrifugal force of the impeller moves the fluid out to the walls creating a surface vortex. This vortex may even reach down to the impeller resulting in air entrainment into the fluid [87].

The characteristic solid body rotation is the primary flow pattern in unbaffled tanks. To avoid these phenomena, baffles are installed in the tank. On wall baffles are sketched in Fig. 7.1. Generally, baffles are placed in the tank to modify the flow and surface destroy vortices. Baffles mounted at the tank wall are most common, but also bottom baffles, floating surface baffles and disk baffles at the impeller shaft are possible. Often tank wall baffles are mounted a certain distance from the wall, as illustrated in Fig. 7.3. This creates a different flow pattern in the tank. The purpose of installing baffles away from the wall is to avoid dead zones where liquid is seldom exchanged and where impurities accumulate. Experiments have confirmed that the flow patterns in baffled agitated tanks are different from the flow patterns in unbaffled agitated tanks. In baffled tanks the discharge flow dissipates partly in the bulk and turns axially near the tank wall. Baffles increase the axial circulation and reduce the tangential velocities. While the axial circulation dominates in the baffled tank, solid body rotation easily form in an unbaffled tank. Due to the high tangential velocity in the unbaffled solid body rotation flow regime, the relative velocity between the fluid and the impeller becomes small, resulting in poorer mixing and circulation in unbaffled tanks compared to baffled tanks. The magnitude of the tangential velocity component is also reflected by the turbulence intensities. The radial and axial turbulence intensities are usually less than the turbulence intensities of the tangential

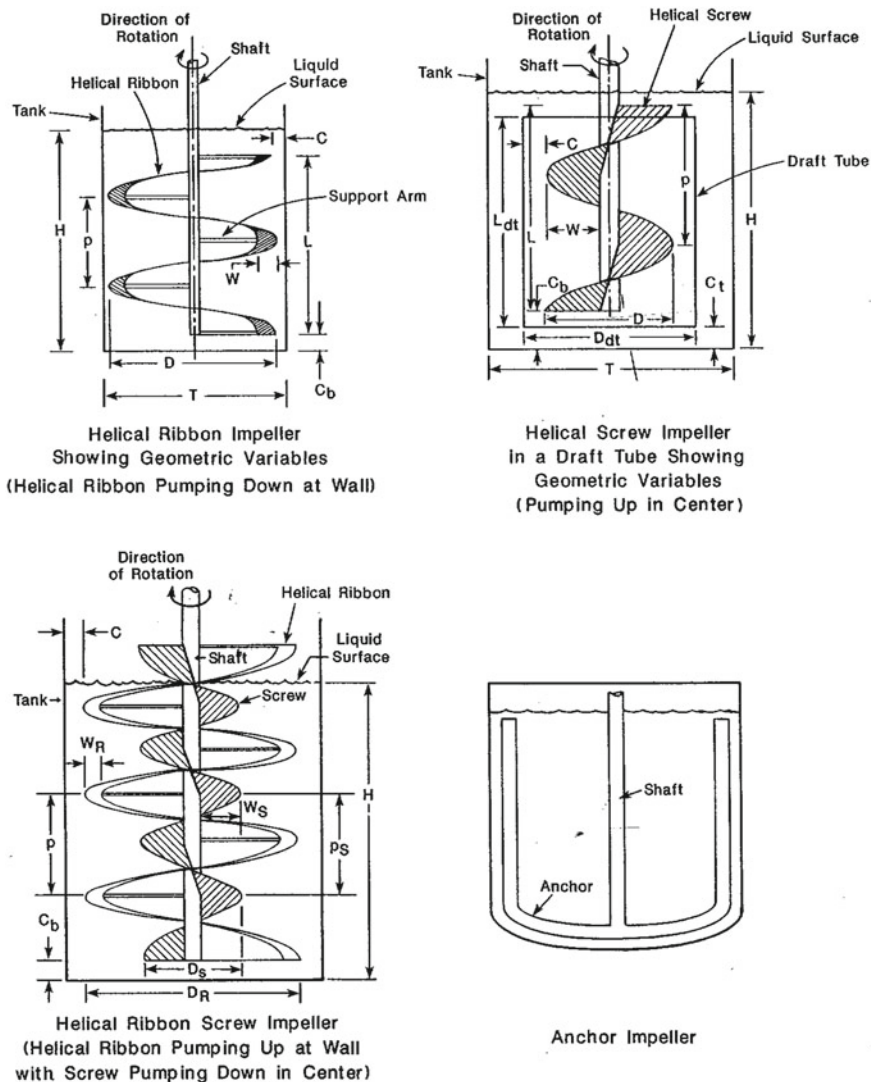

**Fig. 7.3** Vortices in baffled tanks [87]. *Left* Baffle off wall. *Right* Baffle on wall. By permission from Tatterson (personal communications 2006)

velocity, indicating that the flow is non-isotropic, and that the mixing in the radial and axial directions is much lower than in the tangential direction [87]. In a tank with radial impellers, suitable baffles will produce strong top-to-bottom currents from the radial discharge. The installation of baffles generally increase the power consumption [65]. For axial flow impellers, the need for baffling is not as great as for radial flow impellers, thus axial flow impellers also consume less power than radial impellers. Baffles are normally used in turbulent mixing only.

For laminar mixing other impellers are used, some laminar impellers are sketched in Fig. 7.4. To bring the fluid in the entire tank in motion, the diameter of these impellers usually approach the tank diameter since the laminar bulk flow is otherwise relatively low. Laminar impellers with diameter approaching the tank diameter are also called close-clearance impellers. Laminar mixers often have complex geometries, characterized by geometrical variables as the impeller diameter  $D$ , the blade width  $W$ , the pitch  $p$ , the impeller wall clearance  $C$ , and the off-bottom clearance  $C_b$ . In most applications, baffles are not needed and can in fact cause poor mixing behavior [87]. Examples of laminar impellers are helical ribbons, screws, helical ribbon screws and anchor impellers.

In many processes, multiple impellers are applied in order to obtain better mixing of a larger volume. In tall tanks where the liquid height to tank diameter ratio ( $H/T$ ) is greater than 1, the use of multiple impellers will cause better top-to-bottom circulation of the bulk. By using axial impellers, fluid can be pumped upward or downward in the tank into a new impeller's flow area. However, if the axial flow impellers are placed too close together, they may behave as a single larger impeller. A problem associated with multiple radial impellers is the formation of fluid cells or compartments around

**Fig. 7.4** Typical laminar impellers [87]. By permission from Tatterson (personal communications 2006)

each impeller. Exchange of fluid mass between these fluid cells is poor resulting in poor mixing of the whole tank volume.

The viscosity of the fluid is one of several factors affecting the selection of the type of agitator ([27], pp. 142–143). Based on experience the viscosity ranges for which the different agitators can be used might be indicated. Propellers are often used for viscosities of the fluid below about 3 (Pas), turbines may be used below

about 100 (Pa s), modified paddles such as anchor agitators are normally used above 50 (Pa s) to about 500 (Pa s), helical and ribbon type agitators are often used above this range to about 1000 (Pa s) and have been used up to 25000 (Pa s). For viscosities greater than about 2.5–5 (Pa s) and above, baffles are usually not needed since little swirling is present above these viscosities.

## 7.2 Fluid Shear Rates, Impeller Pumping Capacity and Power Consumption

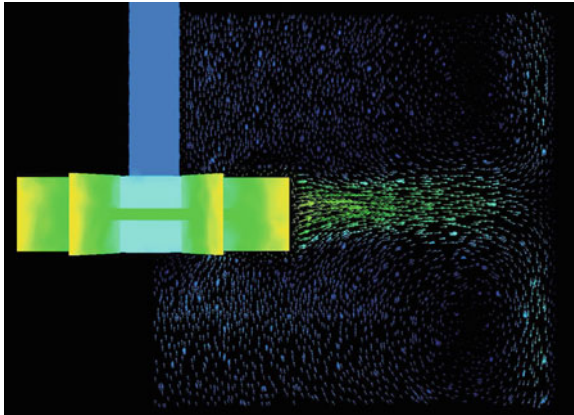

An impeller is essentially a pump, although not a very efficient one. All the energy an impeller supplies to the fluid produces fluid flow and shear. In other words, a rotating impeller transports kinetic energy from the impeller blade to the surrounding fluid. Generally, approximately 80 % of the mixing applications primarily require impeller pumping and mass flow of the batch, such as blending of liquids and solid suspension. These important applications include fermentation, particle degradation in emulsions, gas dispersion and polymerization [65]. For about 20 % of the mixing applications, producing shear is the main requirement for mixing. Many industrial chemical reactive processes require primarily shear in order to provide contact between the reacting components on a molecular level.

### 7.2.1 Fluid Shear Rates

To investigate how changes in impeller speed and impeller size influence on the fluid shear, the fluid discharge velocities from the impeller have been measured and simulated. The maximum shear rate obtained at the fluid boundary, as well as the average shear rate around the entire impeller can be calculated from these data. The maximum shear rates in the tank volume are generally found on the impeller blade. In a baffled tank, the shear rates decrease from impeller tip towards the tank wall and are decreasing with decreasing rotational speed.

Figure 7.5 shows a typical flow pattern produced by a radial impeller. As can be seen from the figure, the velocity of the fluid discharged from the middle of the impeller blade is highest. The shear rate is determined by the gradient of the velocity profile. The velocity gradient multiplied by the kinematic viscosity determines the shear stress. This force is responsible for dispersing gas, stretching liquid particles and intermixing small-scale fluid parcels [65].

**Fig. 7.5** Simulated stirred tank showing a typical flow pattern from a radial impeller. The figure is produced by a FLUENT simulation

### 7.2.2 Impeller Pumping Capacity

Axial turbines are pumping fluid axially in the tank creating a circulating flow pattern. The total volumetric turnover rate in the tank is the total circulation rate taking place in the tank. The pumping capacity,  $Q$ , of an impeller is the volumetric flow rate passing through the planes established by the impeller rotation. The entrained circulation rate is the difference between these two volumetric flow rates. In accordance with the continuity equation on integral form for an incompressible fluid, the volumetric flow rate  $Q$  is proportional to the fluid velocity multiplied by the flow area:

$$Q \propto vA \propto (\pi ND)D^2 \quad (\text{m}^3/\text{s}) \quad (7.1)$$

where the fluid velocity is assumed to be proportional to the impeller tip speed,  $v \propto v_t = (\pi ND)$ , and a size measure of the area is given by the square of the impeller diameter,  $A \propto D^2$ .

We may then introduce a proportionality coefficient,  $N_Q$ , defined as:

$$Q = N_Q ND^3 \quad (\text{m}^3/\text{s}) \quad (7.2)$$

where the flow or pumping number,  $N_Q$ , is a dimensionless group used to quantify the flow pattern in stirred tanks [65].  $N_Q$  varies with impeller type, tank geometry and flow regime.  $N$  is the stirring rate in RPM (rounds per minute).

The impeller Reynolds number is defined as:

$$Re = \frac{\rho v D}{\mu} = \frac{\rho (ND) D}{\mu} = \frac{\rho ND^2}{\mu} \quad (7.3)$$

A similar relation can be derived for radial impellers. Experiments have shown that for a disk style turbine the pumping number decreases with increasing impeller Reynolds number [87] (p. 213), while for a propeller the pumping number seems to increase with increasing Reynolds number. Normally, empirical correlations expressed in terms of the impeller Reynolds number etc. are developed to estimate how the pumping number varies with impeller geometry.

### 7.2.3 Impeller Power Consumption

Impeller power draw is the power transfer from the impeller to the fluid causing fluid motion. This power is eventually dissipated by viscous dissipation into heat within the fluid. Power dissipation is often termed power consumption and is equal to the power draw at steady state according to a global or macro scale kinematic energy balance.

Several approaches have been applied estimating the power consumption. The traditional approach is to use dimensional analysis, creating power laws based on experimental data on torque<sup>2</sup> [87]. The power or Newton number has the same function as the pumping number, accounting for various effects on power consumption.

Impeller power consumption,  $P$ , is primarily a function of system characteristics like impeller speed,  $N$ , impeller diameter,  $D$ , impeller design, physical properties of fluid, vessel size and geometry, impeller location and baffle design. Through extensive experimental work, correlations determining the influence of these quantities upon power consumption have been established. The main purpose of such relations is to estimate the power draw for a given process, so that a tank geometry which maximizes impeller power draw can be designed and scaled to industrial units [87] (p. 22). The power consumption,  $P$ , is given by:

$$P = N_p \rho N^3 D^5 \quad (W) \quad (7.4)$$

where  $N_p$  is the dimensionless Newton number and  $\rho$  is the density of the fluid. The dimensionless Newton number is a characteristic number for the effects of geometry and flow regime on the power consumption.

The power number in (7.4) is usually determined from suitable parameterizations which are functions of Reynolds number, Froude number, and geometry.

---

<sup>2</sup> The torque or angular moment is defined as the tendency of a force to rotate the body to which it is applied. Torque is thus a force that affects rotational motion and is always specified with regard to the axis of rotation.

### 7.2.4 Fundamental Analysis of Impeller Power Consumption

Fundamental momentum and energy analyses can be used to verify the relationships obtained by dimensional analysis. The theory might be of more general interest thus a brief outline is presented in this section.

#### 7.2.4.1 Radial Impeller Power Consumption

In this analysis the moment of a force with respect to an axis, namely, *torque*, is important. Although the linear momentum equation can be used to solve problems involving torques, it is generally more convenient to apply the angular momentum equation for this purpose. By forming the moment of the linear momentum and the resultant force associated with each particle of fluid with respect to a point in an inertial coordinate system, a moment of momentum equation that relates torque and angular momentum flow can be obtained.

Our starting point is the familiar Newton's second law for a single rigid particle:

$$\mathbf{f} = \frac{d(m\mathbf{v})}{dt} \quad (N) \quad (7.5)$$

The torque exerted by the force  $\mathbf{F}$  about a fixed point is [79]:

$$\mathbf{t} = \mathbf{r} \times \mathbf{f} \quad (Nm) \quad (7.6)$$

where  $\mathbf{r}$  is the radius vector from the fixed point to the point of application of  $\mathbf{r}$ .

From Newton's law of motion it is obvious that:

$$\mathbf{t} = \mathbf{r} \times \frac{d(m\mathbf{v})}{dt} \quad (Nm) \quad (7.7)$$

By convention the angular momentum vector  $\mathbf{h}$  is defined as the vector product of the radius vector to the particle and the linear momentum:

$$\mathbf{h} = \mathbf{r} \times (m\mathbf{v}) \quad (\text{kg m}^2/\text{s}) \quad (7.8)$$

Upon differentiating  $\mathbf{h}$  with respect to time, we get:

$$\frac{d\mathbf{h}}{dt} = \frac{d\mathbf{r}}{dt} \times m\mathbf{v} + \mathbf{r} \times \frac{d(m\mathbf{v})}{dt} = \mathbf{r} \times \frac{d(m\mathbf{v})}{dt} \quad (7.9)$$

The first term on the RHS vanishes because the cross product of two parallel vectors is zero (i.e.,  $m d\mathbf{r}/dt \times \mathbf{v} = m\mathbf{v} \times \mathbf{v} = 0$ ).

This relation expresses that the rate of change of angular momentum of a particle about a fixed point is equal to the torque applied to the particle ([94], p. 130 and pp. 158–159):

$$\mathbf{t} = \frac{d\mathbf{h}}{dt} \quad (Nm) \quad (7.10)$$

A similar analysis can be applied to a material control volume. If  $O$  is the point about which moments are desired, the angular momentum about  $O$  for the given system is expressed by:

$$\mathbf{H}_O = \int_{V(t)} \rho(\mathbf{r} \times \mathbf{v}) dv \quad (\text{kg m}^2/\text{s}) \quad (7.11)$$

where  $\mathbf{r}$  is the position vector from  $O$  to the elemental volume  $dv$ , and  $\rho$  and  $\mathbf{v}$  are the fluid density and velocity of that element.

The torque on the material volume is then:

$$\mathbf{T}_O = \frac{D\mathbf{H}_O}{Dt} = \frac{D}{Dt} \int_{V(t)} \rho(\mathbf{r} \times \mathbf{v}) dv \quad (Nm) \quad (7.12)$$

We can now relate the system formulation to an inertial control volume formulation using the Reynolds transport theorem (see Appendix A):

$$\frac{D}{Dt} \int_{V(t)} \rho(\mathbf{r} \times \mathbf{v}) dv = \int_V \frac{\partial}{\partial t} [(\mathbf{r} \times \mathbf{v})\rho] dv + \int_A (\mathbf{r} \times \mathbf{v})\rho\mathbf{v} \cdot \mathbf{n} da \quad (Nm) \quad (7.13)$$

For an Eulerian control volume, (7.12) becomes:

$$\mathbf{T}_O = \frac{\partial}{\partial t} \int_V (\mathbf{r} \times \mathbf{v})\rho dv + \int_A (\mathbf{r} \times \mathbf{v})\rho\mathbf{v} \cdot \mathbf{n} da \quad (Nm) \quad (7.14)$$

This relation is referred to as the *angular momentum theorem*. The first term on the RHS represents the rate of change of angular momentum of the fluid contained in the control volume, and the second term represents the net flux of angular momentum leaving the control volume. The sum is equal to the total torque applied to the mass of fluid that is contained in the control volume at time  $t$ .

For steady flows where the only external torque is applied by a shaft, the angular momentum equation reduces to:

$$\mathbf{T}_{\text{Shaft}} = \int_A (\mathbf{r} \times \mathbf{v})\rho\mathbf{v} \cdot \mathbf{n} da \quad (Nm) \quad (7.15)$$

Furthermore, if there are only 1D inlets and outlets, the angular momentum flux terms evaluated on the control surface become:

$$\int_A (\mathbf{r} \times \mathbf{v}) \rho \mathbf{v} \cdot \mathbf{n} da = \sum (\mathbf{r} \times \mathbf{v})_{\text{Out}} \dot{m}_{\text{Out}} - \sum (\mathbf{r} \times \mathbf{v})_{\text{In}} \dot{m}_{\text{In}} \quad (7.16)$$

For 1D flows where the fluid enters the device at the radial location  $\mathbf{r}_1$  with a uniform absolute velocity  $\mathbf{v}_1$ , and leaving the pump at the radial location  $\mathbf{r}_2$  with a uniform absolute velocity  $\mathbf{v}_2$ , the relation reduces to:

$$T_{\text{Shaft}} = r_2 v_{\theta,2} \dot{m}_2 - r_1 v_{\theta,1} \dot{m}_1 \quad (Nm) \quad (7.17)$$

If the flow enters the impeller with purely axial absolute velocity, the entering fluid has no angular momentum and  $v_{\theta,1} = 0$ . The torque is then given by:

$$T_{\text{Shaft}} = r_2 v_{\theta,2} \dot{m}_2 = \rho Q r_2 v_{\theta,2} \quad (Nm) \quad (7.18)$$

This form of the angular momentum equation can be applied determining the dependence of torque on fluid pumping for a radial impeller. The control volume for radial flow impellers may be defined as a circular cylindrical volume encompassing the impeller plus some fluid surrounding the impeller. The fluid enters the impeller axially and exit radially. Tests have shown that the flow into the impeller has very little angular momentum. Therefore, only the flow exiting from the impeller must be considered for a radial impeller. The angular momentum balance (7.18) can be approximated as ([65], pp. 158–159; [83], pp. 413–414):

$$T_{\text{Shaft}} = r v_{\theta} \dot{m} = \frac{D}{2} v_{\theta} \dot{m} \quad (Nm) \quad (7.19)$$

where  $r$  has been set to  $D/2$ .

The mass flow rate  $\dot{m}$  is given by the radial component of the velocity exiting the impeller:

$$\dot{m} = \rho Q = \rho N_Q N D^3 = \rho \pi D H v_r \quad (\text{kg/s}) \quad (7.20)$$

The principal assumption required to link the angular momentum equation (7.19) and the continuity relation (7.20) is that the flow exiting the impeller is tangential to the blade attachment. Although this is not absolutely correct, it does make a reasonable first approximation [65]:

$$v_r = v \cos \phi \quad (7.21)$$

and

$$v_{\theta} = \pi N D - v \sin \phi \quad (7.22)$$

where  $\phi$  is the blade attachment angle,  $v$  is the fluid velocity parallel to the blade tip and  $H$  is the impeller blade height.

Combining the latter two equations, we can express the tangential component of the flow from the impeller in terms of the tip speed and the impeller flow:

$$v_\theta = \pi ND - v_r \tan \phi \quad (7.23)$$

Using the continuity relation (7.20), the radial component of the velocity can be expressed as a function of the impeller flow number:

$$v_r = \frac{N_Q}{\pi \frac{H}{D}} ND \quad (7.24)$$

Substituting the expressions found for the two velocity components (7.23) and (7.24) into the continuity (7.20) and the angular momentum balance (7.19) gives an expression for the dependence of torque on fluid pumping:

$$P = N T_{\text{Shaft}} = \pi^2 \rho N_Q N^3 D^5 \left(1 - \frac{N_Q}{\pi^2 \frac{H}{D}} \tan \phi\right) = N_P \rho N^3 D^5 \quad (W) \quad (7.25)$$

where

$$N_P = \frac{\pi}{2} N_Q \left(1 - \frac{N_Q}{\pi^2 \frac{H}{D}} \tan \phi\right) \quad (7.26)$$

The result deduced from the fundamental angular momentum equation coincides with the dimensional analysis. The fundamental equation provides additional information relating the dimensionless numbers  $N_P$  and  $N_Q$  to the impeller geometry.

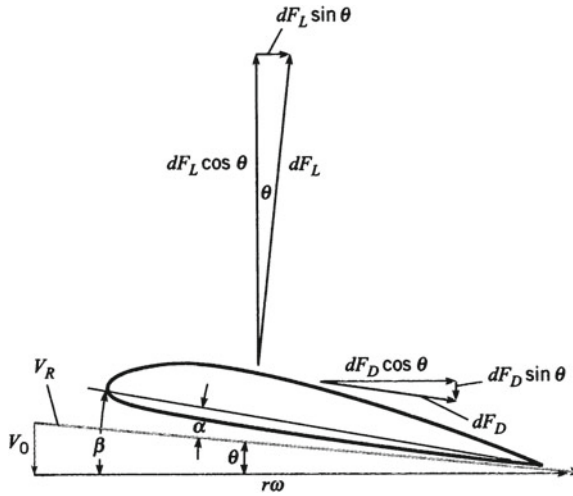

#### 7.2.4.2 Propeller Power Consumption: Angular Momentum Analysis

The design of an axial propeller is based on the fundamental principles of airfoil theory. The device use airfoil sections to change the fluid pressure in order to produce a force, and the change in pressure occurs because the fluid momentum changes. The problem can be described using either the angular momentum equation or the total energy equation. The angular momentum equation analysis is presented first, the approach using the total energy equation is discussed in the next subsection. For chemical engineers the latter approach may seem more physically intuitive.

To simplify the analysis, we assume that the flow into the impeller has no preswirl. Tests have shown that this preswirl is quite small for most cases. Because of the impeller geometry and airfoil coordinate system, the lift and drag terms contribute both to the axial thrust<sup>3</sup> and to the torque forces. The propeller of a boat or a airplane is designed to produce thrust, and since the greatest contribution to thrust comes from the lift force  $F_L$ , the design goal is to maximize lift and minimize drag,  $F_D$ . Since the angle of the blade decreases with an increase in  $r$ , for a well designed propeller the propeller blade must be warped in order to obtain the optimum angle of attack along the length of the blade. This make it very difficult to estimate the resulting velocity profile around the whole surface of the blade, and it becomes very difficult

---

<sup>3</sup> Thrust is defined as the propulsive force developed by a jet-propelled motor.

**Fig. 7.6** Definition sketch for a propeller-blade element.  $V_R$ : Velocity of fluid relative to propeller section.  $F_L$ : Lift force normal to  $V_R$ .  $F_D$ : Drag force acting parallel to  $V_R$ .  $V_0$ : Speed of airplane and propeller.  $V_t = r\omega$ : Tangential velocity resulting from propeller rotation.  $r$ : Radial position on propeller.  $\omega$ : Angular speed of propeller.  $\theta$ : Angle between  $V_t$  and  $V_R$ .  $\alpha$  and  $\beta$ : Angular measures. Reproduced from Crowe et al. [16] with permission from John Wiley & Sons, Inc

to apply the same procedure as for radial devices. To obtain a reasonable estimate of the torque for axial devices we are forced to use the more complex procedure integrating the moment of inertia over the rigid blade surface.

By definition (e.g., [16], Chap. 14), the lift is normal to the relative fluid velocity,  $v_{\text{Relative}}$ , and the drag is the force acting parallel to the same velocity, as sketched in Fig. 7.6. Thus one component of the lift force,  $dF_L \cos \theta$ , produces a positive thrust component,<sup>4</sup> and a component of the drag,  $dF_D \sin \theta$ , produces a negative thrust component:

$$dF_{\text{Thrust}} = dF_L \cos \theta - dF_D \sin \theta \quad (N) \quad (7.27)$$

In a similar manner, it can be shown that the tangential force for this blade element is given by:

$$dF_{\text{Tangential}} = dF_L \sin \theta + dF_D \cos \theta \quad (N) \quad (7.28)$$

The torque,  $T$ , opposing rotation of the propeller (and inducing fluid flow) is given by:

$$dT = r dF_{\text{Tangential}} = (dF_L \sin \theta + dF_D \cos \theta) r \quad (Nm) \quad (7.29)$$

Thus, the differential balance between the torque and the drag forces can be expressed as:

<sup>4</sup> The work done by the impeller on the fluid is equal to the thrust multiplied by the distance [83] (p. 423), as is discussed in the subsequent section.

$$dT = r dF_D \quad (Nm) \quad (7.30)$$

assuming that  $\theta$  is very small so that  $\cos \theta \approx 1$  and  $\sin \theta \approx 0$ .

The steady drag force on the impeller blade section can, as a first approach, be formulated as:

$$F_D = \frac{1}{2} C_D \rho U^2 A \quad (N) \quad (7.31)$$

where  $A$  is the projected area or surface area of the body,  $\rho$  is the density of the fluid and  $U$  is the relative velocity between the blade and the fluid.

Using the differential force balance, the differential torque is given as:

$$dT = r dF_D = \frac{1}{2} C_D \rho U^2 W r dr \quad (7.32)$$

where  $W dr$  is the projected area of the blade section, and  $C_D$  is the average drag coefficient of the blade section.

Equating the relative velocity of the fluid to the blade with the impeller rotational speed ( $U = Nr$ ), assuming no pre-swirl, yields:

$$dT = \frac{1}{2} C_D \rho N^2 W r^3 dr \quad (7.33)$$

Integrating over the impeller radius gives:

$$T = K \rho N^2 W R^4 \quad (7.34)$$

For geometrically similar systems, the impeller radius,  $R$ , and the blade width,  $W$ , are proportional to the impeller diameter,  $D$ .

The torque may thus be approximated by:

$$T = K'' \rho N^2 D^5 \quad (7.35)$$

The power draw yields:

$$P = NT \approx K''' \rho N^3 D^5 \quad (W) \quad (7.36)$$

since power draw is the product of torque and the impeller rotational speed.

For laminar flow a similar differential force balance, balancing the drag force on a blade section and the torque can be formulated. For creeping flow inertial forces are not important and viscous forces completely dominates the flow. The laminar steady drag force on the fluid can be written as  $F \propto \mu U D$ , where  $\mu$  is the fluid viscosity. Substituting  $U$  with  $\pi N D$  the power becomes  $P \propto \mu N^2 D^3$  or  $\frac{P}{\mu N^2 D^3} = K$ , where  $K$  is the Newton number for laminar flow.  $K$  can be rewritten as:

$$K = \frac{P}{\rho N^3 D^5} \times \frac{\rho N D^2}{\mu} = N_p Re \quad (-) \quad (7.37)$$

which shows that for laminar flow:

$$N_p \propto \frac{1}{Re} \quad (7.38)$$

This is in agreement with the observed change in power number under laminar flow conditions [87] (pp. 21–22).

### 7.2.4.3 Propeller Power Consumption: Kinetic Energy Analysis

The application of impellers in mixing vessels denotes a kind of turbomachinery.<sup>5</sup> The principal difference between the two units is the feedback response which results from the fluid being contained in a vessel [65]. This has a major effect on the pumping capacity, the power draw, and the mechanical loads experienced by the structure. Nevertheless, the same broad principles may be applied to predict the impact of impeller geometry changes on the flow and power.

Two theoretical approaches can be applied to predict the head, power, efficiency, and flow rate of a pump or impeller. One way is to apply a simple 1D Euler flow formulation, and the alternative way is to apply more complex 3D models which account for viscous effects. In this section the derivation of the steady state 1D power equation is examined, starting out from the general microscopic energy balance [94] (Sects. 3.6 and 11.2), [62] (Chap. 5) and [99] (Chap. 5).

As explained in Chap. 1, for a fixed control volume the first law of thermodynamics can be written:

$$\dot{Q} + \dot{W} = \frac{DE}{Dt} = \frac{\partial}{\partial t} \int_V \hat{E} \rho dv + \int_A \hat{E} \rho (\mathbf{v} \cdot \mathbf{n}) da \quad (7.39)$$

The total stored energy,  $\hat{E}$ , per unit mass is considered to be the sum of three terms:

$$\hat{E} = e + \frac{1}{2} v^2 + (-\mathbf{g} \cdot \mathbf{r}) \quad (7.40)$$

If  $z$  is defined positive upwards,  $\mathbf{g} = -g\mathbf{e}_z$  and  $(-\mathbf{g} \cdot \mathbf{r}) = (g\mathbf{e}_z \cdot \mathbf{r}) = gz$ , thus:

$$\hat{E} = e + \frac{1}{2} v^2 + gz \quad (7.41)$$

The molecular internal energy,  $e$ , is a function of  $T$  and  $p$  for a single phase pure substance, whereas the potential and kinetic energies are kinetic properties.

---

<sup>5</sup> Turbomachines are dynamic fluid machines that add (for pumps) or extract (for turbines) flow energy.

The heat and work transfer terms need to be examined in detail. In Chap. 1,  $\dot{Q}$  was divided into conduction and radiation effects. Here we leave this term untouched and consider the work term in further detail.

The work term (i.e., the work transfer rate,  $\dot{W}$ , also called power) can be divided into three parts:

$$\dot{W} = \dot{W}_{\text{Shaft}} + \dot{W}_{\text{Pressure}} + \dot{W}_{\text{Viscous stresses}} \quad (7.42)$$

The work of gravitational forces has already been included as potential energy. Other types of work, e.g., those due to electromagnetic forces, are excluded in this analysis.

The shaft work isolates that portion of the work which is deliberately done by a machine (e.g., pump impeller, fan blade, piston, agitation impeller, etc.) protruding through the control surface into the control volume.

The power required to drive the pump is:

$$P_{\text{Shaft}} = \dot{W}_{\text{Shaft, Pump}} = \Omega_{\text{Shaft}} T_{\text{Shaft}} \quad (7.43)$$

where  $\Omega_{\text{Shaft}}$  is the shaft angular velocity and  $T_{\text{Shaft}}$  denotes the shaft torque. When shaft torque and rotation are in the same direction, we are dealing with a pump, otherwise the given turbomachine is a turbine.

The rate of work,  $\dot{W}$ , done by pressure forces occurs at the surface only, all work on internal portions of the material in the control volume is by equal and opposite forces and is self-canceling. The pressure work equals the pressure force on a small surface element,  $da$ , times the normal velocity component into the control volume:

$$d\dot{W}_{\text{Pressure}} = (pda)v_{n,in} = p(-\mathbf{v} \cdot \mathbf{n})da \quad (7.44)$$

The total pressure work is the integral over the control surface:

$$\dot{W}_{\text{Pressure}} = - \int_A p(\mathbf{v} \cdot \mathbf{n})da \quad (7.45)$$

If part of the control surface is the surface of a machine part, one prefers to delegate that portion of the pressure to the shaft work term,  $\dot{W}_{\text{Shaft}}$ , not to  $\dot{W}_{\text{Pressure}}$ , which is primarily meant to isolate the fluid flow pressure work terms.

The shear work due to viscous stresses also occurs at the control surfaces, the internal work terms again being self-canceling, and consists of the product of each viscous stress (one normal and two tangential) and the respective velocity component:

$$d\dot{W}_{\text{Viscous stresses}} = (\boldsymbol{\sigma} \cdot \mathbf{n}) \cdot \mathbf{v}da \quad (7.46)$$

or

$$\dot{W}_{\text{Viscous stresses}} = \int_A (\boldsymbol{\sigma} \cdot \mathbf{n}) \cdot \mathbf{v}da \quad (7.47)$$

where  $(\boldsymbol{\sigma} \cdot \mathbf{n})$  is the stress vector on the elemental surface,  $da$ .

For all parts of the control surface which are *solid walls*,  $\mathbf{v} = 0$  from the viscous no-slip condition. Hence,  $\dot{W}_{\text{Viscous stresses}} = 0$  identically. If parts of the control volume surface denote the *surface of a machine*, the viscous work is contributed by the machine and should rather be absorbed in the term,  $\dot{W}_{\text{Shaft}}$ . At an inlet or outlet, the flow is approximately normal to the element  $da$ . Thus, the only viscous work term comes from the normal stress,  $\sigma_{nn}v_n da$ . Since viscous normal stresses are extremely small in most cases, it is customary to neglect viscous work at inlets and outlets of the control volume.

The net result of the above discussion is that the rate of work term essentially consists of:

$$\dot{W} = \dot{W}_{\text{Shaft}} - \int_A p(\mathbf{v} \cdot \mathbf{n}) da \quad (7.48)$$

Introducing these terms into the energy balance equation, we find that the pressure work term can be combined with the energy flux term since both involve surface integrals of  $(\mathbf{v} \cdot \mathbf{n})$ . The control volume energy equation thus becomes:

$$\dot{Q} + \dot{W}_{\text{Shaft}} = \frac{\partial}{\partial t} \int_V \hat{E} \rho dv + \int_A \left( \hat{E} + \frac{p}{\rho} \right) \rho(\mathbf{v} \cdot \mathbf{n}) da \quad (7.49)$$

The control volume surface integral can be expressed in terms of the enthalpy quantity,  $h = e + p/\rho$ . Then, the final form of the energy equation for a fixed control volume becomes:

$$\dot{Q} + \dot{W}_{\text{Shaft}} = \frac{\partial}{\partial t} \int_V \left( e + \frac{1}{2} v^2 + gz \right) \rho dv + \int_A \left( h + \frac{1}{2} v^2 + gz \right) \rho(\mathbf{v} \cdot \mathbf{n}) da \quad (7.50)$$

If the control volume has a series of 1D inlets and outlets, the surface integral reduces to a summation of outlet fluxes minus inlet fluxes:

$$\int_A \left( h + \frac{1}{2} v^2 + gz \right) \rho(\mathbf{v} \cdot \mathbf{n}) da = \sum \left( h + \frac{1}{2} v^2 + gz \right)_{\text{Out}} \dot{m}_{\text{Out}} - \sum \left( h + \frac{1}{2} v^2 + gz \right)_{\text{In}} \dot{m}_{\text{In}} \quad (7.51)$$

where the values of  $h$ ,  $\frac{1}{2} v^2$  and  $gz$  are taken to be averages over each cross section.

For steady flow with one inlet and outlet, both assumed 1D this equation further reduces to a relation used in many engineering analyzes. Let section 1 be the inlet and section 2 the outlet:

$$\dot{Q} + \dot{W}_{\text{Shaft}} = \sum \left( h + \frac{1}{2} v^2 + gz \right)_2 \dot{m}_2 - \sum \left( h + \frac{1}{2} v^2 + gz \right)_1 \dot{m}_1 \quad (7.52)$$

From continuity we find that,  $\dot{m}_{\text{In}} = \dot{m}_{\text{Out}} = \dot{m}$ , thus:

$$(h + \frac{1}{2}v^2 + gz)_1 = (h + \frac{1}{2}v^2 + gz)_2 - q - w_{\text{Shaft}} \quad (7.53)$$

where  $q = \dot{Q}/\dot{m} = dQ/dm$ , the heat transferred to the fluid per unit mass. Similarly,  $w_{\text{Shaft}} = \dot{W}_{\text{Shaft}}/\dot{m} = dW_{\text{Shaft}}/dm$ .

The steady flow energy equation states that the upstream stagnation enthalpy,  $H_1 = (h + \frac{1}{2}v^2 + gz)_1$ , differs from the downstream value  $H_2$  only if there is heat transfer or shaft work (i.e., neglecting viscous work) between section 1 and 2.

Each term in the latter equation has the dimensions of energy per unit mass, or velocity squared, which is a form commonly used by mechanical engineers. If we divide through by  $g$ , each term becomes a length, or a *head*, which is a form preferred by civil engineers. The traditional symbol for head is  $h$ , so we rewrite the head form of the energy equation in terms of internal energy:

$$(\frac{p}{\rho g} + \frac{e}{g} + \frac{v^2}{2g} + z)_1 = (\frac{p}{\rho g} + \frac{e}{g} + \frac{v^2}{2g} + z)_2 - h_q - h_{\text{Shaft}} \quad (7.54)$$

where  $h_q = q/g$  and  $h_{\text{Shaft}} = w_{\text{Shaft}}/g$  are the head forms of the heat added and shaft work, respectively. The term  $\frac{p}{\rho g}$  is called pressure head and the term  $\frac{v^2}{2g}$  is denoted velocity head.

A very common application of the steady flow energy equation is for low speed flow with no shaft work and negligible viscous work, such as liquid flow in pipes. For this case we may write the energy balance relation as:

$$(\frac{p}{\rho g} + \frac{v^2}{2g} + z)_1 = (\frac{p}{\rho g} + \frac{v^2}{2g} + z)_2 + \frac{e_2 - e_1 - q}{g} \quad (7.55)$$

The last term on the right is the difference between the available head upstream and downstream and is normally positive, representing the loss in head due to friction, denoted as  $h_{\text{Friction}}$ .

An important group of fluid mechanics problems involves 1D, incompressible, steady flow with friction and shaft work. Included in this category are constant density flows through pumps and agitators. Thus, in low speed incompressible flow with one inlet and one exit, we may assume that the previous observation that  $\frac{e_2 - e_1 - q}{g}$  equals the loss in head of available energy due to friction is still valid. Thus, we conclude that the energy equation can be expressed as:

$$(\frac{p}{\rho g} + \frac{v^2}{2g} + z)_2 = (\frac{p}{\rho g} + \frac{v^2}{2g} + z)_1 + h_{\text{Shaft}} - h_{\text{Friction}} \quad (7.56)$$

where  $h_{\text{Shaft}}$  is the head supplied and  $h_{\text{Friction}}$  the losses. This relation is sometimes called the mechanical energy equation or *the extended Bernoulli equation*.

If a turbine is in the control volume, the notation  $h_{\text{Shaft}} = -h_{\text{Turbine}}$  (with  $h_{\text{Turbine}} > 0$ ) is adopted. For a pump or an agitator in the control volume,  $h_{\text{Shaft}} = h_{\text{Pump}}$ . The quantity  $h_{\text{Turbine}}$  is termed the turbine head and  $h_{\text{Pump}}$  is the pump head. The loss term,  $h_{\text{Friction}}$ , is often referred to as head loss.<sup>6</sup>

The above equation may then be written in a more specific form:

$$\left(\frac{p}{\rho g} + \frac{v^2}{2g} + z\right)_2 = \left(\frac{p}{\rho g} + \frac{v^2}{2g} + z\right)_1 - h_{\text{Friction}} + h_{\text{Pump}} - h_{\text{Turbine}} \quad (7.57)$$

The  $h$ -terms are all positive, as friction loss is always positive in real flows, a pump adds energy, and a turbine extracts energy from the flow.

The loss term,  $h_{\text{Friction}}$ , is commonly correlated with flow parameters in pipes, valves, fittings, and other flow devices.

The pipe head loss may be calculated by the well known *Darcy-Weisbach equation* [93], valid for duct flows of any cross section and for laminar and turbulent flow:

$$h_{\text{Friction}} = f_D \frac{L}{d} \frac{v^2}{2g} \quad (7.58)$$

For laminar flow  $f_D$  can be found analytically,  $f_D = 64\mu/\rho vd$ , while for turbulent flows more approximate relations are used.

Assuming steady flow, the pump basically increases the Bernoulli head of the flow between point 1 and 2. Neglecting heat transfer, this change is denoted by  $H$ :

$$H = \left(\frac{p}{\rho g} + \frac{v^2}{2g} + z\right)_2 - \left(\frac{p}{\rho g} + \frac{v^2}{2g} + z\right)_1 = h_{\text{Pump}} - h_{\text{Friction}} \quad (7.59)$$

The net head  $H$  is a primary output parameter for any turbomachine. Usually  $v_1$  and  $v_2$  are about the same,  $z_2 - z_1$  is a meter or so, and the net pump head is essentially equal to the change in pressure head:

$$H \approx \frac{p_2}{\rho g} - \frac{p_1}{\rho g} = \frac{\Delta p}{\rho g} \approx h_{\text{Pump}} - h_{\text{Friction}} \quad (7.60)$$

The power delivered to the fluid yields:

<sup>6</sup> In other contexts, the turbine head is sometimes written as  $h_T = -(h_{\text{Shaft}} - h_{\text{Friction}})_T$ , where the subscript  $T$  refers to the turbine component of the contents of the control volume only. The quantity  $h_T$  is the actual head drop across the turbine and is the sum of the shaft work head out of the turbine and the head loss within the turbine. When a pump is in the control volume,  $h_P = (h_{\text{Shaft}} - h_{\text{Friction}})_P$  is often used where  $h_P$  is the actual head rise across the pump and is equal to the difference between the shaft work into the pump and the head loss within the pump. Notice that the  $h_{\text{Friction}}$  used for the turbine and the pump is the head loss within that unit only. When  $h_s$  is used in the extended Bernoulli equation,  $h_{\text{Friction}}$  involves all losses including those within the turbine, pump or compressor. When  $h_T$  or  $h_P$  is used for  $h_{\text{Shaft}}$ , then  $h_{\text{Friction}}$  includes all losses except those associated with the turbine or pump flows.

$$\begin{aligned}
 P &= \dot{W}_{\text{Pump}} - \dot{W}_{\text{Pump, Friction}} = \dot{m}g(h_{\text{Pump}} - h_{\text{Friction}}) \\
 &= (\rho vA)g(h_{\text{Pump}} - h_{\text{Friction}}) = \rho gQ(h_{\text{Pump}} - h_{\text{Friction}}) = Q\Delta p
 \end{aligned} \tag{7.61}$$

where the  $Q$  quantity in this relation is the volumetric flow rate.

The power draw (i.e., power transferred from the impeller to the fluid by the lift forces) will eventually dissipate to heat (through viscous dissipation in the fluid).

According to the z-component of the linear momentum equation, the thrust force from the impeller blade is balanced by the pressure difference over the pump [83] (p. 423):

$$F_{\text{Thrust}} = \Delta pA = \rho gHA \tag{7.62}$$

The lift force is usually expressed as [16] (p. 635):

$$F_{\text{Thrust}} = \frac{1}{2}C_L\rho U^2A \propto \frac{1}{2}C_L\rho(ND)^2A \tag{7.63}$$

Hence, the impeller power draw can be expressed as:

$$P = Q\Delta p \propto ND^3[\rho(ND)^2] = \rho N^3D^5 \quad (W) \tag{7.64}$$

Introducing a proportionality factor, the Newton number ( $N_P$ ), the following relation occurs:

$$P = N_P\rho N^3D^5 \quad (W) \tag{7.65}$$

This relation determining the dependence of power draw on fluid pumping is identical to the expression we found earlier using the torque analysis. This result should be expected as the mechanical energy balance is not independent of the momentum equations, they basically provide the same information.

### 7.3 Turbulent Mixing

The study of mixing includes understanding of how gas, liquid and solid phases are transported in the tank, and how this transport is affected by the tank and the impeller(s) geometry, as well as the operational conditions such as stirring rate and pumping capacity. Many elements must be taken into consideration designing mixing devices, basically determining the geometry and size of the tank, what type of impeller to use, the size of the impeller, the size and geometry of heat transfer equipment and if baffles are needed. Turbulent mixing includes phenomena on all scales in the turbulence spectra. For reactive mixtures the molecular scale phenomena are also pertinent. In the context of fluid mixing emphasis has been put on the scales assumed relevant to the process and to provide basic understanding of the controlling mechanisms of mixing. A common approach in practical reaction engineering is therefore to describe mixing on macro and micro scales only. Micro mixing is mixing

of individual molecules, while macro mixing is mixing of parcels, groups or aggregates of molecules. For a chemical reaction to take place, direct contact between the reacting molecules must be established. If the reactants  $A$  and  $B$  are introduced into an agitated tank, they will not react immediately because  $A$ -rich regions and  $B$ -rich regions are partially segregated in the tank. By means of shear from an impeller, a homogeneous mixture forms with time. However, before the fluids are completely mixed, reactions at different rates at different points in the reactor may occur, giving a non-uniform product, which may be unacceptable in an industrial process. In fact, this means that different fluid elements of one reactant do not experience mixing with the other reactant at a micro scale level at the same time. Therefore, for fast chemical reactions, an impeller producing high shear is recommended so that different reaction rates at different locations are avoided. The problems related to mixing of fluids are basically associated with fast reactions and all types of heterogeneous systems. Accordingly, for slow reactions, high shear mixing is not that important since the reactants have time to mix at a micro scale level in the whole tank volume before they react at all.

### ***7.3.1 Studies on Turbulent Mixing***

For non-reacting fluids the studies of turbulent mixing can be divided into three categories, the gross scale observations of the global flow pattern, fine scale analysis, and experimental studies on the whole turbulent energy spectra.

#### **7.3.1.1 Gross Scale Studies**

Gross-scale studies are concerned with the overall flow pattern in a tank with measurements of impeller pumping capacity and gross flow rate. Such studies can give qualitative and quantitative results good enough for initial selection of impeller type and may also provide information about the most advantageous design of the system. Circulation and mixing times are other important variables that may be determined in these studies.

#### **7.3.1.2 Fine Scale Studies**

Three different theoretical approaches have been established describing turbulent flows in general, as outlined in Sect. 1.2.7. These methods are the direct numerical simulations (DNS), large eddy simulations (LES), and the Reynolds average Navier-Stokes (RANS) approach.

Only a few LES simulations have been reported describing the turbulent flow in single phase stirred tanks (e.g., [18, 20, 77]). The lattice-Boltzmann method is used in the more recent publications since this scheme is considered to be an efficient

Navier-Stokes solver. Nevertheless, the computational requirements of these models are still prohibitive, therefore the application of this approach is restricted to academic research. No direct simulations of these vessels have been performed yet.

The Reynolds averaging approach has thus been found to represent a trade-off between accuracy and computational costs. Using the Reynolds averaging concept turbulence is interpreted as a waveform and described by the time averaged equations of motion and a turbulence closure. Two-equation turbulence models like the standard  $k$ - $\varepsilon$  and  $k$ - $\omega$  models are common but full Reynolds stress models have also been applied in rare cases.

For model validation measurements of instantaneous-, time average-, and fluctuating velocities, and turbulence energy are required.

### 7.3.1.3 Experimental Studies on the Turbulence Energy Spectra

In this method correlations between various velocity fluctuations are used to determine the turbulent energy spectrum,  $E(k)$ , and several turbulence length scales. The correlations mentioned contain information about how velocities and other flow properties are statistically related in the turbulent flow. Turbulence measured at a fixed point can be described as a fluctuating waveform. If two instantaneous waveforms appear to have a corresponding behavior, they are said to be correlated. Equation (1.317) shows how velocity fluctuations at two points can be statistically correlated if the distance between the two points is small. The velocity fluctuations  $v'_i(t, \mathbf{r})$  and  $v'_j(t, \mathbf{r} + \mathbf{x})$  are said to be correlated if  $R_{ij}(t, \mathbf{x})$  has a non-zero value, and uncorrelated if the Eulerian correlation tensor  $R_{ij}(t, \mathbf{x})$  is zero. The  $R_{ij}(t, \mathbf{x})$  correlation can be normalized by introducing the rms velocity [8]. The Eulerian correlation function is defined by:

$$Q_{ij}(t, \mathbf{x}) = \frac{\overline{v'_i(t, \mathbf{r})v'_j(t, \mathbf{r} + \mathbf{x})}}{v_i^{\text{rms}}(t, \mathbf{r})v_j^{\text{rms}}(t, \mathbf{r} + \mathbf{x})} \quad (7.66)$$

By assuming isotropic turbulence the rms velocity components in all directions are equal, hence (7.66) becomes:

$$Q_{ii}(t, \mathbf{x}) = \frac{\overline{v'_i(t, \mathbf{r})v'_i(t, \mathbf{r} + \mathbf{x})}}{v_i^{\text{rms}}(t, \mathbf{r})v_i^{\text{rms}}(t, \mathbf{r} + \mathbf{x})} \quad (7.67)$$

To calculate  $Q_{ii}(t, \mathbf{x})$ , the  $v'_i$  terms must be determined. Therefore, the scalar function  $f(r)$  called the Eulerian correlation function for isotropic turbulence in Sect. 1.2.7, is introduced (e.g., [88], Chap. 8; [7], Chap. 8; [5], Sect. 3.4):

$$f(t, \mathbf{x}) = \frac{\overline{v'_p(t, \mathbf{r})v'_p(t, \mathbf{r} + \mathbf{x})}}{(v_p^{\text{rms}}(t, \mathbf{r}))^2} \quad (7.68)$$

in which the velocity fluctuations are measured in the direction  $p$  parallel to the vector of separation  $\mathbf{x}$ .

Using the velocity components in the direction normal to  $\mathbf{x}$ , another correlation function  $g(t, \mathbf{x})$  is defined:

$$g(r) = \frac{\overline{v'_n(x)v'_n(t, \mathbf{r} + \mathbf{x})}}{(v_n^{\text{rms}})^2} \quad (7.69)$$

As explained in Sect. 1.2.7, from these correlations the turbulent energy spectra, and the micro and macro scales can be calculated. The values of the different correlations are determined experimentally by measuring mean velocities and velocity fluctuations at different locations in the agitated tank.

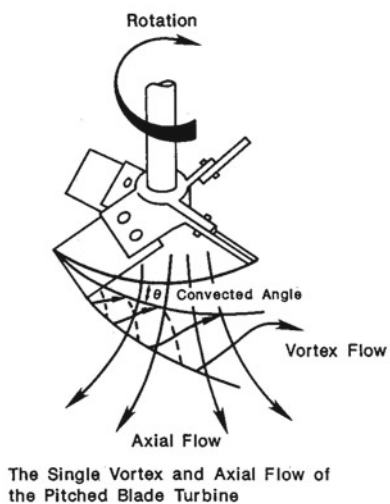

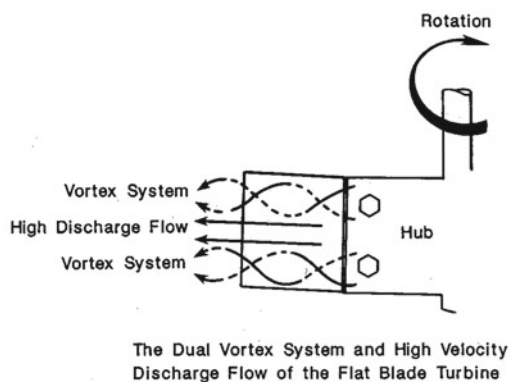

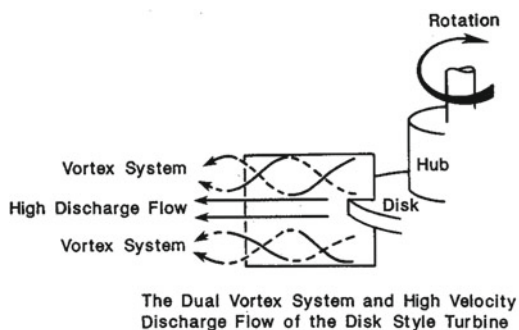

In Sect. 1.2.7 we showed that the dynamics of the one-point velocity correlation,  $\overline{v'_i v'_j}$ , for incompressible flows, can be expressed by four transport equations [41] (p. 323). The analogous transport equation for the dynamics of the two-point velocity correlation,  $\overline{(v'_i)_A (v'_j)_B}$ , for the general case of inhomogeneous, non-isotropic turbulence can be formulated based on the equations for the fluctuating velocity components (i.e., obtained by subtracting the time averaged equation of motion from the corresponding instantaneous equation) referring to point  $A$ , multiplied by the fluctuating velocity component  $(v_j)_B$ , referring to point  $B$ . A similar equation can be formulated based on the equation for the fluctuating velocity components referring to point  $B$ , multiplied by  $(v_j)_A$ . The equation for  $Q_{ij}(r)$  is obtained by adding these two equations. The equation for the two-point velocity correlation predicts the energy transport by means of the velocity fluctuations between the two points  $A$  and  $B$ . In other words, it describes how the turbulence energy is spread out over different eddy sizes and the transfer mechanisms of the energy exchange through the energy cascade. By taking the Fourier transform of this equation, the equation for the energy spectrum  $E(k)$  is obtained ([8, 41]). A typical energy spectrum with essential features is illustrated in Fig. 1.6. The physics represented by the spectra is explained in Sect. 1.3.2.

Several length scales of turbulence can also be determined from the measured correlation functions. The Eulerian length scales obtained from  $f(t, \mathbf{x})$  and  $g(t, \mathbf{x})$  are the longitudinal and transverse integral scales (1.318) and (1.319), respectively. These length scales are characteristics of the larger turbulence vortices in the flow. The Taylor micro scales of turbulence can be calculated from the same functions  $f(t, \mathbf{x})$  and  $g(t, \mathbf{x})$  using (1.323) and (1.325), respectively. However, the resulting scales do not characterize any distinct group of turbulence vortices and are thus not very useful in describing micro mixing in stirred tanks. Instead, the Kolmogorov micro-scales (1.334)–(1.336) characterize the dissipation scales of turbulence and might indicate the effectiveness of micro-mixing in the flow provided that the turbulent energy dissipation rate and the kinematic viscosity of the fluid is known. If the Kolmogorov micro length scale is much larger than the molecular scales, the molecules are not efficiently mixed by turbulent diffusion.

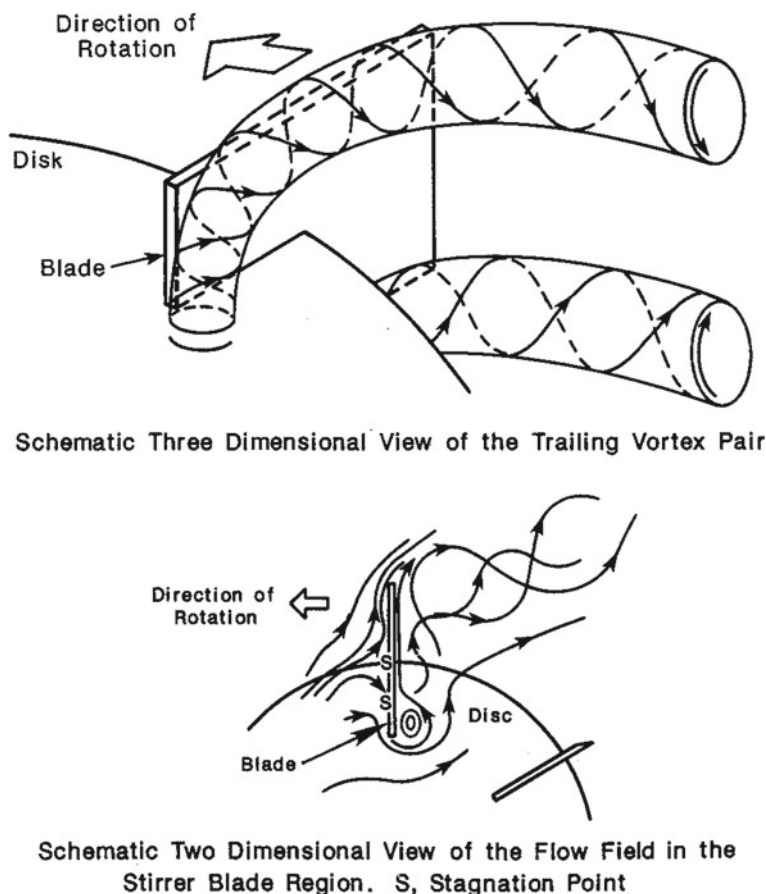

The mean energy dissipation rate can be calculated directly from the energy spectrum using (1.338). Moreover, for isotropic turbulence, the energy dissipation rate and the micro scale are related as expressed by (1.329). Caution is required using the dissipation rate calculated from a turbulence model like the  $k$ - $\varepsilon$  model as in this model the dissipation quantity is merely a tuning variable for the shear stresses in a pipe and not necessarily a true physical dissipation rate. The latter approach requires validation for any applications.

### 7.3.2 Flow Fields in Agitated Tanks

The flow fields in agitated tanks with different geometry and impellers have been studied by many researchers. Qualitative and quantitative observations have been reported for the discharge flow from the impeller, the flow near and around impeller and the flow in the bulk of the tank. The flow field is generally affected by impeller and tank geometry, number of blades, liquid height and fluid properties. Most studies of flow fields have been performed for a standard tank geometry. In most investigations the discharge flow from a Rushton turbine in a baffled tank is considered, but also the discharge flow from pitched blade turbines, propellers and open flat blade turbines have been studied. The discharge flow patterns for three different impellers are illustrated in Fig. 7.7. The discharge flow from a Rushton turbine is characterized by two trailing vortices at the top and bottom of the blade, and a strong radial discharge flow in the middle. This pattern is discharged continuously, but a periodicity is observed. Away from the blade the pattern is disrupted, causing a significant increase in turbulent velocity fluctuations. The most efficient mixing occurs at the location where the discharge flow meets the bulk flow [87]. The magnitude of the maximum velocity in the profile is comparable with the impeller tip velocity,  $v_t$ . Experiments show that the radial discharge velocity profile is not symmetrical around the radial centerline. The strong periodicity in the discharge flow velocity near the blade is caused by the trailing vortices shed by the impeller. In these vortices, the circumferential velocity is of the order of the impeller tip velocity,  $v_t$ , and the diameter of a vortex is about half the blade width  $W$ . Vortices are found to exist all the way to the tank wall, but they do decay with radial distance from impeller. The energy spectrum usually have a peak at the blade passing frequency, as shown by Mujumdar et al. [61]. As the distance from the impeller increases, this peak weakens rapidly. This peak may be due to the presence of trailing vortices, but also influenced by the characteristic periodic component of the impeller discharge flow. Experiments have also shown that the local energy dissipation rates decrease with radial distance from the impeller blade tip. The discharge flow from a flat blade turbine (i.e., a paddle) is shown in Fig. 7.7. The flow is similar to the flow from a disk style turbine, however, the flow pattern from the flat blade turbine is not as stable as that from the disk style turbine due to the absence of the disk. As for the Rushton turbine, the discharge flow is not symmetrical around the centerline of the blade. The energy spectra for the open flat

**Fig. 7.7** The flow patterns around turbulent impellers [87]. By permission from Tatterson (personal communications 2006)

**Fig. 7.8** The vortex system generated by a Rushton turbine [90]. Reprinted with permission from Elsevier

blade turbine has a peak at the blade passing frequency, in addition to the standard  $-5/3$  and  $-7$  regions.

The flow pattern from a pitched blade turbine is shown in Fig. 7.7. The flow pattern is dominated by a large axial flow through the impeller. This pumping does not provide any mixing of the fluid, but the mixing is accomplished by the vortex system formed from the blade tip. The flow from the pitched blade turbine spreads out both axially and radially. The flow pattern developed by a propeller is quite similar to that produced by the pitched blade turbine, but in the propeller discharge mostly axially.

Studies on the velocity flow fields near and around the impeller have primarily been focused on the turbulence structures and the behavior of the trailing vortices [90]. A trailing vortex system generated by a disk style turbine is shown in Fig. 7.8.

As can be seen from the figure, vortices along the top and bottom of the blade are formed. The centrifugal force of the blade throws the fluid outwards as the blade moves forward. This creates a mass deficit which causes the formation of a jet (the discharge flow) and the trailing vortices. The trailing vortices are continuously generated behind the blade, and upon leaving the blade, they have a short duration time before they break up. Upon exiting the blade, the vortex turns tangentially due to strong Coriolis forces. The axis of a vortex is not stationary from one blade passage to the next blade passage, but moves around in an erratic behavior. The flow pattern around a pitched blade turbine is something similar to that for a Rushton turbine illustrated in Fig. 7.8.

### 7.3.3 Circulation and Mixing Times in Turbulent Agitated Tanks

Circulation times are measures of the average bulk fluid motion generated by the liquid pumping of the impeller in a stirred tank. Measurements of circulation and mixing times help us to understand the scalar transport in the tank. Circulation times are associated with the tank's total volumetric flow rate, entrainment flow, and the pumping capacity of the impeller. The mean circulation time,  $\theta_c$ , is given by the total tank volume divided by the pumping capacity [64, 87]:

$$\theta_c = \frac{V}{Q} \quad (7.70)$$

The mean circulation time represents an average value for all the fluid elements in the tank and provide information on how fast the fluid parcels are transported around in the tank.

Mixing times are fundamental knowledge in reactor design and scale-up. Mixing times tell us when the whole tank volume is ideally mixed, or when a non-uniform system is made uniform. Generally, the impeller region is well mixed while the bulk fluid is not. To be able to mix all the bulk fluid of a tank, several tank volumes have to pass the impeller. Hence, the mixing time is usually considerably longer than the mean circulation time. To ensure sufficient mixing, the mixing time has to be shorter than the residence time of the species in the tank. The average residence time of material in a tank is often considered to be the active volume of the tank divided by the volumetric flow rate. The differences between the residence and circulation times depend on the volumes of stagnant dead zones in the tank.

The number of revolutions needed to accomplish mixing is a function of the tank geometry, the impeller geometry, and of the rotational speed of the impeller. For a given geometry the relationship between impeller rotational speed and mixing time can be approximated as:

$$N\theta_m = K \quad (7.71)$$

where  $\theta_m$  is the mixing time,  $N$  the impeller speed and  $K$  a constant determined by the geometry and the size of the tank.

The mixing time is especially important upon scale-up since a larger tank will increase the mixing time, while a larger impeller will reduce the mixing time. These effects might be taken into account through the  $K$  function in (7.71) provided that a appropriate parameterization is available. The main parameters affecting the mixing times are the impeller rotational speed, the impeller and tank diameters, and the presence of baffles [87]. The mixing time is also affected by the presence of multiple impellers. However, for such vessel designs there are inconsistent mixing performance trends reported in the literature, so the mixing times need to be determined experimentally for each application.

### 7.3.4 Turbulent Reactive Flow in Stirred Tank

Turbulent reacting flow modeling is complicated by the fact that these flows contain a wide range of time and length scales (e.g., [25, 26, 71]; [2], Chaps. 6–9). The rates of turbulent diffusion and convection (i.e., macro mixing) are controlled by the energy containing large scale eddies, generally several orders of magnitude larger than the molecular scale. Chemical reactions occur only if reactants are mixed on the molecular level. For non-premixed flows, molecular diffusion (i.e., micro mixing) occurs at intermediate and small scales and must occur before chemical reactions can take place. Because of computational limitations, it is impossible to include a detailed description of all scales of interest simulating industrial reactors. The unresolved phenomena such as micro mixing and chemical reactions must be modeled. Due to the non-linear nature of the chemical reaction terms in the mass balance equation, these simplifications can lead to large errors in the model predictions for turbulent flows. In order to formulate appropriate models for reacting flows, one must understand the complex interactions between turbulence, molecular diffusion, and chemical kinetics. In general, the modeling process for turbulent reacting flows involves at least three steps [25]:

1. Modeling of the molecular diffusion-chemical reaction processes to predict the local reaction rate.
2. Modeling of the turbulent field in enough detail to approximate the rate controlling steps of turbulent mixing.
3. Modeling of local turbulent mixing of the heat and species concentrations.

The relative importance of the specific physical phenomena mentioned strongly depends on the type of flow under consideration. In this section, the discussion is limited to single-phase, constant density flows under isothermal conditions with constant viscosity and equal diffusivities. The emphasis is placed on the modeling of turbulent mixing and on the interactions between turbulent mixing and chemical reactions in non-premixed turbulent reacting flows.

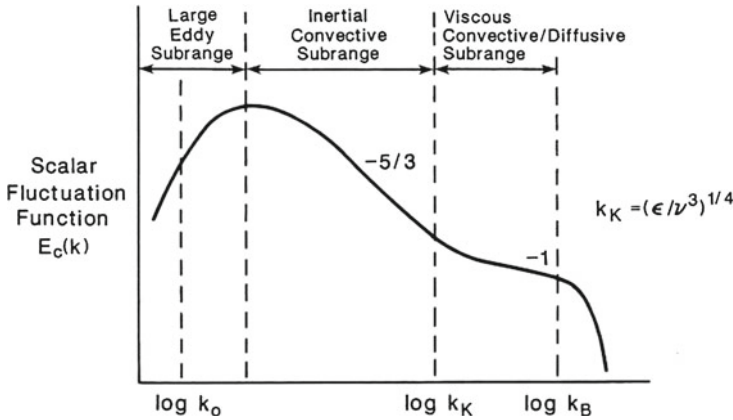

The velocity field in these flows is governed by the incompressible Navier-Stokes equation (1.391) and the corresponding continuity relation (1.388). For

incompressible fluids a generic transport equation for scalar species mass concentration fields can be deduced from (1.460) and expressed as:

$$\frac{\partial \omega_c}{\partial t} + \mathbf{v} \cdot \nabla \omega_c = D \nabla^2 \omega_c + S_{\omega_c} \quad (7.72)$$

In this equation  $D$  is the molecular diffusivity of binary systems, and  $S_{\omega_c}$  is the chemical source term for species  $c$ . The scalar fields are assumed to be passive scalars so that  $\omega_c$  has no significant influence on the momentum and continuity equations. After suitable non-dimensional variables are substituted into the equations, following the same procedure as outlined in Sect. 1.2.5, the important dimensionless groups are obtained for the problem in question. These are the Reynolds number, the Schmidt number, the Peclet number,  $Pe = Re Sc = ul/D$ , and the Damköhler number,  $Da_I = lr/u$ . The  $u$  and  $l$  are the characteristic velocity and length scales, respectively, for the velocity field, and  $r$  denotes a characteristic chemical reaction rate.

Turbulence models are generally limited to fully developed high-Reynolds number flows. Gas-phase flows are normally characterized by  $Sc \approx 1$ , while for liquid phase flows,  $Sc \gg 1$ . The value of this Damköhler number indicates the relative rates of the mixing and chemical reaction rate time scales. Reactive flows might thus be divided into three categories: Slow chemistry ( $Da_I \ll 1$ ), fast chemistry ( $Da_I \gg 1$ ), and finite rate chemistry ( $Da_I \approx 1$ ). The description of turbulent mixing of passive scalars is based on an extension of the turbulence theory developed for the momentum transfer processes, described in Sect. 1.2.7. In particular, the energy cascade idea introduced by Richardson [76] and the Kolmogorov hypotheses [47] are adopted. However, there are important differences between the velocity and the passive scalar spectra (e.g., [4, 8, 13, 14, 68]). The spectra of passive scalars also varies for different systems depending on the value of  $Sc$ . For large Reynolds number the kinetic energy spectrum of turbulence has the form  $E(k) \propto k^{-5/3}$  in inertial sub-range ranging from the energy containing integral scale  $k_0 = 2\pi/L$  to the Kolmogorov micro-scale  $k_K = (2\pi/\lambda_K) = 2\pi(\varepsilon/\nu^3)^{1/4}$ . Beyond the Kolmogorov micro scales the velocity spectrum has the form  $E(k) \propto k^{-7}$  [39, 80]. For mixtures where  $Sc \ll 1$ , the inertial convective subrange for passive scalars is specified by the wave number range  $k_{0,c} = 2\pi/L_c \ll k \ll k_C = 2\pi(\varepsilon/D^3)^{1/4}$ . The wave number of the largest scales for which the scalar has been spread out (i.e., the scale of segregation) is  $k_{0,c} = 2\pi/L_c$ . The integral scale of scalar segregation  $L_c$  can be estimated from an Eulerian scalar correlation function in analogy to the method used determining the integral scale of turbulence [8]. Since  $D \gg \nu$  the spectrum of concentration fluctuations in which  $E_c(k) \propto k^{-5/3}$  is not as extensive as the familiar inertial subrange for the velocity fluctuations [4, 8]. The scalar spectrum begins to fall off more rapidly at wave numbers near the Corrsin [13] micro-scale of turbulence  $k_C = 2\pi/\lambda_C = 2\pi(\varepsilon/D^3)^{1/4}$  as a result of larger effect of diffusion than of viscosity. For mixtures where  $Sc \approx 1$ , the inertial-convective subrange of a scalar quantity spectrum and the inertial subrange of velocity spectrum are of comparable extent and end at the Kolmogorov scale ( $k_K$ ). That is, in both spectra the inertial subrange is specified

**Fig. 7.9** The scalar spectrum in wave number space for systems in which  $Sc \gg 1$  [87]. By permission from Tatterson (personal communications 2006)

by the wave number range  $k_0 \ll k \ll (\epsilon/\nu^3)^{1/4}$ . Beyond the Kolmogorov scale both the scalar and velocity spectra fall off more rapidly than  $E \propto k^{-5/3}$  at the end of the inertia subrange as a consequence of molecular transport processes like viscosity and diffusion becoming important. For mixtures with  $Sc \gg 1$  the classical turbulence theory for scalar fields predicts that the scalar spectrum has a shape similar to  $E(k)$  for  $k < k_K$ . For  $k_K < k < k_B$ , the so-called Batchelor spectrum [4] is found for which  $E_c(k) \propto k^{-1}$ , and for  $k > k_B$ , the scalar spectrum falls rapidly towards zero due to the effect of scalar dissipation by molecular diffusion, as illustrated in Fig. 7.9. The Batchelor [4] wave number is of the order  $k_B \approx 2\pi(\epsilon/\nu D^2)^{1/4}$ . Molecular diffusion occurs near the Batchelor scale  $\lambda_B = (\frac{\nu D^2}{\epsilon})^{1/4} = Sc^{-1/2} \lambda_K$ , defining the end of the Batchelor spectrum where  $E_c(k) \propto k^{-1}$ .

For gases the Schmidt number is close to unity so that no special attention is required for the higher wave numbers. Turbulent reactive gas flows might thus be sufficiently described using the relatively simple gradient hypothesis with a constant Schmidt number. However, from the above discussion it can be concluded that for liquids ( $Sc \gg 1$ ) momentum is transported much faster than mass in the viscous region of the spectrum. Due to this observation, turbulent reactive gas and liquid flows are usually modeled differently, as special emphasis has to be put on the liquid mixing properties avoiding the gradient hypothesis [78].

By far the most widely employed models for turbulent reactive flows in stirred tanks are based on the Reynolds averaged Navier Stokes (RANS) equation. This is a moment equation containing quantities that are averaged over the whole wave spectra, as explained in Sect. 1.2.7. The Reynolds averaged equation for the scalar concentration fields can be deduced from (1.462) and written as:

$$\frac{\partial \bar{\omega}_c}{\partial t} + \bar{\mathbf{v}} \cdot \nabla \bar{\omega}_c = -\nabla \cdot (\bar{\mathbf{v}'\omega'_c}) + D_c \nabla^2 \bar{\omega}_c + \bar{S}_c(\omega) \quad (7.73)$$

Closure of the mean scalar field equation requires a model for the scalar flux term. This term represents the scalar transport due to velocity fluctuations in the inertial subrange of the energy spectrum and is normally independent of the molecular diffusivity. The gradient diffusion model is often successfully employed (e.g., [2, 15, 78]):

$$\overline{\mathbf{v}'\omega_c'} = -D_{t,ij}\nabla\overline{\omega_c} \quad (7.74)$$

where  $D_{t,ij}$  is a tensor that, in general, depends on the Reynolds stresses and mean velocity gradients.

Using the  $k$ - $\epsilon$  model this tensor reduces to:

$$\overline{\mathbf{v}'\omega_c'} = -D_t\nabla\overline{\omega_c} \quad (7.75)$$

in which  $D_t = \mu_t/Sc$  in accordance with the Reynolds analogy for turbulent flow. However, as discussed in Sect. 1.2.7, the gradient-diffusion models can fail because counter-gradient (or up-gradient) transport may occur in certain occasions [15, 85], hence a full second-order closure for the scalar flux (1.474) can be a more accurate but costly alternative (e.g., [2, 78]).

In scalar mixing studies and for infinite-rate reacting flows controlled by mixing, the variance of inert scalars is of interest since it is a measure of the local instantaneous departure of concentration from its local instantaneous mean value. For non-reactive flows the variance can be interpreted as a departure from locally perfect mixing. In this case the dissipation of concentration variance can be interpreted as mixing on the molecular scale. The scalar variance equation (1.468) can be derived from the scalar transport equation (e.g., [2], Sect. 6.4). The relation contains three unknown covariance terms that need to be closed. These are the scalar and scalar variance flux terms, and the scalar dissipation. The flux terms are often macroscopic in nature and are usually modeled by the gradient hypothesis. The scalar dissipation rate describes the decay of scalar variance due to molecular diffusion and thus depends on the smaller scales of turbulence. The determination of the scalar dissipation term is discussed by Pope [71] (Sect. 5.7.3). A simple closure for the scalar dissipation term, suggested by Spalding [84] (A.1–A.11), assumes that the scalar mixing time is proportional to the turbulence time  $\tau_\omega \propto \tau_t$ .

Hence, as a first approach we can approximate  $\varepsilon_\omega$  by:

$$\varepsilon_\omega = \frac{1}{2}C_\omega\overline{\omega'^2}/\tau_t \quad (7.76)$$

in which the decay time scale of the velocity fluctuations can be approximated by  $\tau_t = k/\varepsilon$ . The corresponding decay time scale of the scalar fluctuations is thus determined by  $\tau_\omega = \frac{1}{2}\overline{\omega'^2}/\varepsilon_\omega$ . The empirical constant  $C_\omega$  is usually taken to be 2.0. More advanced dynamic models for  $\varepsilon_\omega$  have also been proposed [25, 26, 60]. In these models a separate transport equation is formulated, modeled and solved numerically to predict this variable field.

The most difficult term to close in (7.73) is the reaction rate terms denoted by  $\overline{S_c(\omega)}$ . To simulate turbulent reactive flows accurate modeling of this term is very important. For slow reactions (i.e.,  $Da_I \ll 1$ ) the turbulent mixing is completed before the reaction can take place thus an adequate closure is available:

$$\overline{S_c(\omega)} = S_c(\bar{\omega}) \quad (7.77)$$

For very fast reactions local instantaneous chemical equilibrium might be assumed in the flow so that negligible turbulence-chemistry interactions prevail and the turbulence mixing behavior of a non-reactive but otherwise identical mixture can be adopted describing the evolution of the reactive process. The statistics of the reaction rate term can thus be predicted by the method of moments provided that an appropriate PDF for the turbulent mixing process is known. In this way the micro mixing models intend to restore some of the information that were lost in the averaging process. Such a procedure must require additional empirical information to determine the PDF. In particular, the mean concentration of the species can be calculated in terms of a presumed PDF estimated from a few of the lower moments of the local mixture fraction  $f$  (e.g., see [72], Chap. 12 and [2], Chaps. 6-9. The presumed PDFs are usually based on two moments, the mean mixture fraction  $\bar{f}$  and the variance about the mean  $\sigma^2 = \overline{(f')^2}$ . A typical presumed PDF can be represented by (i.e., the normal or Gaussian distribution):

$$\Phi(f) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(f - \bar{f})^2}{2\sigma^2}\right] \quad (7.78)$$

Other presumed PDFs exist as well. Each PDF has its own advantages and disadvantages, but none of them are generally applicable.

The use of the PDF is best illustrated by use of a simple example for a single irreversible second order reaction at isotherm conditions, defined by:

The corresponding reaction rate is given by:

$$r_{\text{products}} = k c_A c_B = \frac{k}{M_{wA} M_{wB}} \rho_A \rho_B \quad (7.79)$$

By performing Reynolds decomposition and time averaging the given reaction rate can be expressed as:

$$\overline{r_{\text{products}}} = k \overline{c_A c_B} = k(\overline{c_A} \overline{c_B} + \overline{c'_A c'_B}) \quad (7.80)$$

In general the covariance term is non-zero, hence  $\overline{r_{\text{products}}} \neq r_{\text{products}}(\overline{c_A}, \overline{c_B})$ , since the average reaction term is not determined by the mean concentrations alone.

A proper closure strategy for the reaction rate thus depends on the ratio of the rate of reactions and the rate of mixing. In the previous case, considering very slow reactions the concentration fluctuations decay to zero before the reactions occur and no turbulence modeling is needed. The other extreme involves infinitely fast reactions so that local instantaneous chemical equilibrium prevails everywhere in the mixture. If the rate constant is very large ( $k \rightarrow \infty$ ), the reaction rate can only be finite when  $\overline{c_A c_B} + \overline{c'_A c'_B} \approx 0$ .

The concentration of  $A$  and  $B$  can then be related to the PDF of a passive scalar or tracer. Consider again the instantaneous transport equations for  $A$  and  $B$ , assuming equal diffusivity of both species, constant total molar concentration and that the molar average and mass average velocities are about equal we get:

$$\frac{\partial c_A}{\partial t} + \mathbf{v} \cdot \nabla c_A = D_{AB} \nabla^2 c_A + r_A(c_A, c_B) \quad (7.81)$$

and

$$\frac{\partial c_B}{\partial t} + \mathbf{v} \cdot \nabla c_B = D_{BA} \nabla^2 c_B + r_B(c_A, c_B) \quad (7.82)$$

Subtracting the latter relation from the previous one, the source term can be eliminated and we obtain a transport equation for a conserved scalar which behaves as a non-reacting tracer:

$$\frac{\partial (c_A - c_B)}{\partial t} + \mathbf{v} \cdot \nabla (c_A - c_B) = D_{AB} \nabla^2 (c_A - c_B) \quad (7.83)$$

since  $r_B(c_A, c_B) - r_A(c_A, c_B) = 0$ .

By normalization, the mixture fraction is defined by:

$$f = \frac{c_A - c_B + c_{B0}}{c_{A0} + c_{B0}} \quad (7.84)$$

where  $c_{A0} + c_{B0}$  are the initial concentrations of the reactants  $A$  and  $B$  at the inlet and  $f$  is the mixture fraction denoting the normalized conserved scalar tracer. The mixture fraction is unity on the  $A$  inlet and zero on the  $B$  inlet.

The moment method states that given the probability density function  $\Phi$  of  $f$ , the average concentrations of the reactive scalars can be calculated by:

$$\frac{\overline{\rho_A}}{\rho_{A,0}} = \int_0^1 \frac{\rho_A(f)}{\rho_{A,0}} \Phi(f) df \quad (7.85)$$

$$\frac{\overline{\rho_B}}{\rho_{B,0}} = \int_0^1 \frac{\rho_B(f)}{\rho_{B,0}} \Phi(f) df \quad (7.86)$$

For the particular case of second-order kinetics the concentration covariance term is given by:

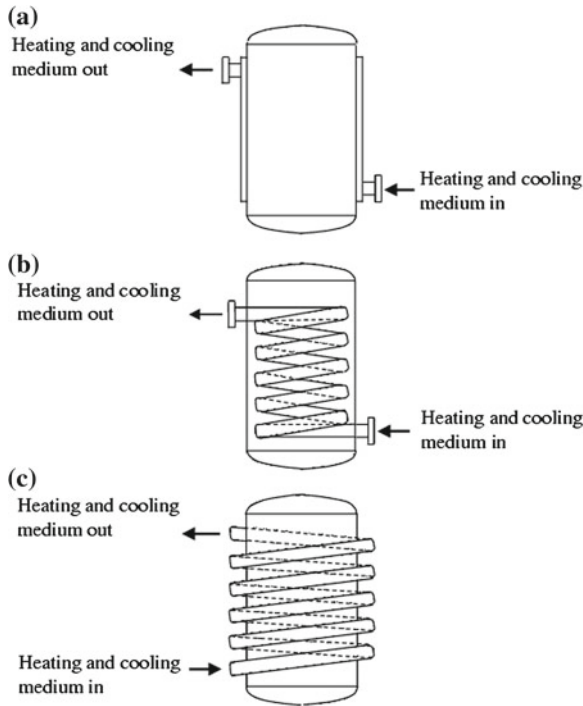

$$\overline{\rho'_A \rho'_B} = \int_0^1 \rho_A(f) \rho_B(f) \Phi(f) df \quad (7.87)$$

For instantaneous reactions the problem is thus reduced to the calculation of the presumed PDF of a passive scalar or tracer. A large number of alternative presumed PDFs have been listed and discussed by [2, 60, 67]. Each presumed PDF has its advantages and disadvantages, but none of them are generally applicable. The concept of the full PDF approaches is to formulate and solve additional transport equations for the PDFs determining the evolution of turbulent flows with chemical reactions. These models thus require modeling and solution of additional balance equations for the one-point joint velocity-composition PDF. The full PDF models are thus much more CPU intensive than the moment closures and hardly tractable for process engineering calculations. These theories are comprehensive and well covered by others (e.g., [2, 8, 26]), thus these closures are not examined further in this book. For finite rate chemical reaction processes neither of the asymptotic simplifications explained above are applicable and appropriate closures for  $\overline{S_c(\omega)}$  are very difficult to achieve.

The improvement in accuracy achieved by the complex closures compared to the simpler ones can also be questionable. Osenbroch [67] and Mortensen [60] successfully applied the combined particle image velocimetry (PIV)/planar laser induced fluorescence (PLIF) technique to measure the instantaneous velocity and reacting species concentration in mixing devices like a mixing channel, pipe, and multi-functional channel reactor. The measured data was used to validate computational fluid dynamics simulations of reactive flows adopting numerous scalar mixing closures. Based on these studies it can be concluded that further work is needed developing sufficient models for the prediction of the turbulence-chemistry interaction processes occurring in chemical reactors.

## 7.4 Heat Transfer in Stirred Tank Reactors

The temperature in stirred tank reactors may be influenced by chemical or physical reactions within the tank. Cooling or heating devices might be required to control the process temperature. In many endothermic processes heat has to be added to raise and maintain the temperature of the bulk. In other exothermic processes heat is removed to avoid hot spots. Heating and cooling of the process fluid are accomplished by heat transfer between the process fluid and a heating or cooling media that is circulated within a closed heat transfer surface. Different types of heat transfer equipment are used in industrial processes such as jackets, external or internal helical coils, as sketched in Fig. 7.10. Heat transfer from the bulk of the tank to the heat transfer medium can be calculated by the standard heat transfer model:

**Fig. 7.10** Different heat transfer equipment. **a** Vessel with jacket. **b** Vessel with internal helical coil. **c** Vessel with external helical coil

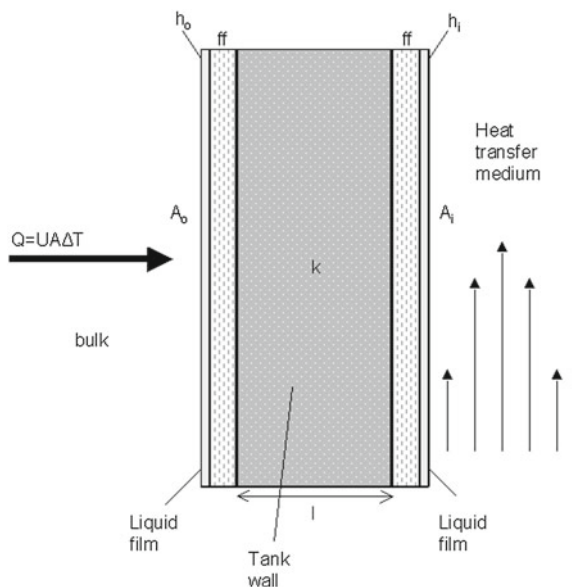

$$Q = U_0 A_0 \Delta T \quad (W) \quad (7.88)$$

where  $U_0$  is the overall heat transfer coefficient,  $A_0$  the heat transfer surface area and  $\Delta T$  the temperature driving force. An illustration of the heat transfer model is given in Fig. 7.11.

The overall heat transfer resistance ( $1/U_o$ ) is calculated as the sum of the individual resistances in analogy to Ohm's law. The relationship between the overall resistance and the different contributions is expressed as:

$$\frac{1}{U} = \frac{1}{h_o} + \frac{l}{k} + \frac{1}{h_i} \frac{A_o}{A_i} + ff \quad (Km^2/W) \quad (7.89)$$

where  $h_o$  is the convective heat transfer coefficient at the process side,  $l$  is the thickness of the tank wall,  $k$  is the conductivity of the wall material and  $h_i$  is the convective heat transfer coefficient at the heat transfer liquid side related to a common heat transfer area basis, and  $ff$  is a fouling factor accounting for corrosion or dirt films on either side of the heat transfer surface [65].

**Fig. 7.11** A sketch of the heat transfer flux model, determining the flux from the bulk of the tank to the heat transfer medium

The stirring and the resulting flow pattern inside the tank can be very important for the overall heat transfer resistance, because the performance of the reactor affects the heat transfer coefficient at the process side  $h_o$ . The other resistances are determined by the materials used and the properties of the cooling/heating media and are thus not influenced by the reactor performance. To determine the process side heat transfer coefficient,  $h_o$ , empirical correlations for many impeller types and tank geometries have been established. The parameterizations are generally expressed in terms of dimensionless numbers, geometrical ratios and viscosity ratios (see e.g., [23, 40, 65] and references therein).

## 7.5 Scale-up of Single Phase Non-reactive Turbulent Stirred Tanks

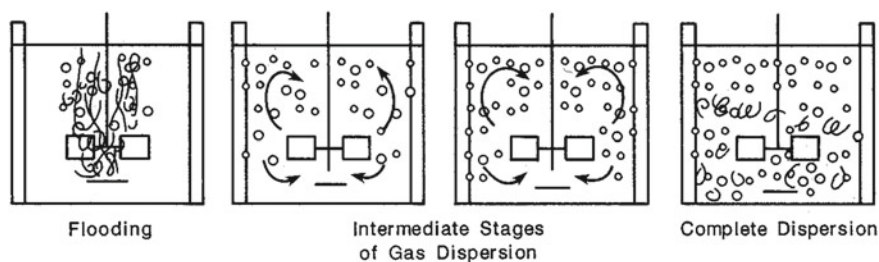

Mixing properties and flow fields in stirred tanks are usually studied on a laboratory scale. Practical scale-up of a stirred tank cannot be performed requiring that every individual mixing and fluid mechanical parameters in the small scale tank should be maintained in the larger one. Therefore, scale-up procedures for different types of processes have been determined through experience, testing and computational fluid dynamics simulations. Over the years several guidelines have been developed for the optimal scale-up of stirred tanks, usually reflected through the concepts of

geometric-, dynamic- and kinematic similarities [65]. *Geometric similarity* means that all the pertinent dimensions are similar and have a common constant ratio. *Kinematic similarity* requires that all the velocities at the two different scales have a common constant ratio. *Dynamic similarity* requires that all pertinent force ratios must have a common constant ratio.

The concepts of similarity suggest the use of dimensionless groups. There are, however, other process parameters that could be held constant. Such parameters could be, the blending time, the power per unit volume, the superficial gas velocity, the shear rates and the heat transfer coefficient. Which scale-up criteria that should be chosen depends on the actual process, since the sensitivity to each parameter appears to be different for the various processes. A general trend is observed which might be used as a rule of thumb. In a small tank the blending time is relatively short, the pumping capacity is relatively high, the average shear rate is relatively high, and a smaller range of shear rates is observed compare to what is found in larger tanks. To obtain a similar flow pattern in a large scale tank, the geometry must change. Larger volumes require taller vessels, but not an equally larger diameter. When taller vessels are applied, the need for multiple impellers arises in order to obtain turbulent mixing in the whole volume. When it comes to mixing in a laboratory scale unit, the content of the whole vessel is typically well mixed. At a larger scale, bulk mixing may be a problem. In a large tank, the fluid at the top of the vessel might participate irregularly in the general circulation. In the upper part turbulence is usually not well developed. However, experiments have shown that for fast reactions the product distribution can be unaffected by scale-up if the energy dissipation rate is held constant in the reaction zone. On the other hand, if local energy dissipation rate variations occur in the bulk, this may affect the micro mixing [87]. The integral length scales or macro scales of turbulence are generally of the same order of magnitude as the impeller blade width. In addition, the macro scale of turbulence is found to scale with the impeller size. This means that for a large scale vessel, larger eddies will form than in a small vessel. Consequently, large variations in velocities and concentrations can be expected in the vessel upon scale-up.

## 7.6 Mixing of Multi-Phase Systems

The previous sections describe how mixing is accomplished in a liquid phase. However, many industrial processes carried out in stirred tank reactors involve mixing of solids, gases and other liquids in a continuous liquid phase. The presence of a second phase will affect both the power consumption and the flow pattern in the tank. In the sequel, the mixing phenomena caused by the presence of gas bubbles, liquid droplets and solid particles are discussed.

**Fig. 7.12** Gas dispersion flow regimes [87]. By permission from Tatterson (personal communications 2006)

### 7.6.1 Gas-Liquid Dispersions

To disperse gas, the gas is usually injected into the liquid from the bottom of the tank or near the impeller to enhance dispersion. Disk style turbines are found to be most convenient for gas dispersion because the disk disturbs the freely rising gas bubbles. The turbines with flat blades give radial flow and are very useful for gas dispersion where the gas is introduced just below the impeller at its axis and drawn up to the blades and chopped into fine bubbles.

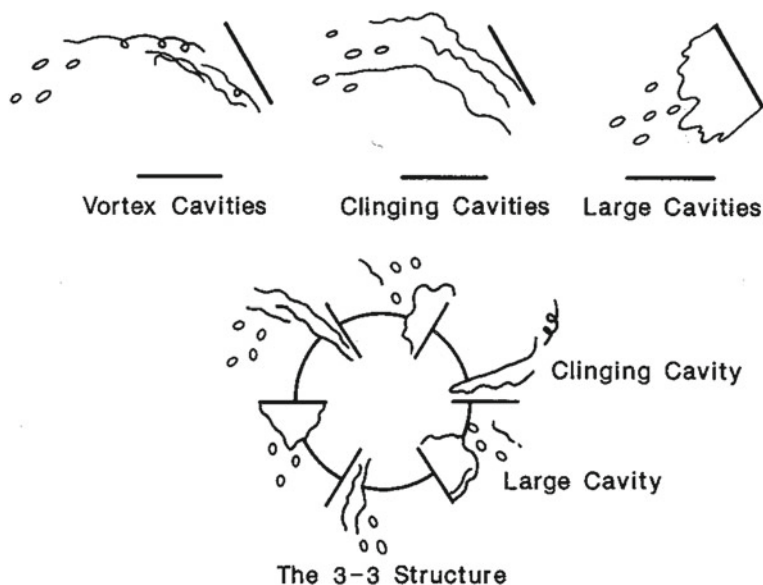

With axial flow impellers, the upward flowing gas bubbles are allowed to rise near the shaft where the shear forces are small, so that the flow pattern and pumping effect is disrupted. Therefore, axial flow impellers are not very useful for gas dispersion [65].

How gas disperses in the liquid phase depends primarily on the impeller speed and the gas injection rate. The different flow regimes that may occur are illustrated in Fig. 7.12.

The isothermal expansion power is the energy supplied to the system by the gas stream dispersing the gas in the liquid. When the power due to the impeller rotation is less than the isothermal expansion power of the gas, the flooded regime which is characterized by gas rising unhindered near the impeller shaft prevails. The distribution of gas in the tank is non-uniform. When the mixer power is approximately equal to the gas stream energy, a surface picture may indicate a well-dispersed uniform flow of gas bubbles leaving the liquid phase. However, in the bulk of the tank the gas flow dominates the flow pattern. Radial impellers will help to disperse the gas bubbles towards the walls of the tank as the gas rises. At a mixer power input of two to three times the gas stream energy, the flow pattern is controlled by the mixer [65]. If the mixer power is then increased to five times the gas expansion energy, the bubbles are driven down to the bottom of the tank, resulting in a completely uniform distribution of gas in the liquid phase.

Cavitation is a function of pressure drop occurring across the impeller blades, the fluid temperature and the vapor pressure of the fluid. If the fluid is near its boiling point, cavitation will occur with the turbulent impellers. Cavities are bubbles that are gathering behind the blades of a rotating impeller, these are characterized as

**Fig. 7.13** Different types of cavities in gas dispersion systems [87]. The 3–3 cavity structure consists of three large cavities and three clinging cavities in a symmetrical pattern around a six-blade disk style turbine. By permission from Tatterson (personal communications 2006)

vortex cavities, clinging cavities, large cavities and ragged cavities, and the 3–3 cavity structure. The different types of cavities are sketched in Fig. 7.13. Vortex cavities may occur at very low gas rates, while large cavities can be found at high gas rates. Ragged cavities are large cavities at flooded conditions, and clinging cavities are intermediately between vortex and large cavities. The 3–3 structure is typically formed on a disk style turbine.

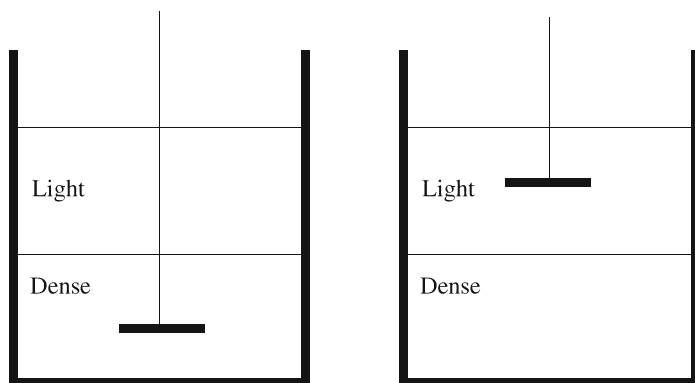

The purpose of most gas dispersion processes is to transfer gas into the liquid, sometimes to obtain a chemical reaction. The mass transfer rate across the gas–liquid interface can thus be the rate limiting step in the process, especially when the chemical reaction is fast. The rate of mass transfer is generally described by the mass transfer coefficients  $k_l$  and  $k_g$ , which are the coefficients for the liquid and the gas side, respectively. Usually, the gas side coefficient is neglected because the resistance to mass transfer on the liquid side is generally much higher than on the gas side.

The bubble size distribution is among the important factors controlling the interfacial mass transfer rate in gas liquid stirred tank reactors. This distribution is determined by a balance of coalescence and breakage rates. For this reason the trailing vortices play an important role in the gas dispersion processes in gas–liquid stirred tanks. This role stems from the vortex’s ability to capture gas bubbles in the vicinity of the impeller, accumulate them inside the vortex and disperse them as small bubbles in the vortex tail. This ability is related to the high vorticity associated with the rotation of the vortex. Sudiyo [86] investigated bubble coalescence in a 2.6 L stirred tank.

Instantaneous velocity fields were measured using PIV and corresponding turbulent kinetic energy, dissipation rate, various length and time scales were estimated. A shadowgraph technique was employed to measure the bubble size distribution and the coalescence rate. The results show that bubble coalescence takes place mostly near the tank wall, especially on the leeward side of baffles. Moreover, the most important factors affecting coalescence are the gas volume fraction, fluctuation of liquid velocity, different rise velocities of bubbles, and trapping of bubbles in stationary and turbulent vortices. Andersson [1] investigated the breakage mechanisms of bubbles in a stirred tank with a high-speed imaging technique. It was observed that bubbles tend to generate unequal sized fragments. The measurements also showed that binary bubble breakage is frequent.

### ***7.6.2 Liquid–Liquid Emulsions***

The dispersion of one liquid into another immiscible liquid occurs in the manufacture of many kinds of emulsion products. The design of a mixing equipment is usually based on experience with the type of product desired, and seldom upon model calculations of the actual drop sizes or interfacial areas. Reliable models for the drop size and interfacial area could be very useful as they may explain how changes in operating conditions or physical system variables will affect an operating system. However, it is very difficult in industrial applications to calculate the local drop sizes and drop size distributions. One of the difficulties is the wide variety of shear rates that exist in stirred tanks. The shear rate affects the droplet size, and since the shear rate near the impeller is much higher than the shear rate in the bulk, a distribution of droplet sizes result. In the shear rate zone around the impeller, the dispersing zone, the droplets are teared apart, while in the coalescing zone throughout the rest of the tank the droplets are interacting resulting in larger droplets [65]. This makes the determination of an average droplet size difficult. However, some empirical correlations have been proposed for design purposes. As the stirring speed increases, the peak in the distribution gets narrower and is moved towards smaller droplet sizes. This skewness in distribution is also a result of the interfacial tension between the two liquid phases. As the droplet size decreases, the interfacial tension is the dominating force. There is thus a minimum droplet size that can be achieved by the maximum shear stress near the impeller [33]. Andersson [1] investigated the breakage mechanisms of fluid particles with a high-speed imaging technique. Experiments of bubbles and droplets were made in the same vessel under identical operating conditions making a comparison between bubble and drop breakage dynamics possible. It was shown that bubbles tend to generate unequal sized fragments, whereas droplets form equal sized fragments. This difference was explained by an internal flow redistribution mechanism, active only for bubbles. The number of fragments produced upon breakage is also quite different for bubbles and droplets. For droplets breakage normally resulted in more than two fragments, whereas binary breakage is a common outcome for bubbles as mentioned in the previous section. When operating liquid–liquid systems, it

Light phase dispersed in dense phase. Dense phase dispersed in light phase.

**Fig. 7.14** Methods for dispersion of a light and a dense liquid phase

is important to know which one of the phases that is dispersed. If a tank is filled with 50 % of each phase, the result will depend on how the mixing is performed. For void fractions of 20 % of one liquid and 80 % of the other, one can be quite sure that the 20 % liquid will be dispersed because this phase could not possibly be the continuous phase.

Generally, to create a stable emulsion between a light and a dense liquid phase, the impeller should be placed in the phase which is going to be the continuous phase. With time, the other phase is then drawn into this phase. Figure 7.14 illustrates how to mix a light and a dense phase. There can be some practical problems dispersing the heavy phase in the light phase. If it is not sufficient to agitate in the light phase or optionally at the interface, it might be necessary to add the dense phase to the tank during agitation [65].

Like for gas–liquid dispersions, the liquid–liquid mass transfer flux is generally described by the mass transfer coefficient,  $k_l$ . One of the main factors limiting the mass transfer rate in industrial systems is impurities on the interface causing changes in the foam and settling characteristics of the system. Therefore, experimental data is always required to validate mass transfer models.

### 7.6.3 Solid–Liquid Suspensions

The suspension of solids in a liquid is perhaps the most common application of stirred tanks. Usually, the solid particles are denser than the carrying fluid resulting in continuous settling of the particles towards the bottom of the tank. To avoid permanent settling of solids and to obtain a satisfactory mass transfer flux to the solid surface, mixing is provided to keep the solids in suspension. To describe the solid–liquid suspension process, the settling velocity is one of the most important

parameters. The settling velocity of a particle is obtained by measuring the falling velocity of an unhindered particle. A drag force will act on the falling particle, as explained in Sect. 5.1.1. This force can be described by an empirical correlation for the drag coefficient (5.30). The drag coefficient changes with flow regime. As can be seen from Fig. 5.2, the drag coefficient decreases with increasing Reynolds number in the laminar regime, while it remains roughly constant under turbulent flow conditions. The solids are kept in suspension if the pumping capacity of the impeller causes strong enough circulation of the liquid. In most processes, complete suspension of the particles is not required. Often, so-called off-bottom suspension is sufficient, which means that all particles are moving above the bottom of the tank with some vertical velocity. Radial flow impellers are usually not very effective in suspending solid particles. Actually, about three times more power is required for a radial turbine to provide the same degree of uniformity compared to an axial turbine. This is because the radial turbines pick up particles from the bottom of the tank by the suction side of the impeller, which is only half of the total flow from the impeller. Due to the appearance of an upper and a lower circulation zone, the contents of the two zones are not sufficiently mixed. Axial impellers are therefore most frequently used for the suspension of solids in stirred tanks [65].

In solid–liquid systems the size and shape of the baffles are important design parameters. The standard baffling is illustrated in Fig. 7.1. As the solid concentration increases and the viscosity becomes high, narrower baffles (approximately  $1/24T$ ) placed a distance from the wall, should be used. This design is normally employed to avoid permanent settling of particles in the low velocity zones. In some processes such fillets (settled particles) can nevertheless be advantageous for the power consumption.

### 7.6.4 Gas–Liquid–Solid Systems

Some industrial processes involve mixing of both gases, liquids and solids. In slurry stirred tank reactors the liquid phase is the continuous phase where gas is dispersed and solid is suspended. In many of the processes performed in tank reactors, the purpose of fluid mixing is to dissolve the gas in the liquid and transport the species from the gas phase to the surface of the solid particles. In most chemical processes the solid particles act as catalysts to promote a chemical reaction. However, in a few processes, like in polymerization, the solid particles are the product of the reaction.

The choice of impeller for three-phase systems is a compromise between dispersing gas in the liquid and suspending the particles in the liquid. We recall that the axial-flow impellers are usually used for solid–liquid systems, while radial impellers are used for gas–liquid systems. Introducing gas from the bottom of a tank containing a solid–liquid suspension will destroy the flow pattern created by an axial impeller. Therefore, radial impellers are usually more effective in three phase systems even if they require more power for the same level of suspension [65]. Another solution is to apply multiple impellers, one to fulfill the criterion for gas dispersion and another

one to fulfill the criterion for solids suspension [87]. The existence of solid particles might also modify the interfacial area between gas and liquid compared to gas–liquid systems.

## 7.7 Governing Equations in Relative and Absolute Frames

In this section the governing equations employed in the different impeller model implementations are presented. The fictitious forces are conventionally derived with the help of the framework of classical mechanics of a point particle. Newtonian mechanics recognizes a special class of coordinate systems called inertial frames. The Newton's laws of motion are defined in such a frame. A Newtonian frame (sometimes also referred to as a fixed, absolute or absolute frame) is undergoing no accelerations and conventionally constitute a coordinate system at rest with respect to the fixed stars or any coordinate system moving with constant velocity and without rotation relative to the inertial frame. The latter concept is known as the principle of Galilean relativity. Speaking about a rotating frame of reference we refer to a coordinate system that is rotating relative to an inertial frame. The Laboratory framework is frequently assumed to be inertial and adequate for practical engineering problems on the earth although the laboratory framework is actually fixed to a rotating planet and is therefore strictly speaking an accelerated frame (i.e., this approximation is not valid for large scale ocean and atmospheric flows). To describe the fluid flow caused by the impeller motion in stirred tanks both rotating and laboratory frames have been employed. For completeness it is mentioned that the transformations between different sets of coordinates describing the same motion, characterize a branch of classical mechanics named kinematics which is fundamentally mathematical methods, and is not based on physical principles.

### 7.7.1 Governing Eulerian Flow Equations in the Laboratory Frame

The general equations of continuity (1.26) and momentum (1.86) in vector notation are introduced in Chap. 1 employing a Laboratory frame. To describe the flow in the stirred vessels the governing equations are conveniently transformed and written in cylindrical coordinates<sup>7</sup> (e.g., [6]; [34], p. 139 and p. 555; [10];[29]; [42], p. 73; [94], pp. 137–141):

*Continuity:*

$$\frac{\partial \rho}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r} (\rho r v_r) + \frac{1}{r} \frac{\partial}{\partial \theta} (\rho v_\theta) + \frac{\partial}{\partial z} (\rho v_z) = 0 \quad (7.90)$$

---

<sup>7</sup> The laboratory frame equations can also be obtained from the rotational frame formulation, if we let  $\Omega = 0$ .

*Momentum equation:*

The  $r$ -component:

$$\begin{aligned} \frac{\partial(\rho v_r)}{\partial t} + \frac{1}{r} \frac{\partial(r \rho v_r v_r)}{\partial r} + \frac{1}{r} \frac{\partial(\rho v_\theta v_r)}{\partial \theta} - \frac{\rho v_\theta v_\theta}{r} + \frac{\partial(\rho v_z v_r)}{\partial z} \\ = -\frac{\partial p}{\partial r} - \left( \frac{1}{r} \frac{\partial(r \sigma_{rr})}{\partial r} + \frac{1}{r} \frac{\partial \sigma_{\theta r}}{\partial \theta} - \frac{\sigma_{\theta \theta}}{r} + \frac{\partial \sigma_{zr}}{\partial z} \right) + \rho g_r \end{aligned} \quad (7.91)$$

The  $\theta$ -component:

$$\begin{aligned} \frac{\partial(\rho v_\theta)}{\partial t} + \frac{1}{r} \frac{\partial(r \rho v_r v_\theta)}{\partial r} + \frac{1}{r} \frac{\partial(\rho v_\theta v_\theta)}{\partial \theta} + \frac{\rho v_r v_\theta}{r} + \frac{\partial(\rho v_z v_\theta)}{\partial z} \\ = -\frac{1}{r} \frac{\partial p}{\partial \theta} - \left( \frac{1}{r} \frac{\partial(r \sigma_{r\theta})}{\partial r} + \frac{\sigma_{r\theta}}{r} + \frac{1}{r} \frac{\partial \sigma_{\theta \theta}}{\partial \theta} + \frac{\partial \sigma_{z\theta}}{\partial z} \right) + \rho g_\theta \end{aligned} \quad (7.92)$$

The  $z$ -component:

$$\begin{aligned} \frac{\partial(\rho v_z)}{\partial t} + \frac{1}{r} \frac{\partial(r \rho v_r v_z)}{\partial r} + \frac{1}{r} \frac{\partial(\rho v_\theta v_z)}{\partial \theta} + \frac{\partial(\rho v_z v_z)}{\partial z} \\ = -\frac{\partial p}{\partial z} - \left( \frac{1}{r} \frac{\partial(r \sigma_{rz})}{\partial r} + \frac{1}{r} \frac{\partial \sigma_{\theta z}}{\partial \theta} + \frac{\partial \sigma_{zz}}{\partial z} \right) + \rho g_z \end{aligned} \quad (7.93)$$

The nine components of the viscous stress tensor  $\sigma$  are given in App C and defined by:

$$\begin{aligned} \sigma_{rr} &= 2\mu \frac{\partial v_r}{\partial r} - \frac{2}{3}\mu \nabla \cdot \mathbf{v} & \sigma_{\theta r} &= \sigma_{r\theta} = \mu \left( \frac{1}{r} \frac{\partial v_r}{\partial \theta} + r \frac{\partial}{\partial r} \frac{v_\theta}{r} \right) \\ \sigma_{\theta \theta} &= 2\mu \left( \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right) - \frac{2}{3}\mu \nabla \cdot \mathbf{v} & \sigma_{zr} &= \sigma_{rz} = \mu \left( \frac{\partial v_r}{\partial z} + \frac{\partial v_z}{\partial r} \right) \\ \sigma_{zz} &= 2\mu \frac{\partial v_z}{\partial z} - \frac{2}{3}\mu \nabla \cdot \mathbf{v} & \sigma_{z\theta} &= \sigma_{\theta z} = \mu \left( \frac{1}{r} \frac{\partial v_z}{\partial \theta} + \frac{\partial v_\theta}{\partial z} \right) \end{aligned}$$

It turns out that two fictitious forces occur in the momentum equation when written in cylindrical coordinates. The term  $\rho v_\theta v_r/r$  is an effective force in the  $\theta$ -direction when there is flow in both the  $r$ - and  $\theta$ -directions. The term  $\rho v_\theta^2/r$  gives the effective force in the  $r$ -direction resulting from fluid motion in the  $\theta$ -direction. These terms do *not* represent the familiar Coriolis and centrifugal forces due to the earth's rotation.<sup>8</sup> Instead, they arise automatically on transformation of the momentum equations from Cartesian to cylindrical coordinates and are thus not added on physical grounds (kinematics). Nevertheless, the  $\rho v_\theta^2/r$  term is sometimes referred to as a Coriolis

<sup>8</sup> The virtual Coriolis and centrifugal forces due to the earth's rotation are normally added to  $g_\theta$  and  $g_r$ , as shown in (7.115).

force and the  $\rho v_\theta^2/r$  term is often called a centrifugal force. It is thus important to distinguish between the different types of fictitious forces.

### 7.7.2 Coriolis and Centrifugal Forces

In most textbooks the apparent forces, like the Coriolis and the centrifugal forces, are derived with the help of the framework of classical mechanics of a point particle. To examine the elementary mathematical operations involved in Newtonian mechanics, for example, we describe the motion of a material particle by the Newton's second law of motion. The Newtonian frame of reference adopted is henceforth named  $\mathbf{O}$ . The moving relative reference frame is designated  $\bar{\mathbf{O}}$ . The basic task is thus to transform the Newton's second law of motion as formulated in an inertial frame of reference into a relative rotating frame of reference.

Let the translative velocity (i.e., the relative movement without any rotating component) of the reference frame  $\bar{\mathbf{O}}$  relative to  $\mathbf{O}$  be designated  $\mathbf{v}_0$ , and the angular velocity of  $\bar{\mathbf{O}}$  relative to  $\mathbf{O}$  denoted by  $\boldsymbol{\Omega}$ , as sketched in Fig. 7.15. In the inertial frame in which  $\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z$  are fixed orthogonal unit vectors, we define the vector of rotation and the rotational acceleration vector (in the common  $x$ - $y$  and  $\bar{x}$ - $\bar{y}$  plane):

$$\begin{aligned}\boldsymbol{\Omega} &= \Omega \mathbf{e}_z \\ \dot{\boldsymbol{\Omega}} &= \dot{\Omega} \mathbf{e}_z\end{aligned}\quad (7.94)$$

where  $\mathbf{e}_z$  is the unit vector in the  $z$ -direction (which is common to both systems of reference since the axes  $z$  and  $\bar{z}$  are parallel and normal to the figure plan). The quantities  $\mathbf{r}_0(t)$ ,  $\mathbf{v}_0(t)$  and  $\mathbf{a}_0(t)$  are time dependent functions relative to  $\mathbf{O}$ .

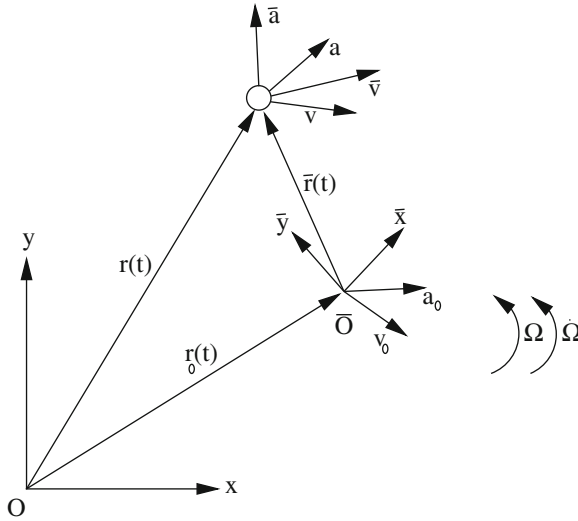

The vector  $\mathbf{r}$ , shown in Fig. 7.15, can be determined in both coordinate systems  $\mathbf{O}$  and  $\bar{\mathbf{O}}$ :

$$\mathbf{r} = \bar{\mathbf{r}} + \mathbf{r}_0 = r_x \mathbf{e}_x + r_y \mathbf{e}_y + r_z \mathbf{e}_z = \bar{r}_x \bar{\mathbf{e}}_x + \bar{r}_y \bar{\mathbf{e}}_y + \bar{r}_z \bar{\mathbf{e}}_z + \mathbf{r}_0 \quad (7.95)$$

A change of  $\bar{\mathbf{r}}$  with respect to time seen from  $\mathbf{O}$  then occurs as a result of both change of the components  $\bar{r}_x, \bar{r}_y$  and  $\bar{r}_z$  in the moving relative frame and change of the unit vectors  $\bar{\mathbf{e}}_x, \bar{\mathbf{e}}_y$  and  $\bar{\mathbf{e}}_z$ :

$$\begin{aligned}\dot{\bar{\mathbf{r}}} &= \frac{d(\bar{r}_x \bar{\mathbf{e}}_x)}{dt} + \frac{d(\bar{r}_y \bar{\mathbf{e}}_y)}{dt} + \frac{d(\bar{r}_z \bar{\mathbf{e}}_z)}{dt} \\ &= \frac{d\bar{r}_x}{dt} \bar{\mathbf{e}}_x + \bar{r}_x \frac{d\bar{\mathbf{e}}_x}{dt} + \frac{d\bar{r}_y}{dt} \bar{\mathbf{e}}_y + \bar{r}_y \frac{d\bar{\mathbf{e}}_y}{dt} + \frac{d\bar{r}_z}{dt} \bar{\mathbf{e}}_z + \bar{r}_z \frac{d\bar{\mathbf{e}}_z}{dt} \\ &= \bar{\mathbf{v}} + \boldsymbol{\Omega} \times \bar{\mathbf{r}}\end{aligned}\quad (7.96)$$

in which we have employed a set of predefined relations for the time derivatives of the unit vectors.

**Fig. 7.15** Visualization of vectors of location, velocity and acceleration in the inertial and moving reference frames

The time derivatives of the unit vectors referred above are defined by (similar to a planar movement of a solid body):

$$\frac{d\bar{\mathbf{e}}_x}{dt} = \boldsymbol{\Omega} \times \bar{\mathbf{e}}_x \quad (7.97)$$

$$\frac{d\bar{\mathbf{e}}_y}{dt} = \boldsymbol{\Omega} \times \bar{\mathbf{e}}_y \quad (7.98)$$

$$\frac{d\bar{\mathbf{e}}_z}{dt} = \boldsymbol{\Omega} \times \bar{\mathbf{e}}_z = 0 \quad (7.99)$$

These relationships can be derived recognizing that the unit vectors  $\bar{\mathbf{e}}_x$  and  $\bar{\mathbf{e}}_y$  in  $\bar{\mathbf{O}}$  are time dependent functions in  $\mathbf{O}$ , whereas  $\bar{\mathbf{e}}_z = \mathbf{e}_z$ .

A relation derived based on the same principles as used in (7.96) is valid for the velocity vector  $\bar{\mathbf{v}}$ :

$$\dot{\bar{\mathbf{v}}} = \bar{\mathbf{a}} + \boldsymbol{\Omega} \times \bar{\mathbf{v}} \quad (7.100)$$

From (7.95) we know that  $\mathbf{r} = \bar{\mathbf{r}} + \mathbf{r}_0$  (see Fig. 7.15). By derivation of the position vector with respect to time, and using (7.96), we find that the velocity vector  $\mathbf{v}$  can be expressed by:

$$\mathbf{v} = \dot{\mathbf{r}} = \dot{\bar{\mathbf{r}}} + \dot{\mathbf{r}}_0 = \bar{\mathbf{v}} + \boldsymbol{\Omega} \times \bar{\mathbf{r}} + \mathbf{v}_0 \quad (7.101)$$

By derivation of (7.101) with respect to time, followed by use of (7.96) and (7.100), the acceleration  $\mathbf{a}$  can be expressed in terms of  $\bar{\mathbf{O}}$ :

$$\begin{aligned}
\mathbf{a} = \dot{\mathbf{v}} &= \dot{\bar{\mathbf{v}}} + \frac{d\boldsymbol{\Omega}}{dt} \times \bar{\mathbf{r}} + \boldsymbol{\Omega} \times \dot{\bar{\mathbf{r}}} + \dot{\mathbf{v}}_0 \\
&= (\bar{\mathbf{a}} + \boldsymbol{\Omega} \times \bar{\mathbf{v}}) + \frac{d\boldsymbol{\Omega}}{dt} \times \bar{\mathbf{r}} + \boldsymbol{\Omega} \times (\bar{\mathbf{v}} + \boldsymbol{\Omega} \times \bar{\mathbf{r}}) + \dot{\mathbf{v}}_0 \\
&= \bar{\mathbf{a}} + 2\boldsymbol{\Omega} \times \bar{\mathbf{v}} + \frac{d\boldsymbol{\Omega}}{dt} \times \bar{\mathbf{r}} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \bar{\mathbf{r}}) + \mathbf{a}_0
\end{aligned} \tag{7.102}$$

We can now illustrate the fictitious modifications required employing a relative frame in Newtonian mechanics. The Newton's second law of motion in the initial (i.e., non-rotating) reference frame, is defined by:

$$m\mathbf{a} = \mathbf{f} \tag{7.103}$$

in which  $m$  is the mass of our point on the object, and  $\mathbf{f}$  is the non-fictitious force acting on it. Note that, if these forces are Galilean invariant, the force definitions are equivalent in both reference frames.

Making use of the relation (7.102) connecting the accelerations in the two frameworks, the apparent equation of motion of the point particle in the rotating reference frame takes the form:

$$m\bar{\mathbf{a}} = \mathbf{f} - m(2\boldsymbol{\Omega} \times \bar{\mathbf{v}} + \frac{d\boldsymbol{\Omega}}{dt} \times \bar{\mathbf{r}} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \bar{\mathbf{r}}) + \mathbf{a}_0) \tag{7.104}$$

A comparison of Eqs. (7.103) and (7.104) shows that the Newton's second law of motion in the inertial frame  $\mathbf{O}$  is identical in form to that in  $\bar{\mathbf{O}}$  except that the latter formulation contains several additional fictitious body forces. The term  $-2m\boldsymbol{\Omega} \times \bar{\mathbf{v}}$  is the Coriolis force, and  $-m\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \bar{\mathbf{r}})$  designates the centrifugal force. No name is in general use for the term  $-m\frac{d\boldsymbol{\Omega}}{dt} \times \bar{\mathbf{r}}$ . The acceleration  $-\mathbf{a}_0$  compensates for the translational acceleration of the frame.

### 7.7.3 Governing Eulerian Equations in a Rotating Frame

By use of the result obtained from Newtonian mechanics, relating the acceleration  $\mathbf{a}$  and  $\bar{\mathbf{a}}$ , we can convert (1.86), which is written in terms of  $\mathbf{O}$ , into a momentum balance as seen from an observer in  $\bar{\mathbf{O}}$ .

In fluid mechanics the time rate of change of a vector  $\boldsymbol{\psi}$  is then written as  $D\boldsymbol{\psi}/Dt = \bar{D}\boldsymbol{\psi}/\bar{Dt} + \boldsymbol{\Omega} \times \boldsymbol{\psi}$  in analogy to the result from classical mechanics. The above relation for the generalized vector  $\boldsymbol{\psi}$  is applied to a fluid parcel's position  $\mathbf{r}$  and then to its velocity  $\mathbf{v}$ , leading to the relation:

$$\frac{D\mathbf{v}}{Dt} = \frac{\bar{D}\bar{\mathbf{v}}}{\bar{Dt}} + 2\boldsymbol{\Omega} \times \bar{\mathbf{v}} + \frac{\bar{D}\boldsymbol{\Omega}}{\bar{Dt}} \times \bar{\mathbf{r}} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \bar{\mathbf{r}}) + \frac{D\mathbf{v}_0}{Dt} \tag{7.105}$$

Note that the rate of change of  $\boldsymbol{\Omega}$  is the same in the rotating frame as in an absolute frame [6].

Assuming that  $D\mathbf{v}/Dt$  is equal to the local force acting per unit mass on a fluid parcel, the apparent forces in the rotating frame are derived. The above derivation can be called a Lagrangian approach since it exploits the concept of the fluid parcel.<sup>9</sup> In this framework we define:

$$\mathbf{a} = \frac{D\mathbf{v}}{Dt} = \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \quad (7.106)$$

and

$$\bar{\mathbf{a}} = \frac{\bar{D}\bar{\mathbf{v}}}{\bar{D}t} = \frac{\partial \bar{\mathbf{v}}}{\partial t} + \bar{\mathbf{v}} \cdot \bar{\nabla} \bar{\mathbf{v}} \quad (7.107)$$

The momentum equation (1.86) in  $\mathbf{O}$  is then transformed from the flux form to the advective (non-flux) form:

$$\rho \left( \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) + \mathbf{v} \cdot \left( \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right) = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} \quad (7.108)$$

The two terms in the second bracket is zero in accordance with the continuity Eq. (1.26).

By use of (7.105) and (7.106), the substantial derivative in the inertial frame is transformed into the rotating framework:

$$\rho \left( \frac{\bar{D}\bar{\mathbf{v}}}{\bar{D}t} + 2\boldsymbol{\Omega} \times \bar{\mathbf{v}} + \frac{\bar{D}\boldsymbol{\Omega}}{\bar{D}t} \times \bar{\mathbf{r}} + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \bar{\mathbf{r}}) + \frac{D\mathbf{v}_0}{Dt} \right) = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} \quad (7.109)$$

The rate of deformation and the pressure are frame-indifferent (e.g., see [6], p. 141; [54], p. 400; [28, 31, 34]) so we can simply re-write the divergence operator and the stress terms into the rotating reference frame notation. The transformed momentum equation yields:

$$\rho \frac{\bar{D}\bar{\mathbf{v}}}{\bar{D}t} = \rho (-2\boldsymbol{\Omega} \times \bar{\mathbf{v}} - \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \bar{\mathbf{r}})) - \bar{\nabla} p - \bar{\nabla} \cdot \bar{\boldsymbol{\sigma}} + \rho \bar{\mathbf{g}} \quad (7.110)$$

It is common practice to omit the bars as it is now understood that the equation is formulated in the rotating reference framework.

Greenspan [31] outline the transformation of the Eulerian equations governing the motion of an incompressible viscous fluid from an inertial to a rotational frame. The transformation of the Navier-Stokes equations simply results in adding the artificial forces in the momentum balance. The additional equations are apparently not changed as the substantial derivative of scalar functions are Galilean invariant so the form of the terms do not change.

---

<sup>9</sup> Recently, an Eulerian derivation of the Coriolis force has been reported by Kageyama and Hyodo [45]. They present a general procedure to derive the transformed equations in the rotating frame of reference based on the local Galilean transformation and rotational coordinate transformation of field quantities.

Batchelor [6] and Ghil and Childress [28] examine the transformation of the governing Eulerian equations for compressible flows from an inertial to a rotational frame. As it turns out, only the momentum equation is actually effected by this transformation because the material or substantial derivative operator of scalar functions is invariant to rotation.

Of particular interest in the context of stirred tank reactor theory is the case of steadily rotating axes of reference ( $D\mathbf{\Omega}/Dt = 0$ ) without translating acceleration ( $D\mathbf{v}_0/Dt$ ). Equation (7.109) can then be written as:

$$\rho \frac{D\bar{\mathbf{v}}}{Dt} = \rho (-2\mathbf{\Omega} \times \bar{\mathbf{v}} - \mathbf{\Omega} \times (\mathbf{\Omega} \times \bar{\mathbf{r}})) - \nabla p - \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} \quad (7.111)$$

To describe the flow in a stirred tank the governing equations are often written in cylindrical coordinates,<sup>10</sup> as listed in Sect. 7.7.1. The remaining task is thus to transform these governing Eulerian equations formulated in an inertial Laboratory frame into a relative rotating frame of reference. We outline this procedure by examining the transformation of the momentum equation components (7.91)–(7.93).

In the common case of  $\mathbf{\Omega}$  consisting only of a z-component orthogonal to the vector  $\bar{\mathbf{r}}$ , we define:

$$\mathbf{\Omega} = \begin{pmatrix} 0 & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ \bar{\Omega} & \bar{\mathbf{e}}_z \end{pmatrix} \quad (7.112)$$

The fictitious body forces in cylindrical coordinates are thus written as:  
Coriolis force:

$$-2\mathbf{\Omega} \times \bar{\mathbf{v}} = -2 \begin{pmatrix} 0 & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ \bar{\Omega} & \bar{\mathbf{e}}_z \end{pmatrix} \times \begin{pmatrix} \bar{v}_r & \bar{\mathbf{e}}_r \\ \bar{v}_\theta & \bar{\mathbf{e}}_\theta \\ \bar{v}_z & \bar{\mathbf{e}}_z \end{pmatrix} = \begin{pmatrix} 2\bar{\Omega}\bar{v}_\theta & \bar{\mathbf{e}}_r \\ -2\bar{\Omega}\bar{v}_r & \bar{\mathbf{e}}_\theta \\ 0 & \bar{\mathbf{e}}_z \end{pmatrix} \quad (7.113)$$

Centrifugal force:

$$\begin{aligned} -\mathbf{\Omega} \times (\mathbf{\Omega} \times \bar{\mathbf{r}}) &= - \begin{pmatrix} 0 & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ \bar{\Omega} & \bar{\mathbf{e}}_z \end{pmatrix} \times \left[ \begin{pmatrix} 0 & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ \bar{\Omega} & \bar{\mathbf{e}}_z \end{pmatrix} \times \begin{pmatrix} \bar{r} & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ 0 & \bar{\mathbf{e}}_z \end{pmatrix} \right] \\ &= - \begin{pmatrix} 0 & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ \bar{\Omega} & \bar{\mathbf{e}}_z \end{pmatrix} \times \begin{pmatrix} 0 & \bar{\mathbf{e}}_r \\ \bar{\Omega}\bar{r} & \bar{\mathbf{e}}_\theta \\ 0 & \bar{\mathbf{e}}_z \end{pmatrix} \\ &= \begin{pmatrix} \bar{\Omega}^2 \bar{r} & \bar{\mathbf{e}}_r \\ 0 & \bar{\mathbf{e}}_\theta \\ 0 & \bar{\mathbf{e}}_z \end{pmatrix} \end{aligned} \quad (7.114)$$

<sup>10</sup> Hansen [34] gives an informative derivation of the momentum equations in cylindrical coordinates employing an inertial frame.

The components of these fictitious forces are usually added to the body force  $\mathbf{g}$  of momentum equation components (7.91)–(7.93). For the different components of the momentum equation we get:

$$\begin{aligned} g_r &= \left( \bar{\Omega}^2 \bar{r} + 2\bar{\Omega} \bar{v}_\theta \right) \\ g_\theta &= (-2\bar{\Omega} \bar{v}_r) \\ g_z &= -g \end{aligned} \quad (7.115)$$

For turbulent flows the governing equations are usually Reynolds averaged. The resulting models are often closed by employing the eddy viscosity hypothesis. In these cases the laminar viscosity in the viscous stress terms are substituted with an effective viscosity  $\mu_{eff} = \mu + \mu_t$ . Moreover, the eddy viscosity is normally calculated using a kind of  $k$ - $\epsilon$  model [50], as presented in Sect. 1.2.7. Using a rotating reference frame to model the impeller effects no additional covariance terms are occurring due to the fictitious terms.

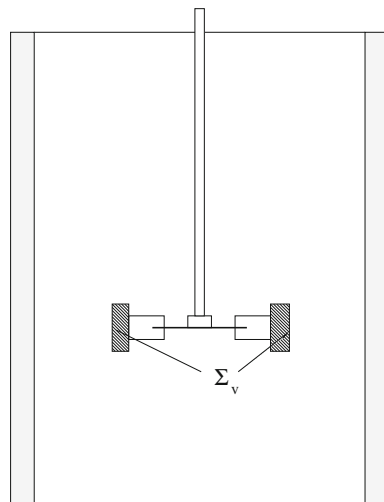

## 7.8 Impeller Modeling Strategies

In this section the different impeller modeling strategies employed simulating the flow fields in stirred tanks are examined.

### 7.8.1 The Impeller Boundary Conditions (IBC) Method

The IBC method represents the traditional way to model the effect of the impeller in a stirred tank reactor. Harvey and Greaves [37, 38] were among the first to apply this method. Pericleous and Patel [69] used this method to simulate both tangential and axial agitators in chemical reactors. It is also noted that Gosman et al. [30] simulated several two-phase flows in tanks stirred by Rushton turbines using a dynamic two-fluid model. However, the steady state condition is normally imposed and no moving reference frame, neither rotating nor translating, is considered. This means that all the transient terms, as well as the Coriolis- and centrifugal forces, vanish from the governing equations. Gravitation is the only body force considered. The rotating impeller is modeled by empirical boundary conditions being imposed on the surface of the impeller blades. For Rushton turbines, for example, empirical profiles for the physical quantities like  $v_r$ ,  $v_\theta$ ,  $v_z$ ,  $k$  and  $\epsilon$  as functions of  $z$  only (the method does not resolve the impeller region so only azimuthally uniform values are possible) were normally imposed on the vertical control surface  $\sum_v$  bounding the impeller-swept region in a stirred vessel [10], as illustrated in Fig. 7.16. The flow field in the impeller region is computed as in any other part of the computational domain.

**Fig. 7.16** Simulating the effect of a Rushton turbine on the flow one practice is to impose empirical profiles for the physical quantities like  $v_r$ ,  $v_\theta$ ,  $k$  and  $\epsilon$  on the vertical control surface  $\Sigma_v$  bounding the impeller-swept region in a stirred vessel [10]

The shaft, hub and disc of the Rushton turbine (see Fig. 7.16), excluding the impeller blades, are treated as solid volumes. For different impeller geometries (and in rare cases also for the Rushton turbine), the impeller region has been bounded by two surfaces, one horizontal and one vertical [73]. In order to reduce the computational efforts one may utilize symmetries in the problem so that only a part of the domain needs to be simulated, but the domain applied must still include at least one baffle. To determine appropriate boundary conditions for the impeller surface, experimental data are required. In fact the method relies on experimental data for each geometry and fluid in question. The need for such amounts of empirical information is the main limitation of the IBC method. Moreover, the reliability on the results of a simulation using the IBC method depends directly on the quality of the experimental data [10].

### 7.8.2 The Snapshot (SS) Method

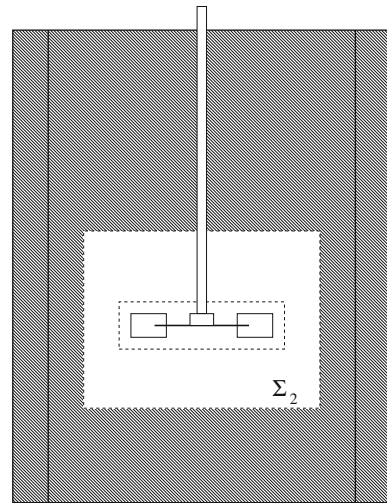

Ranade and Van den Akker [74] introduced the *snapshot* method for simulating flows in baffled stirred tanks. The snapshot method has many similarities with the traditional IBC method but differs in that the effect of the impeller rotation is approximately modeled mechanistically and not deduced from empirical data analysis solely. The snapshot method thus represents an early attempt to improve on the main limitation associated with the IBC method.

The basic idea is to describe a snapshot of the flow in a stirred vessel with a fixed relative position of blades and baffles. It is assumed that the main flow characteristics of a stirred vessel at the particular time instant in question can be captured approximately from the solution of the steady-state equations, provided that artificial cell

volume adjustments and momentum sources are implemented to represent the effect of the impeller rotation. A particular simulation of the flow is performed using a fixed reference frame for a specific blade position. The snapshot model equations are thus basically the same as those used in the traditional IBC method. The modeling of the effects of the impeller rotation on the flow is based on a simple analysis of the physical problem [75]. In particular, the blade rotation causes suction of fluid at the rear side of the blades and equivalent ejection of fluid from the front side of the blades. These dynamic phenomena in the impeller region are thus modeled approximately by including apparent volume corrections (i.e., net time average effects) in the continuity equation for the computational cells attached to the front and rear sides of the impeller blades. In addition, since the impeller blades are treated as stationary walls, additional momentum source terms (i.e., net time average effects) representing the effect of shear caused by the rotating impeller blades are implemented for the computational cells attached to the edges of the impeller blades. These momentum sources are estimated for the contact area between the cell and impeller blade using an adjusted turbulence wall function model. Furthermore, empirical information is required to quantify the size and location of the inner region where these artificial sources are needed. In the outer region the apparent effects of the transient terms are neglected as the flow is assumed to be in steady-state. Simulating the flow generated by a Rushton turbine the governing equations are usually solved for half of the vessel volume due to symmetry considerations. The standard boundary conditions are implemented at the stationary wall, for the impeller shaft, disc and hub, an angular velocity corresponding to the impeller rotation speed was specified. The top fluid surface is assumed flat and modeled as a wall. Cyclic boundary conditions were imposed at the open surfaces of the solution domain. Simulations of flows generated by different impellers have also been performed requiring appropriate changes in the boundary conditions and calculation domain. To achieve steady-state values for comparison with experimental data different calculations have to be carried out at different time instants representing an average for the different positions of the impeller blades relative to the baffles.

Ranade and Krishnan [75] reported an evaluation of the snapshot approach. It was concluded that the simulations captured most of the key features of near-impeller flows with fair accuracy. Ranade and Van den Akker [74], for example, used the snapshot method for simulating gas–liquid flows in baffled stirred tanks using a time after volume averaged two-fluid model for incompressible flows (as described in Sect. 3.3). These multiphase simulations also predicted the near-impeller flows with fair accuracy. Most important, the cavities due to the accumulation of gas in the low-pressure region behind the impeller blades were detected. Nevertheless, the artificial source term modeling approach has not been fully accepted as a predictive tool for simulating swirling flows. In one view the snapshot approach is not much better than the IBC method, because the artificial sources have to be validated for every case investigated requiring many costly experimental investigations. For this reason it will not be further assessed in this book.

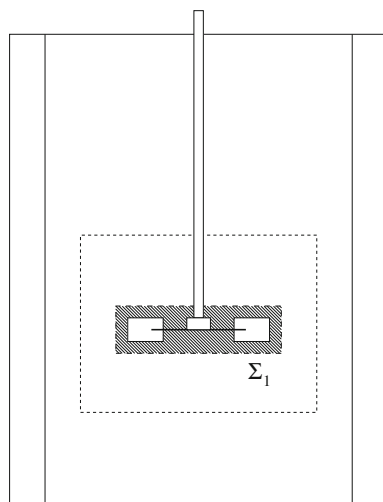

**Fig. 7.17** Computational domain for the inner simulation, lined region is excluded from the domain. The figure is drawn based on a similar figure published by Brucato et al. [10]

### 7.8.3 The Inner-Outer (IO) Method and the Multiple Reference Frame Approach (MRF)

The inner-outer method was first presented by Brucato et al. [9, 10]. This iterative procedure was proposed intending to design a relatively simple engineering simulation, which enable approximate predictions of the effect of the rotating impellers on the fluid motion in stirred tanks, without resorting to empirical source terms relying on experimental data. This procedure thus represents an advanced attempt to improve on the main limitation associated with the IBC method. The model formulation is based on a simple physical analysis of the stirred tank problem which reveals the following characteristics. In the view of an observer fixed on the vessel wall, the impeller is rotating. On the other hand, considering an observer following the impeller, the vessel itself appears to be rotating. In the *inner-outer* iterative procedure the whole vessel volume domain is thus subdivided into two overlapping zones. These are the inner domain containing the impeller and the outer one including the baffles. Accordingly, the global iterative procedure is also subdivided into two major steps. In the first iterative step of this method the simulation of the flow in the inner domain is carried out using a model formulation considering a reference frame rotating with the impeller, with a first guess for the boundary conditions (e.g., initially a still fluid may suffice) imposed on the artificial surface  $\Sigma_2$  dividing the two sub-domains, as illustrated in Fig. 7.17. Thus, (7.109) is to be solved taking the Coriolis- and centrifugal force into account. The steady state condition imposed on the simulation requires that the transient terms are neglected. The impeller region is resolved so physical boundary conditions are required implementing the actual surfaces. After the first trial flow field in the impeller region is obtained, the corrected values for the different quantities (e.g.,  $\mathbf{v}$ ,  $k$  and  $\varepsilon$ ) are imposed as boundary conditions on the inner surface  $\Sigma_1$  of the

**Fig. 7.18** Computational domain for the outer simulation, lined region is excluded from the domain. The figure is drawn based on a similar figure published by Brucato et al. [10]

outer domain (Fig. 7.18). Since the two frames are different, the information which is exchanged has to be adjusted for the relative motion and averaged over the azimuthal direction (due to an imposed symmetry requirement). Thereafter, in the second step of the procedure the calculation is carried out using a model formulation considering a fixed laboratory reference frame for the outer domain, in which the Coriolis- and centrifugal body forces are not included (i.e., except those for the earth's rotation). In this case the updated boundary conditions on the inner surface  $\Sigma_1$  of the outer domain (Fig. 7.18) is employed. The baffle region is resolved so physical boundary conditions are required implementing the actual surfaces. Subsequent to obtaining convergence (at least performing a few iterations) on the outer part of the domain, a first iteration on the whole flow field has been achieved. After the results for the outer domain have been obtained, a new guess for the boundary conditions for the inner domain iteration can be imposed on surface  $\Sigma_2$ . A new estimate for the solution of the inner domain can then be calculated, and similar inner-outer iterations can be repeated until the whole calculation domain attains a satisfactory numerical convergence. Simplified versions of the IO-method with no overlap between the inner and outer regions have been used by Marshall et al. [55] and Luo et al. [52]. Since there is no overlapping zone between the two regions, the solution is matched at the interface between the rotating and stationary regions. A general formula for transforming the interface velocity between the two frames of reference was given by [52]. However, the location of the interface may not be arbitrary, since in one view the concept requires that the surface has to be placed at a location where the flow variables do not change significantly with time or with  $\theta$ . Otherwise, a predictor-corrector approach may be needed in conjunction with the MRF method in order to find an optimal location of the interface. Notwithstanding, with a perfect first guess of the interface location (or in particular cases for which the interface location is not of crucial importance) the

multiple reference frame (MRF) method is computationally less expensive than the IO-method. For this reason the MRF-method has been implemented in most of the commercial CFD codes. It is further noted that in some commercial codes basically the same approach is known under the name the Multiple Rotating Reference Frame (MRRF).

To validate the predicted results several simulations have to be carried out specifying different positions of the impeller blades relative to the baffles to achieve average steady-state values for comparison with experimental data. This averaging procedure is analogous to the one used employing the snapshot method.

### 7.8.4 The Moving Deforming Mesh (MDM) Technique

Perng and Murthy [70] introduced the moving deforming mesh technique for simulating unsteady flows in mixing vessels. The model formulation used with moving meshes is of the arbitrary-Lagrangian-Eulerian (ALE) type.

The integral form of the equations governing the incompressible Newtonian fluid in a time-varying control-volume  $V(t)$  is written as:

$$\frac{d}{dt} \int_{V(t)} dv = \oint_{A(t)} \mathbf{u} \cdot \mathbf{n} da \quad (7.116)$$

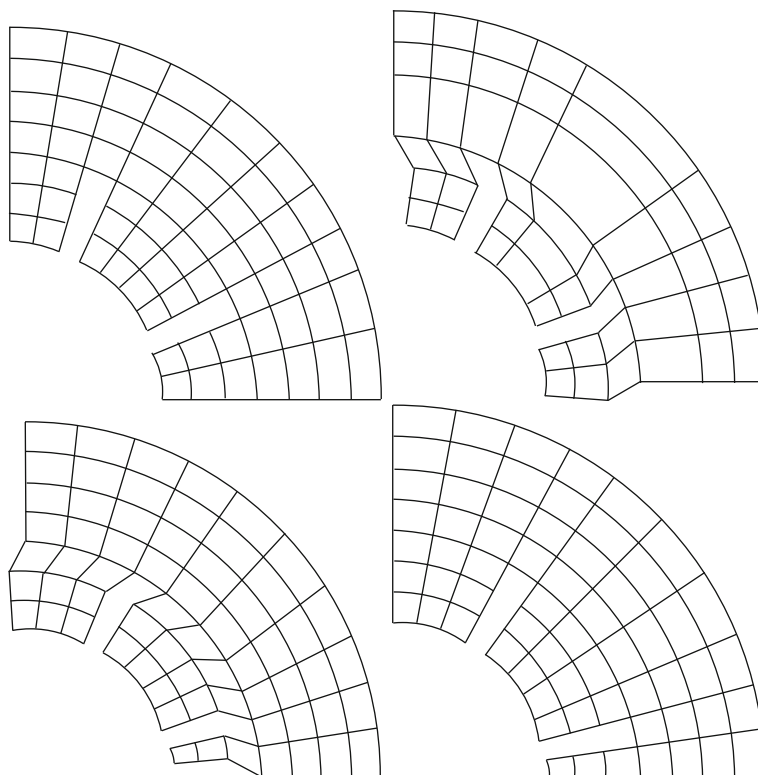

$$\frac{d}{dt} \int_{V(t)} \rho dv = \oint_{A(t)} \rho(\mathbf{u} - \mathbf{v}) \cdot \mathbf{n} da \quad (7.117)$$

$$\frac{d}{dt} \int_{V(t)} \rho \mathbf{v} dv = \oint_{A(t)} [\rho(\mathbf{u} - \mathbf{v})\mathbf{v} - \mathbf{T}_{\text{eff}}] \cdot \mathbf{n} da + \int_{V(t)} S_v dv \quad (7.118)$$

$$\frac{d}{dt} \int_{V(t)} \rho \psi dv = \oint_{A(t)} [\rho(\mathbf{u} - \mathbf{v})\psi - \mathbf{J}_{\text{eff}}] \cdot \mathbf{n} da + \int_{V(t)} S_\psi dv \quad (7.119)$$

where  $\mathbf{u}$  is the control volume surface velocity vector arising from the motion of the moving grid.  $S_v$  and  $S_\psi$  are the source terms for  $\mathbf{v}$  and  $\psi$  equations, respectively.  $d/dt$  is the total derivative.

A single mesh for both the moving and the stationary part is used in this approach. The grid attached to the rotor moves with it and causes the interfacial mesh to deform. When mesh deformation becomes acute, the grid is regenerated locally and the flow variables are transferred to the regenerated mesh. Figure 7.19 shows an illustrative example in which only a single row of cells are deformed. Regenerating the grid means, as indicated in the figure, *snapping* back the grid by one cell. At this point all the cells and grid nodes are renumbered and the procedure continues. Further details of the techniques for mesh deformation, regeneration and variable interpolation are

**Fig. 7.19** Grid motion through deformation and snapping (from *left to right*) [70]: 1. initial grid, 2. grid moves and deforms, 3. the right boundary and cells are snapped to the *left*, 4. grid advances one cell distance. Reproduced with permission by John Wiley & Sons, Inc

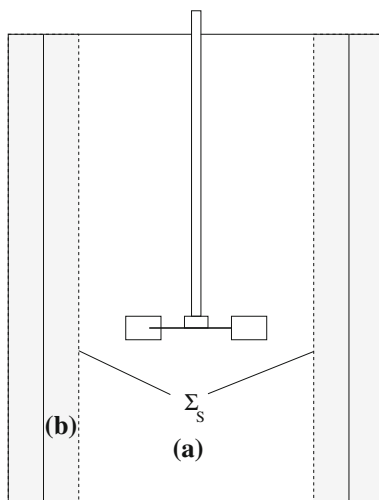

explained by [70]. Note that this strategy may lose accuracy if the interface grid is allowed to deform excessively before regeneration.

To validate the predicted results only one time dependent simulation has to be carried out to achieve time and impeller region average values for comparison with experimental data and the steady-state results obtained by the IBC, IO and snapshot methods.

### 7.8.5 The Sliding Grid (SG) or Sliding Mesh (SM) Method

Murthy et al. [63] were the first who used the sliding grid method for the simulation of unsteady flows in mixing vessels. The model formulation used with moving meshes is of the arbitrary-Lagrangian-Eulerian (ALE) type [70]. In this particular approach the flow domain is divided into two cylindrical, non-overlapping sub-domains, each

**Fig. 7.20** Multiblock sliding grid approach. **a** = inner, rotating, block; **b** = outer, stationary, block;  $\Sigma_s$  = sliding interface. The figure is drawn based on a similar figure published by Brucato et al. [10]

gridded as a separate block. The outer grid is fixed to the laboratory reference frame, the inner grid rotates with the impeller as illustrated in Figs. 7.20 and 7.21.

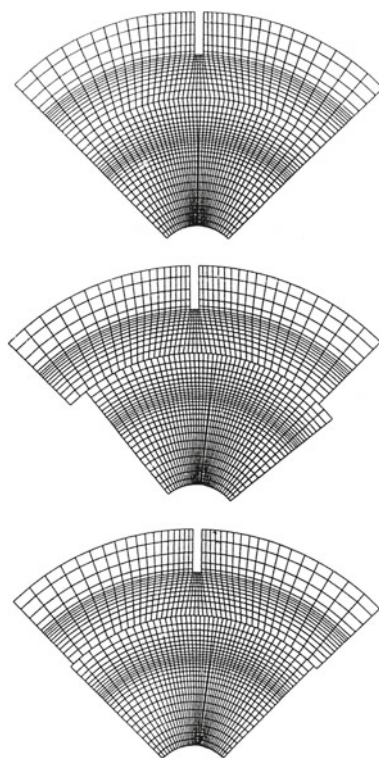

The governing equations for both the fixed and the rotating sub-domain grids are written with respect to the laboratory reference frame. In the inner domain the rotation of the grid is accounted for by transforming the total time derivative in the familiar Eulerian conservation equations into an Arbitrary-Eulerian-Lagrangian form similar to the model used in the MDM method [70]. The moving grid for the inner domain is allowed to slide relative to the stationary outer domain along a surface of slip. A conservative interpolation procedure is used to connect the necessary flow variables and face fluxes across this surface. Again, due to symmetry, the whole vessel does not need to be calculated. However, the domain must include an integer number of both blades and baffles.

To validate the predicted results only one of these time dependent simulations has to be carried out to achieve time (steady-state) and impeller region average values for comparison with experimental data and simulated results obtained by the IBC, IO and snapshot methods. This validation procedure is the same as the one used for the MDM method.

### 7.8.6 Model Validation

In order to validate the different approaches it is necessary to compare the results with experimental data. In addition, the IBC method relies on empirical data in order to implement the momentum source induced by the stirrer. Brucato et al. [10] give a review of the different methods of measuring the velocity field. The most commonly used measurement technique is the Laser Doppler Velocimetry (LDV).

**Fig. 7.21** Sliding grid motion [63]. *Upper* subfigure: sketch of the initial grid. *Mid* subfigure: Impeller grid rotation in clockwise direction. *Lower* subfigure: Cyclic rearrangement of impeller grid. Reproduced with permission by IChemE

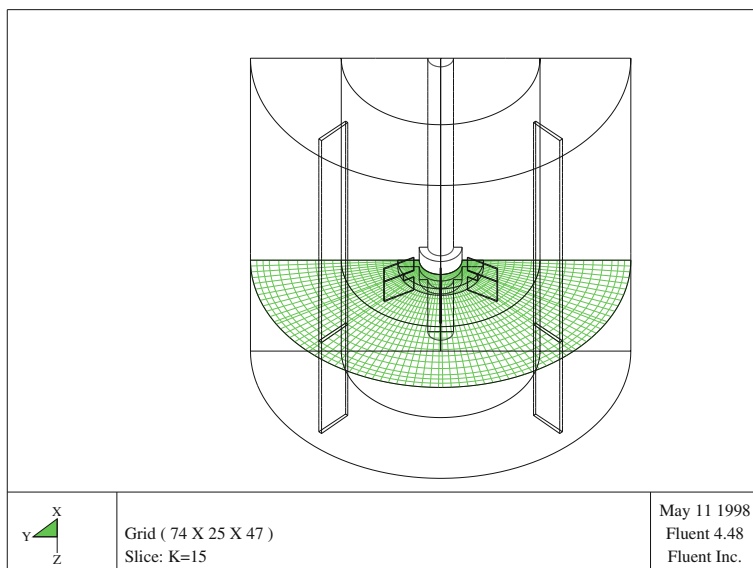

Measurements for radial impellers were made for example by Dyster et al. [19] who reported detailed mean and fluctuating velocity profiles in the impeller stream. Kemoun et al. [46] used LDV to receive data in a closed surface surrounding the impeller. Another method that has been used to determine the velocities in the impeller region is to mount a hot wire on the rotating impeller, like Güinkel and Weber [32] did for radial impellers. In addition, Van't Riet and Smith [89, 90] and Van't Riet et al. [91] used a camera mounted on a turntable rotating with the stirrer and obtained pictures of tracer particles relative to the rotating impeller. Less experimental work has been performed for axial impellers. Kresta and Wood [48] performed LDV measurements of mean and fluctuating radial, axial and tangential velocities in cylindrical tanks with a 45-pitched, four blade turbine at 400 rpm. A review of experimental investigations of turbulent flow in closed and free-surface unbaffled tanks stirred by radial impellers can be found in Ciofalo et al. [12]. Experimental investigations of wall heat transfer in stirred tank reactors have been reported by Engeskaug et al. [23], Oldshue [65], Hewitt et al. [40], among others. Harris et al. [36] and Brucato et al. [10] reviewed the status on modeling baffled stirred tank reactors. Simulations using the impeller boundary condition (IBC) method, the inner-outer approach, and the sliding mesh method were compared. Although reasonable flow predictions have been obtained for the liquid bulk by use of the IBC

method, this approach is subject to the availability of velocities and turbulence data for formulating appropriate boundary conditions. This method is thus not feasible for multiphase flows and industrial scale reactors because of the difficulties in obtaining data for the boundary treatment. Moreover, the IBC method has no predictive value for the flow and turbulence in the impeller region, even its capabilities in predicting global parameters like the power and pumping numbers are limited. The IO simulations confirmed that the IO procedure is capable of predicting the near impeller flow and turbulence fields with a reasonable accuracy, thus to some extent reducing the need for empirical information. Hence, the IO method is often preferred compared to the IBC method although it was 1–4 times more cpu demanding for one of the particular cases referred. The SM method provides the advantage of enabling transient simulations for problems in which the flow and mixing phenomena occurring at impeller startup or as a consequence of changes in impeller rotational speed are of interest. The sliding mesh method generally provides more accurate results than the inner-outer approach, but in one of the cases referred it did also require a factor of four more computing time. The SM method also required 7–20 times larger cpu times than for the IBC runs for some problems. Lane et al. [49] did compare the performance of simulations with the SM and the MRF approach in predicting flow fields within a standard stirred tank equipped with a Rushton turbine. Reasonable agreement with experimental data in terms of mean velocities is obtained with both methods. Nevertheless, the MRF method provides a saving in computational time of about an order of magnitude. Based on the impeller modeling analyses mentioned above, among other similar investigations, it is customarily concluded that for most industrial applications the MRF method is an appropriate simulation tool. The method represents a trade-off between accuracy and computational demands. However, the averaging process needed to obtain representative data in the impeller region is tedious as it requires many (several) similar simulations at different snapshots (representing different impeller blade positions). In academia the SM method is considered a more fundamental method than the MRRF method because the former approach is transient and do not rely on a manual re-gridding of the geometry. The SM method has the potential of being predictive provided that the governing equations are solved with sufficient accuracy (i.e., for DNS). However, future work might improve on the direct fluid-impeller structure interaction mapping, enabling an efficient dynamic update of the impeller grid as the impeller moves and the flow evolves in a DNS without the interpolation costs of a sliding grid.

## 7.9 Assessment of Multiple Rotating Reference Frame Model Simulations

In this section a series of simulations of a standard vessel equipped with a Rushton turbine, as obtained by use of the Multiple Rotating Reference Frame (MRRF) method, are evaluated. The simulations are performed with the commercial software FLUENT [24]. The simulations were run with a resolution of 86950 cells.

**Fig. 7.22** A representative grid employed for the multiple rotating reference frame (MRRF) model simulations

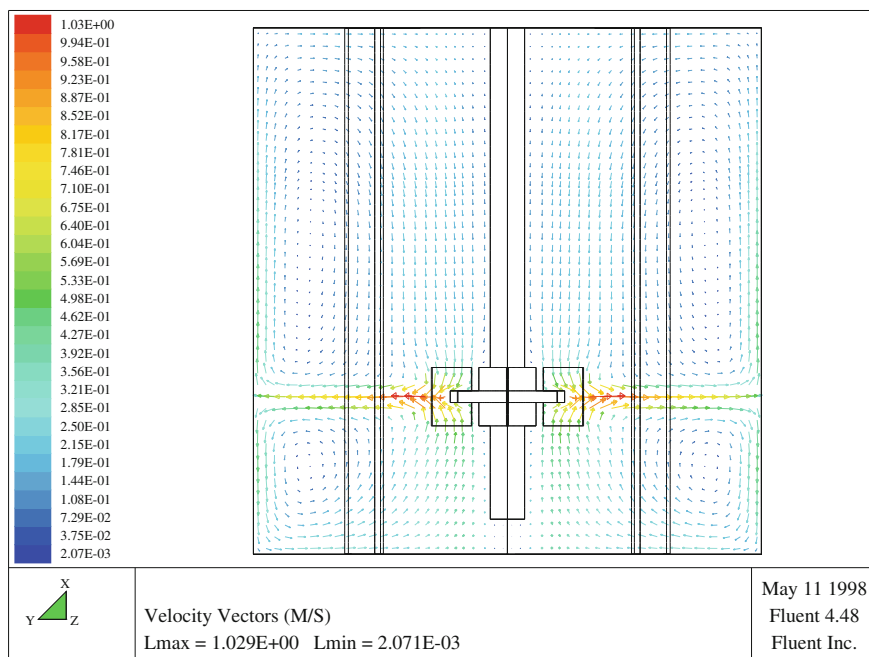

The turbulent effects are described by a modified (RNG)  $k$ - $\epsilon$  model<sup>11</sup> [66, 82, 96–98]. For model validation experimental LDA data characterizing a standard vessel of laboratory scale, as reported by Engeskaug [22], is used. The simulations considered in this section have been reported by Engeskaug [22], Druecker [17] and Jakobsen [43].

The stirred tank geometry used in these investigations:

- The tank diameter,  $T = 0.222$  (m)
- The liquid height in the vessel,  $H = T = 0.222$  (m)
- The impeller diameter,  $D = 0.076$  (m)
- The impeller blade width,  $W = 0.020$  (m)
- The impeller blade height,  $W = 0.020$  (m)
- The impeller clearance,  $C_b = 0.100$  (m)
- The width of wall baffles,  $B = 0.022$  (m)
- The wall baffles wall clearance,  $C_B = 0.011$  (m)
- The diameter of the impeller axis,  $T_I = 0.015$  (m)
- The thickness of the impeller blades is 1 (mm), the baffles 2 (mm) and of the Rushton Turbine's disc 3 (mm)
- The impeller rotates at 300 (rpm).

The grid used in these MRRF stirred tank simulations is shown in Fig. 7.22.

<sup>11</sup> This turbulence model is similar to the standard  $k$ - $\epsilon$  model, but with altered model parameter values and the effect of swirl on turbulence is included in the RNG mode intending to enhance the accuracy of swirling flow simulations.

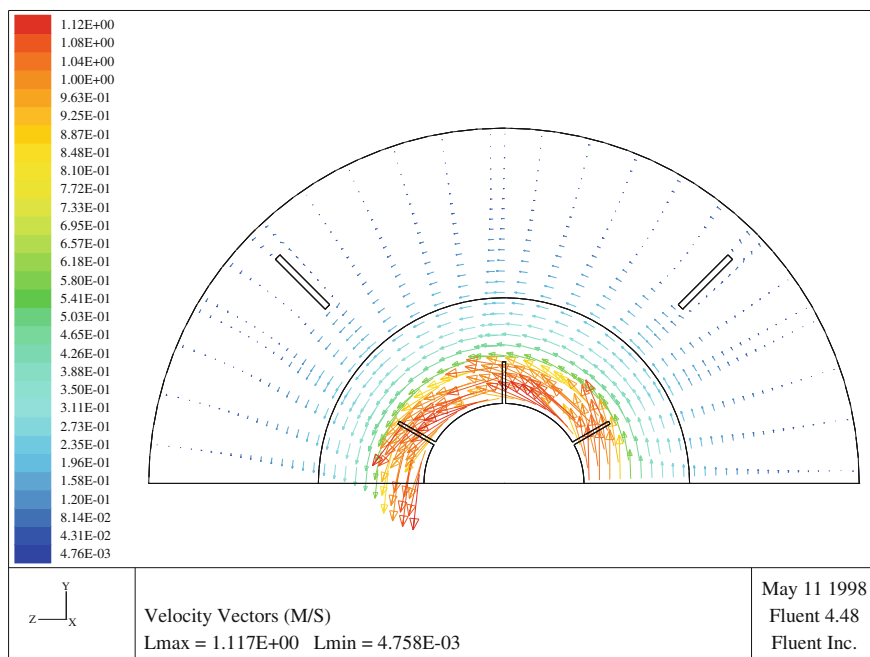

**Fig. 7.23** Simulated velocity in a vertical plane of stirred tank reactor

The overall flow fields in a vertical layer between two baffles and in a horizontal layer at the disc axial level are shown as vector plots in Figs. 7.23 and 7.24. Sometimes it is more informative to present the corresponding speed or velocity magnitude quantity in a contour plot, for example to identify the location of the highest kinetic energy as shown in Figs. 7.25 and 7.26. Qualitatively the general flow field is described fairly well. The two main vortexes above and below the impeller can be identified and the highest speed occur at the impeller blade tips in agreement with the experimental observations.

A plot of the predicted turbulent kinetic energy at the disc axial level is shown in Fig. 7.27. The turbulent kinetic energy values are questionable because the energy level is quite low in the impeller region where the velocity gradients are the largest.

In the following a quantitative comparison of the predicted velocity and turbulent kinematic energy profiles with experimental data is discussed. In each figure several graphs are compared. Considering velocities the meaning of the different lines are: The *blue line* denotes the experimental data [22] (Laser), the *black line* denotes MRRF simulations at high resolution (86950 cells) in which the sum of the residuals for each field is less than 0.001 (MRRF e-3), the *green line* denotes MRRF simulations at high resolution (86950 cells) in which the sum of the residuals for each field is less than 0.0001 (MRRF e-4), the *red line* denotes MRRF simulations at low resolution (~50000 cells) in which the sum of the residuals for each field is less than 0.0001

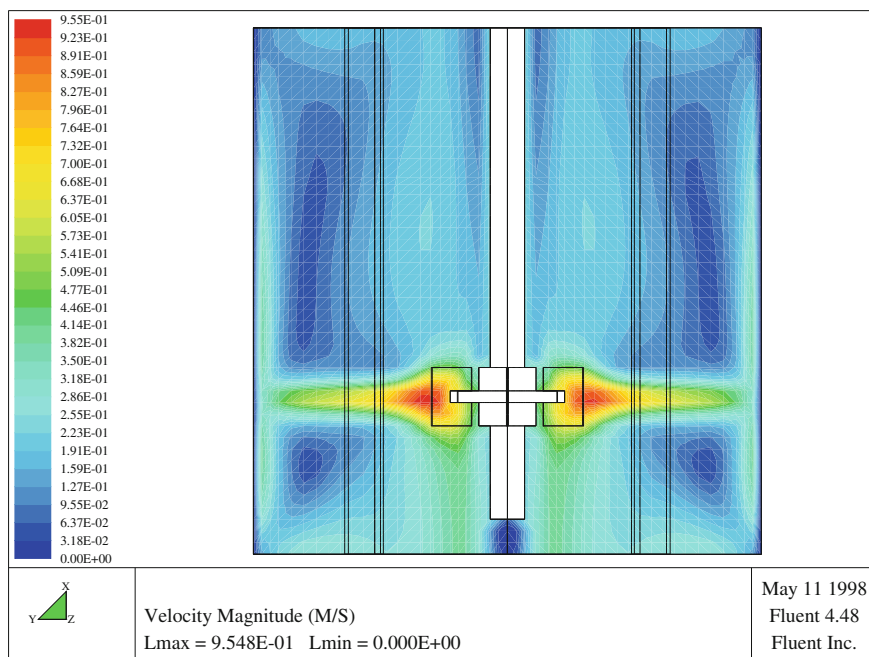

**Fig. 7.24** Simulated velocity in a horizontal plane of stirred tank reactor

(MRRF low res.), and the *pink line* represents the MRRF simulations of Engeskaug [22] at high resolution (86950 cells) in which the residuals for each field is less than 0.0001 (Engeskaug (MRRF)). Considering the turbulent kinetic energy the meaning of the different lines are modified: The *blue line* denotes the experimental data [22] (Laser), the *green line* denotes MRRF simulations at high resolution (86950 cells) in which the sum of the residuals for each field is less than 0.0001 (MRRF e-4), the *red line* denotes SM simulations at high resolution (86950 cells) in which the sum of the residuals for each field is less than 0.0001, the *black line* denotes SM simulations at low resolution ( $\sim 50000$  cells) in which the sum of the residuals for each field is less than 0.0001 (SM low res.), and the *pink line* represents the SM simulations of Engeskaug [22] at high resolution (86950 cells) in which the sum of the residuals for each field is less than 0.0001 (Engeskaug (MRRF)).

The radial velocity profiles (i.e., the three velocity components are given as azimuthal average functions of radial position in the vessel) obtained by the MRRF simulations for the axial level of the impeller are in good agreement with the experimental data both in the impeller region and in the area closer to the wall outside the impeller region, as can be seen from Figs. 7.28, 7.29 and 7.30. However, the turbulent kinetic energy is not accurately predicted compared to the measured values, as shown in Fig. 7.31. The highest turbulent kinetic energy values for the disc axial level are observed at the outer radius of the impeller where the impeller blades create

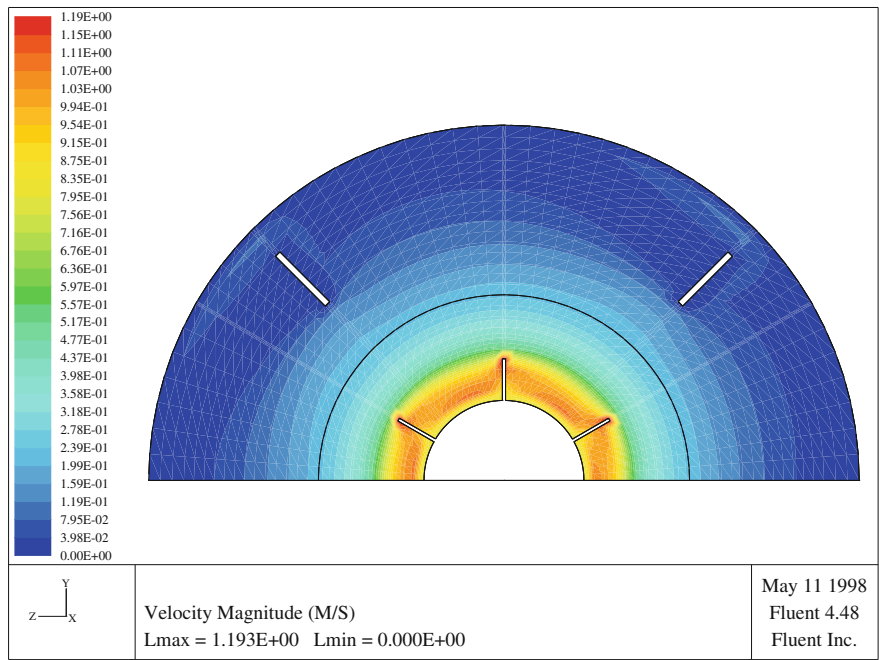

**Fig. 7.25** Simulated velocity magnitude in a vertical plane of stirred tank reactor

the strongest swirls. The simulated turbulent kinetic energy is much smaller than the experimental values over the whole cross section of the reactor. Below and above the disc the highest kinetic energy levels occur near the walls in the gap between the baffles and the walls (not shown).

Engeskaug [22] and Druecker [17] compared a compatible set of simulated sliding mesh (SM) and multiple rotating reference frame (MRRF) results with the experimental data. An identical numerical grid spacing was used for both methods, but in the SM method two non-overlapping sub-domains are sliding relative to each other whereas for the MRRF method the two subdomains are fixed. It was found that the MRRF and SM results are similar, but in most areas the MRRF velocity predictions were in better agreement with the experimental data than the SM results (not shown). On the other hand, quite surprisingly, the turbulent kinetic energy profiles are in most areas much better predicted with the SM method compared to the MRRF simulations (see Fig. 7.31). However, it is difficult to determine if these differences in the predictions are due to the different averaging procedures applied to the simulated results, differences in the numerical model implementation, interpolation schemes, or differences in the two model formulations.

The computational time required by these impeller modeling methods were also compared. For baffled tanks the computational time required by these two impeller methods are quite similar as several MRRF simulations have to be run per one SM

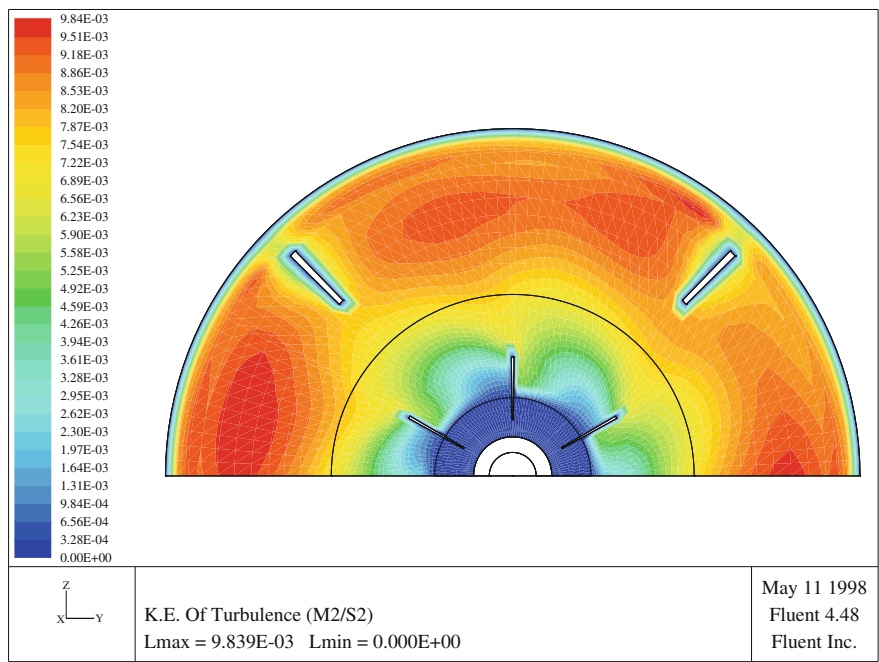

**Fig. 7.26** Simulated velocity magnitude in a horizontal plane of stirred tank reactor

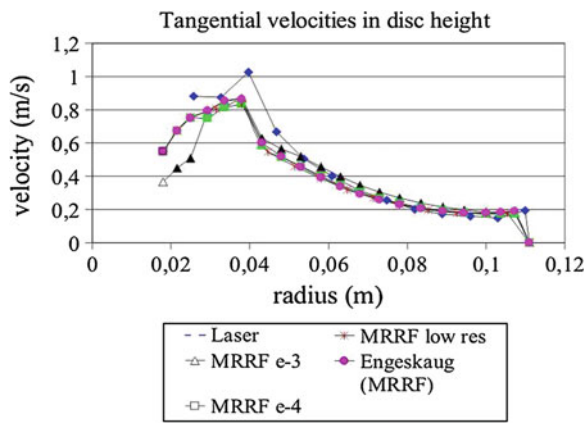

simulation because a manual change in the relative impeller-baffle positions are performed to resolve the flow in the impeller region. The SM simulations are time dependent so the results have to be averaged over a sufficient period in time. For unbaffled vessels only one MRRF simulation is required, so the MRRF method is significantly cheaper than the SM method in these cases.

The simulated results evaluated in this section are about ten years old, thus today the numerical resolution used in this work might be considered coarse. However, although the present computers allow better resolutions to be used in the simulations the status on stirred tank modeling is still very similar. For single phase flows the limiting steps are basically related to the turbulence modeling and the computational efficiency. For multi-phase flows additional limitations regarding the closure laws determining interfacial transfer fluxes, particle growth, particle coalescence and breakage processes, etc are prohibitive and make predictive simulations very difficult.

It is noted that in recent papers several extended turbulence models, i.e., the standard  $k-\varepsilon$  [50], RNG  $k-\varepsilon$  [66, 82, 96–98], realizable  $k-\varepsilon$  [81], Chen-Kim  $k-\varepsilon$  [11], optimized Chen-Kim  $k-\varepsilon$  [44], standard  $k-\omega$  [95],  $k-\omega$  shear-stress transport (SST) [56–58] and the standard Reynolds stress models, have been proposed and validated. However, little or no significant improvements have been achieved considering the predictivity of the turbulence models, although each of them may have minor

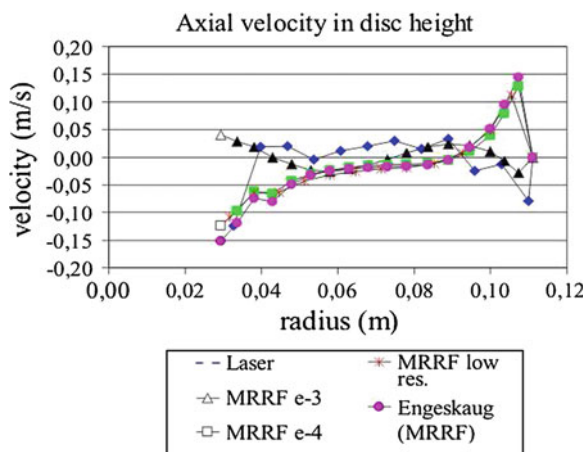

**Fig. 7.27** Simulated turbulent kinetic energy in horizontal plane of stirred tank reactor

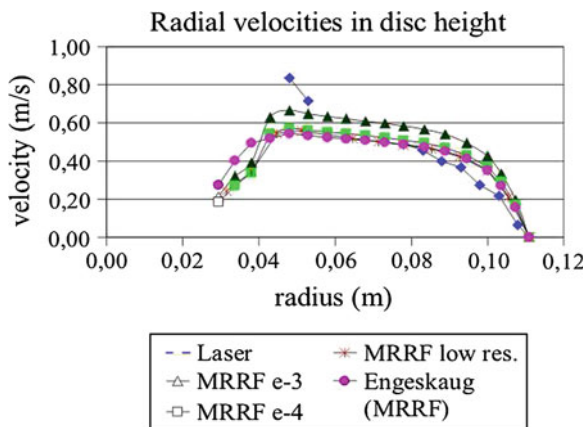

**Fig. 7.28** Measured and simulated radial profiles of the tangential velocity component at the axial level of the disc

advantages and disadvantages. A few recent investigations of the flow in stirred tanks are assessed to support this conclusion.

Jenne and Reuss [44] performed critical assessments of the use of  $k-\varepsilon$  turbulence models for simulations of turbulent single phase flow induced by the impellers in

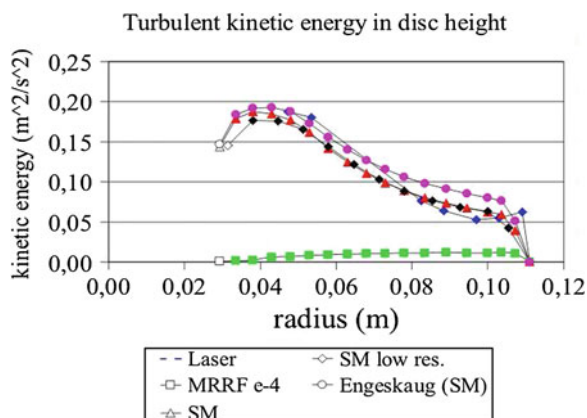

**Fig. 7.29** Measured and simulated radial profiles of the axial velocity component at the axial level of the disc

**Fig. 7.30** Measured and simulated radial profiles of the radial velocity component at the axial level of the disc

baffled/unbaffled stirred tanks. A standard consuration stirred-tank reactor equipped with a Rushton turbine was simulated by use of the PHOENICS code in which the effect of the impeller is described by the empirical source term method. The accuracy reflected by three  $k-\varepsilon$  turbulence models (i.e., the standard  $k-\varepsilon$ , Chen and Kim  $k-\varepsilon$ , RNG  $k-\varepsilon$  models) in predicting the mean flow and turbulence quantities is tested by 3D simulations. The different simulations were compared with experimental data, revealing that none of the possible  $k-\varepsilon$  models performs satisfactory reproducing a known flow field without an optimization of the model parameters for the vessel in question. By parameter fitting/tuning an optimized Chen-Kim  $k-\varepsilon$  turbulence model was obtained. By use of the optimized turbulence model fair agreement was achieved

**Fig. 7.31** Measured and simulated radial profiles of the turbulent kinetic energy at the axial level of the disc

between measured flow details and the predicted results for vessels and impellers of somewhat different geometry.

Zakrzewska and Jaworski [100] performed single phase CFD simulations of turbulent jacket heat transfer in a Rushton turbine stirred vessel using the eight turbulence models mentioned above as implemented in FLUENT. In all simulations the boundary flow at the vessel wall was described by the standard logarithmic wall functions. The predicted values of the local heat transfer coefficient were compared with measured values. In these simulations the standard  $k-\varepsilon$ , the optimized Chen-Kim  $k-\varepsilon$  and the  $k-\omega$  SST model results were in fair agreement with experimental data, whereas the realizable  $k-\varepsilon$ , RNG  $k-\varepsilon$  and the Reynolds stress model were not recommended.

Haque et al. [35] simulated turbulent flows with a free-surface in unbaffled agitated vessels using three turbulence models (i.e., the Reynolds stress, standard  $k-\varepsilon$  and  $k-\omega$  SST models) as implemented in CFX. In this case it appears that the SST model did perform better than the standard  $k-\varepsilon$  model, whereas some features of the flow structure and the mean velocity profiles were better predicted by the Reynolds stress model.

Lo [51] simulated two- and three phase isothermal non-reacting stirred tanks with two downward pumping  $45^\circ$  pitched -blade disc turbines and one curved-blade impeller at the bottom. Four or six baffles were placed at equal distance around the vessel wall. An Eulerian multiphase-population balance (MUltiple-SIze-Group, MUSIG) model was used as implemented in CFX. Turbulence of the continuous phase was modeled by the standard  $k-\varepsilon$  turbulence model, and an algebraic relation was used for the particle induced eddy viscosity. The sliding mesh impeller method was used. The phase distribution in the tanks were in fair agreement with experimental data. Comparisons of the measured and predicted shaft power were generally within  $\pm 20\%$  deviation. No detailed evaluation of the performance of the turbulence model was reported.

A similar pseudo-two phase investigation was reported by Venneker et al. [92] using the empirical source term impeller method in FLUENT. They simulated the turbulent flow pattern in a baffled agitated vessel equipped with a six-blade disc turbine and a ring sparger. The transport of bubbles throughout the vessel was simulated by a scaled single-phase flow field. The single phase turbulence field was modeled with the Reynolds stress model. Compared to LDA measurements the overall predictions were qualitatively correct, but the turbulent kinetic energy and energy dissipation rate fields need further improvements. Local gas fraction and bubble size distributions in the tank was described by a population balance model. Model predictions for the gas fractions in pseudoplastic Xanthan solutions were compared with local measurements and agreed fairly well qualitatively.

Basara et al. [3] simulated single- and two-phase turbulent flows in stirred vessels equipped with six- and four blade Rushton-type turbines using the sliding mesh impeller method. To describe turbulence in the liquid phase a standard  $k-\varepsilon$  model was used for single phase calculations and an extended  $k-\varepsilon$  model was employed for the two-phase simulations. These simulations were performed in transient mode with 1 (ms) time steps. The whole calculation contains 3900 time steps, which means approximately 4 s of real time and 17 complete rotations of the impeller. One such simulation took 13 days of CPU time using an Intel single processor with 2.6 (GHz). The flow pattern predictions were compared with experimental data and fair agreement was obtained. It was stated that the standard  $k-\varepsilon$  model over-predicted the turbulence kinetic energy, and that might be achieved using more accurate turbulence models.

Moilanen et al. [59] did use CFX to simulate two-phase aerated fermenters. A MRRF technique was employed to describe the impeller motion. The results obtained using two different turbulence closures were compared with experimental and visual observations. The two turbulence models tested were the standard  $k-\varepsilon$  and the SST models. It was stated that the  $k-\varepsilon$  model did behave unphysically in the bulk regions of the vessel by generating unreasonable turbulence properties. The SST model gave more reasonable results.

## Chapter 8

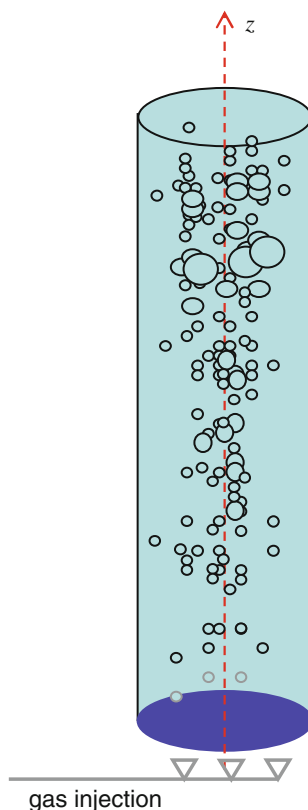

# Bubble Column Reactors

In this chapter the elementary hydrodynamic characteristics of simple bubble columns are summarized. Different designs of bubble columns are sketched, and examples of their industrial applications are outlined. An overview of the status on Eulerian bubble column modeling is presented.

### 8.1 Hydrodynamics of Simple Bubble Columns

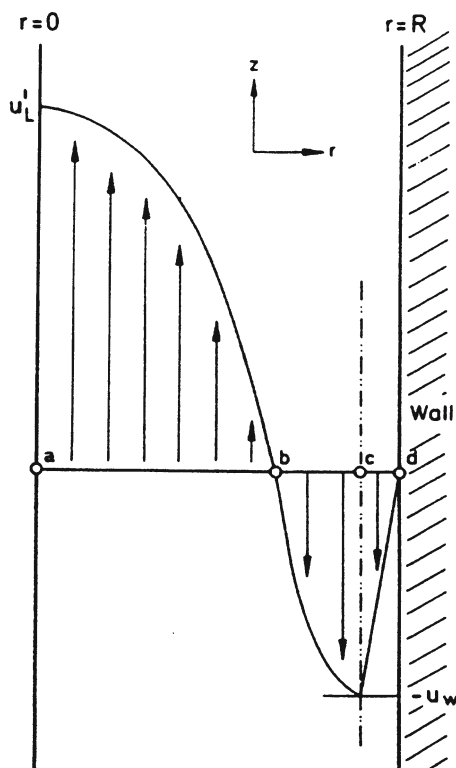

In its most simple form a bubble column reactor basically consists of a vertical cylinder with a gas distributor at the inlet, as sketched in Fig. 8.1. Simple construction and lack of any mechanically operated parts are two characteristic aspects of the reactor. In general, the bubble column is an adaptable type of reactor which is reasonable in price and can be built in large sizes. The ratio between length and diameter may vary, but ratios between 3 and 10 are most common [29]. Units of 100–200 m<sup>3</sup> are regarded as very large in the chemical industry. The liquid phase may be operated in batch mode or it may move co-currently or counter-currently to the flow of the gas phase. The gas usually enters at the bottom of the column through a gas distributor which may vary in design. The gas phase is dispersed by the distributor into bubbles entering a continuous liquid phase. In addition, reactive or catalytic particles may be suspended in the liquid phase. The liquid flow rate passing through a bubble column is usually very low. The gas throughput on the other hand may vary widely according to the specified conversion level. The normal ranges of liquid and gas superficial velocities, based on empty reactor cross-sectional area, are in the region of 0–3 and 3–25 cm/s, respectively. The reactor may be cooled or heated by means of internal heat exchanges. One of the main features is very high heat transfer coefficients [75], thus ensuring a fairly uniform temperature throughout the reactor even with strong exothermic/endothermic reactions. This is of special significance when reactions in which the selectivity is highly dependent on temperature are involved. The rising gas bubbles entrain an amount of liquid with them which is considerably greater than that

**Fig. 8.1** A sketch of a simple bubble column

corresponding to the liquid throughput [29]. The larger bubbles plus entrained liquid tend to rise up through the center of the column. Thus, continuity will ensure that fluid returns down the column close to the wall, transporting smaller bubbles with it, forming a distinctive circulating flow pattern. Large bubble swarms with length scales of the same order as the column diameter are observed rising in a helical fashion towards the top of the column. However, averaged over a long period of time (in the order of 10–30 s) this transient circulation pattern vanishes. Yet non-uniform time averaged radial gas holdup and velocity profiles result despite a uniform initial distribution of gas across the whole cross-section of the reactor. The mean liquid axial velocity profiles have been found to be relatively stable with a general shape as shown in Fig. 8.2. Nevertheless, a transient radial cross-exchange of fluid elements is superimposed on the mean axial circulation pattern, giving rise to a relatively high radial intermixing. For water and dilute aqueous solutions the bubbles are generally uniformly distributed in the liquid at low gas flow rates [148]. The bubble size distribution is relatively narrow and the bubbles rise uniformly through the column. This is known as homogeneous flow and is sketched in Fig. 8.3. Homogeneous bubbly flow may occur in small scale apparatus with superficial gas velocities below 5 cm/s.

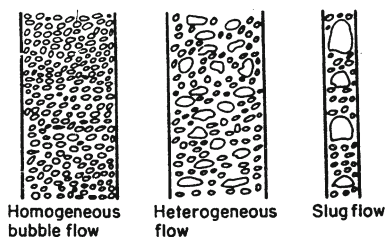

**Fig. 8.2** Liquid flow profile in a simple bubble column [174]. Reproduced with permission from John Wiley & Sons, Inc. Copyright 1979 American Institute of Chemical Engineers (AIChE)

This state is not maintained when the gas passes more rapidly through the column. Coalescence and bubble breakage lead to a wider bubble size distribution. Large bubbles are formed and these may rise more rapidly than the smaller bubbles. This type of flow is referred to as heterogeneous, Fig. 8.3, and is quite common as a result of the high gas rates frequently adopted in industry. For water and dilute aqueous solutions heterogeneous churn-turbulent flow may occur in columns with diameters larger than about 20 cm and when the superficial gas velocity exceeds about 7 cm/s. In narrow bubble columns the large bubbles in the heterogeneous zone are stabilized by the tube wall and move upwards through the column in a piston-like manner. These elongated bubbles or slugs fill practically the whole cross-section and continue to grow by collecting smaller bubbles continuously throughout their upward journey. This is known as slug flow, Fig. 8.3, and for water and dilute aqueous solutions this regime is most likely to occur in tall appliances with column diameters of around 20 cm or less and with superficial gas velocities above 7 cm/s. Note that the flow chart is system dependent and may change somewhat for other mixtures and operating conditions [148].

Bubble columns have been found to work well when the gas throughput is high even in the case of the simple type shown in Fig. 8.1, since the high rate of liquid

**Fig. 8.3** Operating states in bubble columns. Figure depicted from Deckwer [29]. Reproduced with permission from John Wiley & Sons Limited

circulation ensures that when any solids involved, such as catalyst, reagent or biomass are uniformly distributed [29]. However, liquid circulation does have the adverse effect of increasing the back-mixing and if conversion expectations are high, the reactor volume may increase accordingly. The effect of back-mixing on the conversion is of course dependent on the chemical reacting system in question. The short gas residence time, determined mainly by the bubble rise velocity, is a further disadvantage.

### ***8.1.1 Experimental Characterization of Cylindrical Bubble Column Flow***

The literature reporting measurements of gas and liquid velocities, flow patterns, and phase distribution of two-phase flow in pipes or cylindrical columns is extensive. Introductory, a few essential observations are summarized.

Several thorough reviews on the characteristics of vertical bubbly flows have been reported [64, 67, 71, 114]. Bubble columns are usually operated at very low or zero liquid fluxes, and larger gas fluxes. Experimental investigations performed by several groups show that under these flow conditions, core peaking is the rule.

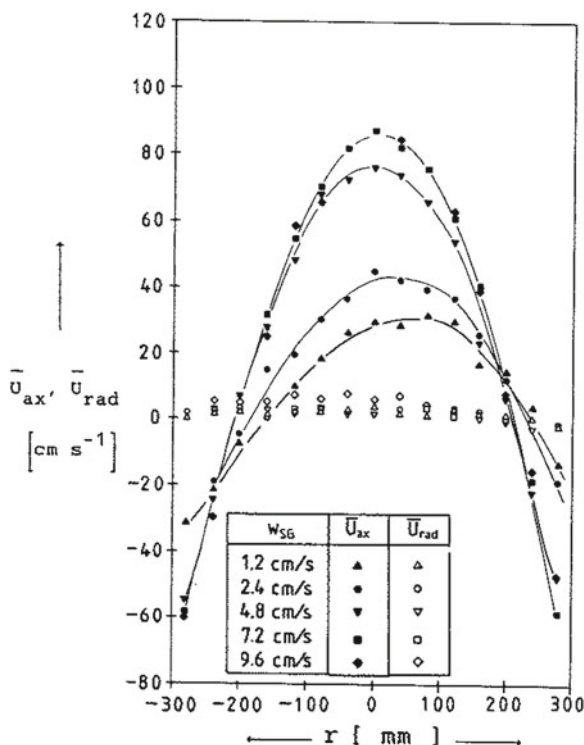

In a pioneering investigation, Serizawa [143, 144] measured the lateral void distribution as well as the turbulent axial liquid velocity fluctuations for bubbly air/water up-flows in a vertical pipe of diameter 60 mm inner diameter. They used electrical resistivity probes to measure the local void fraction, the bubble impaction rate, the bubble velocity and its spectrum. Turbulence quantities, such as the liquid phase mean velocity, and the axial turbulent fluctuations were measured using a hot-film anemometer. A supplementary experimental investigation of phase distribution phenomena in a 57.15 mm inner diameter pipe was performed by Wang et al. [182]. By a hot-film anemometer they measured the lateral void distribution as well as the mean and fluctuations in the axial liquid velocity for both bubbly up-flows and down-flows. To measure all components of the Reynolds stress tensor in the liquid phase, a special 3D conical probe was used. It was confirmed that the lateral void distribution is strongly influenced by the flow direction. Moreover, in this study it was also found that for up flows wall peaking become more pronounced for higher liquid flows, while liquid flow rate appeared to have little effect on the void fraction profiles for down flows.

Serizawa and Kataoka [145] made some interesting observations of phase distribution in bubbly flow in a 30 mm inner diameter circular tube. A variation of the phase distribution patterns as a function of the superficial liquid velocity (or liquid flux) was observed. In stagnant liquid (i.e., having zero superficial liquid velocity) no significant wall peaking was observed. The gas bubbles seemed to choose a pattern in the core of the tube, creating core peaking. For superficial liquid velocities ranging from 0.5 to 3.0 m/s, wall peaking was observed. For superficial liquid velocities higher than 3.0 m/s, they observed a gas phase maximum at a position shifting towards the tube center (intermediate peaking). Serizawa and Kataoka [145] also reviewed and interpreted data from other studies on two-phase flow phase distribution and sketched a rough flow regime map. Serizawa and Kataoka [145] concluded that there are three basic types of radial phase distributions. These are, wall peaking, intermediate peaking and core peaking. Other types of patterns are supposed to be a combination of these three regimes. Serizawa and Kataoka also speculated that the physical phenomena taking place in the region near walls were the governing mechanisms which dominate the whole picture of upward two-phase flow in pipes. It was further indicated that bubble size and shape might play an important role determining the lateral void distribution.

In a series of papers Žun [184–187] studied the phase distribution of two-phase turbulent up-flows in a 25.4 mm square Plexiglas channel. The liquid (water) volumetric fluxes were between 0 and 0.97 m/s. Air bubbles were generated on single nozzles, but about 50 different nozzle diameters were used to keep the bubbles size constant at different air and water flow rates. Ellipsoidal bubbles in the equivalent sphere diameter range from 0.6 to 5.3 mm with a distinctive intrinsic later space displacement were studied. The void fraction profiles were measured by micro-resistivity probes of 0.011 mm diameter. Žun found that the transition from wall to core void peaking would happen when the liquid flux was decreased. He also claimed that bubble size would be important in determining the phase distribution. Larger bubbles would cause core peaking, while smaller bubbles would cause wall peaking.

Hills [61] studied the radial variation of gas holdup and liquid velocity in a bubble column with diameter 138 mm. The gas holdup was measured with a conductivity probe, while the liquid velocity was measured using a modified Pitot tube. He used three different gas distributors. The superficial gas velocity was varied from 5 to 169 mm/s, while there was no net liquid flow through the column. He observed that the gas holdup was significantly larger (up to 35 % gas void fraction) in the center of the column than at the walls where it would typically fall off to between 0 and 10 % gas void fraction. He also found that, on average, the gas would rise in the center of the column giving large upward vertical liquid and gas velocities there, and down-flow along the wall. Large vortices were superimposed on the averaged pattern, thus the flow was not regular.

Menzel et al. [108] found core peaking for all the gas fluxes they studied in their investigation, and the time averaged radially varying velocity component profiles have a maximum at the core of the column as shown in Fig. 8.4. The column used had a diameter of 0.6 m, and a height of 5.44 m. The system considered was air-water.

**Fig. 8.4** Mean liquid velocities in axial and radial direction for different gas fluxes. Reprinted with permission from [108]. Copyright 1990 American Chemical Society

The water was operated in batch mode. The velocity measurements were performed with a hot-film anemometer.

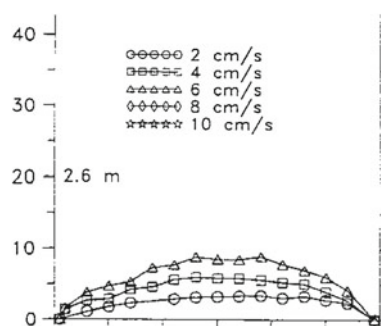

Torvik [173] also used a hot-film anemometer and measured velocities, void fractions, and turbulent kinetic energy of a bubble column with diameter 0.29 m and height 4.52 m. Both the air and the water were operated in continuous modes in the column. The liquid superficial velocity was low. Results at level 2.6 m above gas distributor at different gas velocities are shown in Fig. 8.5.

Gasche [46], Gasche et al. [47], Grienberger [50], Grienberger and Hofmann [51], Hillmer [59] and Hillmer et al. [60] also studied the flow in two-phase bubble columns using a hot-film anemometer.

Groen et al. [52] measured the local and time-dependent behavior of the two-phase flow in a bubble column. Measurements with Laser Doppler Anemometry (LDA) and with glass fibre probes were performed in two air/water bubble columns of inner diameter 15 and 23 cm, respectively. These measurements showed that the time averaged axi-symmetric liquid velocity profiles are a result of the passage of coherent structures (bubble swarms). It was concluded that considering the flow in a bubble column as stationary by far oversimplifies the actual phenomena present.

**Fig. 8.5** Radial volume fraction profiles of gas at axial level 2.6 m above inlet in a two phase bubble column. The measurements are performed for five different superficial gas velocities. The figure is depicted from Torvik [173]

Lance and Bataille [87] studied grid-generated turbulent bubbly flow in a 45 cm  $\times$  45 cm rectangular pipe. Laser-Doppler and hot-film anemometry were used for the experimental investigation. The high-frequency of spectra of the velocity components were determined by the power  $-8/3$ . A decade later Mudde et al. [112] reported LDA-measurements characterizing 15 and 23 cm inner diameter bubble columns containing air-water mixtures with gas fractions ranging from 4 to 25 %. The high-frequency of spectra of the axial and tangential velocity components did follow the Kolmogorov  $-5/3$  law. However, Hartevelde [58] studied the accuracy of the estimation of turbulence power spectra from LDA signals in bubbly flows. It was found that the estimated spectra of bubble signals with reconstruction techniques give poor results. In other words, the power law of Lance and Bataille is probably more reliable than the one proposed by Mudde et al.

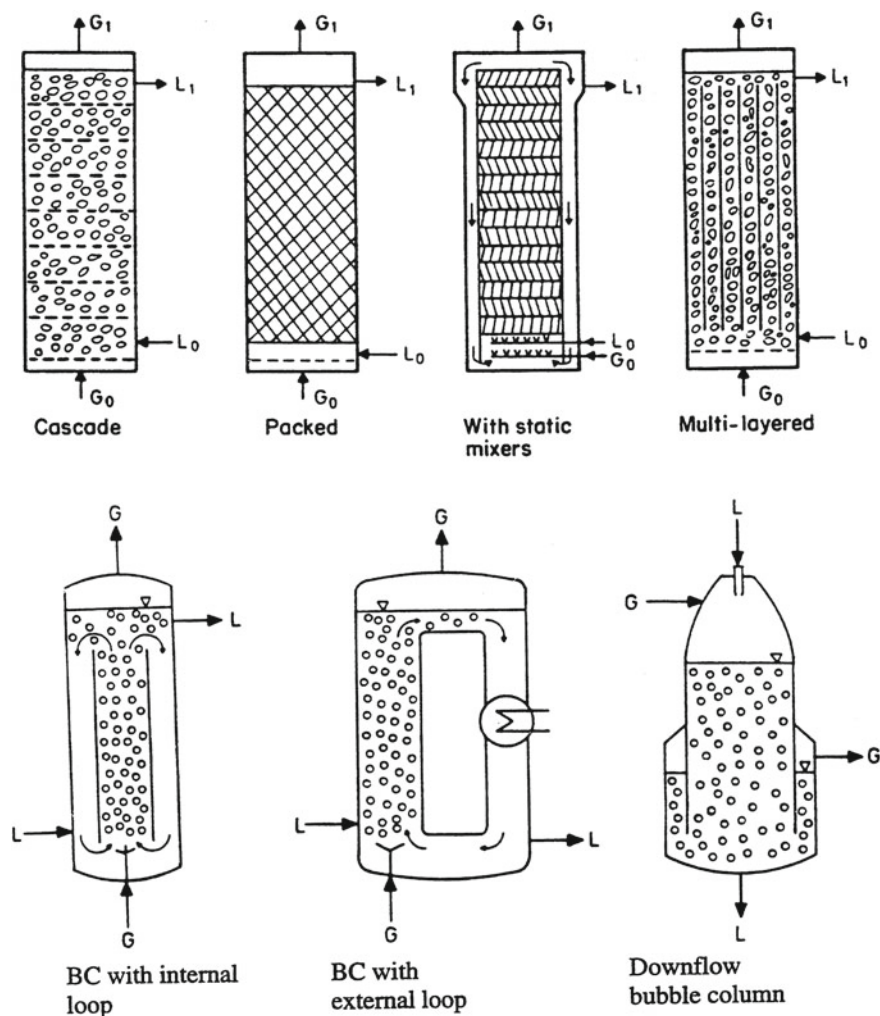

Recently, Garnier et al. [44] performed experiments in a cylindrical column of 80 mm diameter and 310 mm height and reported that the vertical air/water bubbly flow is very uniform provided that a special design of the gas injection device is used. They used a gas injection device made of a regular array of 271 hollow needles, which are 126 mm long with a 0.62 mm internal diameter, through which gas bubbles were blown. The aim of the experiment was to produce a mono-disperse injection with as uniform as possible a distribution of void fraction. Garnier et al. observed uniform flow up to 40 % voidage and the radial void profiles were almost flat.

Hartevelde et al. [57, 114] reported similar experiments in a 15 cm diameter bubble column with gas fractions around 10 %. A special sparger consisting of 561 needles was used to generate bubbles with a very narrow size distribution with a  $\sim 4.6$  mm equivalent diameter. When the sparging of the bubbles was uniform, the radial gas fraction profile was almost completely flat, but with a small peak at the wall. The flow was uniform and there was no large-scale liquid circulation. The turbulence levels are also low. If the outer ring of 0.75 cm thickness of needles was switched off, a weak circulation was observed but the flow was still stable and no large vortices were observed. Switching off a second ring so that the thickness of ungassed ring is about 1.6 cm, the flow became strongly time dependent with the familiar large-scale circulation and the vortical structures present. It was later confirmed by experiments that the flow was stable at uniform gassing even up to gas fractions of 25 %. These experiments clearly indicates that the sparger has a profound influence on the flow.

## 8.2 Types of Bubble Columns

Many different bubble column designs have been used over the years, all adapted to particular practical needs [149]. Figure 8.6 depicts a few of the modifications frequently used. A special case is the down-flow bubble column. In the column part of this reactor flow of the two phases is co-current from top to bottom as shown in Fig. 8.6. The advantages of this type of reactor is that the relatively short gas residence times obtained in up-flow reactors, can be increased since the residence time is determined by the bubble rise velocity [29]. Furthermore, incorporation of additional perforated plates transforms the simple column, sketched in Fig. 8.1, into a multistage cascade version, Fig. 8.6. This redistribution of gas over the perforated plates intensifies mass transfer, reduces the fraction of large bubbles and prevents back-mixing in both phases. Back-mixing is also decreased by filling the bubble column with a packing or by use of static mixers Fig. 8.6. Multi-layer appliances, as obtained by incorporating cooling devices, prevent bulk circulation and a uniform gas flow can be achieved throughout the reactor, provided a suitable gas distributor is fitted [29]. Internal, axially oriented heat exchanger tubes may also increase the recirculation [11, 12].

Two main groups of bubble columns can be distinguished, these are simple bubble columns (Fig. 8.1) and bubble columns with enforced circulation via a loop (Fig. 8.6). Depending on the way in which the loop is realized, the latter group may be subdivided into bubble columns with internal or external loop. Compared to the types of bubble columns with reduced back-mixing as described above, bubble columns with loop show more complex mixing behavior having a greater tendency of homogenizing the total reaction mixture. Loop reactors also permit the processing of large amounts of gas and provide a homogeneous flow zone. The homogeneous flow pattern is caused by directional fluid circulation being stabilized by means of an inserted loop eliminating complete radial transfer over the whole cross-sectional area. The high rate of circulation obtained gives shorter mixing times and hence a lack of any significant concentration gradient [29]. This is of special advantage for biotechnological processes in which it is important that the biomass is surrounded by material of constant composition. These reactors are thus often used in biotechnology, for instance as air-lift fermenters. In addition, these types of bubble column reactors can, compared to a stirred tank, decrease the shear stress induced cell damage for sensitive cultures. In bubble columns with internal loop, the gas may either be supplied into the draft tube region or the annular region. If efficient degassing of the down-flowing liquid is required, the draft tube region is to be preferred with a conical widening of the top part of the bubble column allowing less turbulent liquid flow in this zone [122]. External loop bubble columns are often equipped with a pump for circulating the liquid. This may be necessary when a heat exchanger with a high pressure drop has been installed in the external loop (Fig. 8.6). Alternatively, additional impulse for liquid circulation in the loop can be introduced, by feeding both the gas and liquid through a jet. Reactors with this type of gas sparging devices are called jet loop reactors. In general, the gas may be dispersed in several ways,

**Fig. 8.6** Special types of bubble column reactors. Figures depicted from Onken [122] (Reproduced by permission from Verein Deutscher Ingenieure (VDI)-Gesellschaft Verfahrenstechnik und Chemieingenieurwesen 2007) and Deckwer [29] (Copyright John Wiley & Sons Limited. Reproduced with permission). Similar figures can also be found in Shah and Sharma [149] and Shah et al. [148]

for instance through a perforated plate, sinter plate, or by various types of jets. Gas dispersion by use of a jet requires more energy compared to the distributor plates, but it may be advantageous if high utilization of the reacting gas is desired due to the high interfacial areas obtained [29]. Sintered plates produce small bubbles and a uniform bubble distribution. However, as sintered plates tend to become encrusted and clogged up and thus may cease to function, they are seldom used for process

gas dispersion despite the advantages which they offer. Perforated plates with holes between 1 and 5 mm in diameter are thus commonly used. This kind of gas distributor plate gives rise to a more non-uniform bubble distribution, but is usually not associated with problems of deposits and encrustation. The bubble distribution in the inlet zone, caused by the construction of the gas distributor, have a decisive influence on gas holdup, interfacial area and the level of mass transfer [29].

### 8.3 Applications of Bubble Columns in Chemical Processes

Two-phase and slurry bubble columns are widely used in the chemical- and biochemical industry for carrying out gas–liquid and gas–liquid–solid (catalytic) reaction processes [28–30, 35–37, 131]. The surveys on applications of bubble columns in industrial processes given by Deckwer [29] and Onken [122] show that in many cases the simple type of bubble column is not used, but modifications, such as loop, multistage and down-flow bubble columns, depending on specific requirements of the individual process. Schügerl et al. [142] describe special requirements associated with bio-processes. In the present summary of applications of the various types of bubble columns in chemical processes, the special use of bubble columns as bio-reactors at sterile conditions is excluded. However, aerobic fermentations can be considered as three-phase reactors [122], with suspended biomass as the third phase. The largest bubble column reactors that have been erected for fermentation processes operated at un-sterile conditions, referred to as the Bayer Tower Biology (simple bubble column) and the Biohoch Reactor Hoechst (jet loop reactor), have a volume of more than 10000 m<sup>3</sup> per reactor unit [122]. Moreover, for the aerobic treatment of small quantities of highly polluted effluents a process has been developed in which a down-flow bubble column is employed. This demonstrates that even for the same reactions different types of bubble columns may be suited, depending on the given conditions. Additional application examples of bubble column reactors are given in Table 8.1.

Bubble columns are also used for a number of conventional processes such as oxidation, hydrogenation, chlorination, chemical gas cleaning and also various biotechnological applications [29, 122, 142, 148, 149].

### 8.4 Modeling of Bubble Column Reactors

The historical development of bubble column modeling has been discussed by Deckwer [29] and Dudukovic [35]. Models for bubble column reactors can be divided into various categories according to the degree of mixing in each phase. Perfect mixing (CSTR), partial mixing (ADM) or no mixing (PFR) characteristics may be found in both gas and liquid phase. The mixing in the liquid phase is often more intense than within the gas phase due to the turbulent motion induced by the gas bubbles, hence the early bubble column models were defined using a simple and ideal CSTR model

**Table 8.1** Examples of bubble column reactor applications in the chemical process industry

| Process                                                                  | Type of reactor                  | Reference                                 |
|--------------------------------------------------------------------------|----------------------------------|-------------------------------------------|
| Partial oxidation of ethylene to acetaldehyde                            | BC with external loop            | Onken [122], Deckwer [29]                 |
| Oxidation of acetaldehyde to acetic acid                                 | Cascade BC                       | Shah et al. [148], Onken [122]            |
| Oxidation of p-xylene to Dimethylterephthalate                           | BC with external loop or cascade | Onken [122]                               |
| Hydrogenation of benzene to cyclohexane                                  | Slurry BC with external loop     | Onken [122], Deckwer [29]                 |
| Synthesis of hydrocarbons, Fischer-Tropsch synthesis in the liquid phase | Slurry BC                        | Dry [34], Deckwer [29], Shah et al. [148] |
| Synthesis of methanol                                                    | Slurry BC                        | Shah et al. [148], Deckwer [29]           |
| Oxychlorination of ethylene to 1,2-Dichloroethane                        | Packed BC                        | Onken [122], Deckwer [29]                 |
| Hydrolysis of phosgene                                                   | Downflow BC                      | Onken [122]                               |
| Ozonization of waste water                                               | Downflow BC                      | Onken [122]                               |
| Biological waste water purification (aerobic)                            |                                  | Onken [122], Deckwer [29]                 |
| (a) Bayer tower biology                                                  | Simple BC                        |                                           |
| (b) Biohoch reactor                                                      | Jet internal loop BC             |                                           |
| (c) Compact reactor                                                      | Downflow BC                      |                                           |

BC Bubble column

for the Liquid phase and a PFR model for the gas phase. However, the heterogeneous axial dispersion model (ADM), consisting of the mass (3.505) and heat (3.506) balances as assessed in Chap. 6, can be considered a more general formulation for both the gas and liquid (slurry) phases in bubble columns [29, 63, 149, 188].

For two-phase bubble columns the balance equations determining the liquid (slurry) phase axial dispersion model can be written as [29, 149]:

$$\frac{d(\rho_L v_L^S \omega_{i,L})}{dz} = \frac{d}{dz} \left( \varepsilon_L \rho_L D_{\text{eff},z,L} \frac{d\omega_{i,L}}{dz} \right) + k_{L,i} a (\rho_{L,i}^* - \rho_{L,i}) + \varepsilon_L \sum_r \nu_{i,r} R_{L,r} \quad (8.1)$$

$$\begin{aligned} \rho_L C_{P,L} v_L^S \frac{dT_L}{dz} = & \frac{d}{dz} \left( \varepsilon_L k_{\text{eff},z,L} \frac{dT_L}{dz} \right) + 4 \frac{U}{d_t} (T_{\text{sur}} - T_L) \\ & + h_L a (T_G - T_L) + \varepsilon_L \sum_r (-\Delta H_r) R_{r,L} \end{aligned} \quad (8.2)$$

For the gas phase the axial dispersion model is written as:

$$\frac{d(\rho_G v_G^S \omega_{i,G})}{dz} = \frac{d}{dz} \left( \varepsilon_G \rho_G D_{\text{eff},z,G} \frac{d\omega_{i,G}}{dz} \right) - k_{L,i} a (\rho_{L,i}^* - \rho_{L,i}) \quad (8.3)$$

$$\frac{d(\rho_G v_G^S)}{dz} = - \sum_i k_{L,i} a (\rho_{L,i}^* - \rho_{L,i}) \quad (8.4)$$

$$\rho_G C_{P,G} v_G^S \frac{dT_G}{dz} = \frac{d}{dz} \left( \varepsilon_G \lambda_{\text{eff},z,G} \frac{dT_G}{dz} \right) - h_L a (T_G - T_L) \quad (8.5)$$

The species balance equations are normally solved with the standard Danckwerts boundary conditions [27].

For the phase  $k(= G, L)$  the inlet boundary conditions at  $z = 0$  yield:

$$\rho_k(0) v_k^S(0) \omega_{i,k}(0) - \varepsilon_k(0) \rho_k(0) D_{\text{eff},k}(0) \frac{d\omega_{i,k}(0)}{dz} = v_{\text{in},k}^S \rho_{\text{in},k} \omega_{i,\text{in},k} \quad (8.6)$$

$$\rho_k(0) v_k^S(0) c_{p,k}(0) T_k(0) - \varepsilon_k(0) k_{\text{eff},k}(0) \frac{dT_k(0)}{dz} = \rho_{\text{in},k} v_{z,\text{in},k} c_{p,k} T_{\text{in},k} \quad (8.7)$$

$$v_G^S(0) = v_{z,\text{in},G} \quad (8.8)$$

The outlet boundary conditions at  $z = L$  yield:

$$\frac{d\omega_c(z=L)}{dz} = \frac{dT(z=L)}{dz} = 0 \quad (8.9)$$

where the superficial velocity is linked to the local velocity through  $v_k^S = v_k \varepsilon_k$ .

The total pressure of the gas can be calculated from the ideal gas law:  $p_G = \rho_{G,i} RT_G / \overline{M}_w$ . For high pressure systems the operating pressure is dominated by the imposed pressure and is thus often assumed constant, whereas for atmospheric and low pressure processes the axial pressure profile is often dominated by the static pressure of the liquid phase,  $\frac{dp_L}{dz} = -\varepsilon_L \rho_L g_z$ . The pressures in the two phases are generally assumed to be equal,  $p_G \approx p_L$ . To close the interfacial mass transfer model a simple Henry's law equilibrium relation is frequently employed,  $\rho_{L,i}^* = M_{\omega_i} p_i / H_i = \rho_{G,i} RT_G / H_i$ .

In these balance equations all terms should be described at the same level of accuracy. It certainly does not pay to have the finest description of one term in the balance equations if the others can only be very crudely described. Current demands for increased selectivity and volumetric productivity require more precise reactor models, and also force reactor operation to churn turbulent flow which to a great extent is uncharted territory. An improvement in accuracy and a more detailed description of the molecular scale events describing the rate of generation terms in the heat- and mass balance equations has in turn pushed forward a need for a more detailed description of the transport terms (i.e., in the convection/advection and dispersion/conduction terms in the basic mass- and heat balances).

Experimental evidence show that the liquid axial velocity is far from being flat and independent of the radial space coordinate [29], and the use of a cross-sectional average velocity variable seems not to be sufficient. The back mixing induced by the global liquid flow pattern was commonly accounted for by adjusting the axial dispersion coefficient accordingly. However, while (slurry) bubble column performance

often can be fitted with an axial dispersion model, decades of research have failed to produce a predictive equation for the axial dispersion coefficient. Hence, research is in progress to quantify these based on first principles (e.g., see Jakobsen et al. [67, 71], Joshi [74], Sokolichin et al. [157], Rafique et al. [131], Portela and Olie-mans [129], and references therein). However, despite of their simple construction, the fluid dynamics observed in these columns is very complex. Even though the CFD modeling concepts have been extended over the last two decades in accordance with the rapid progress in computer performance, the model complexity required resolving all the important phenomena in these systems are still not feasible within reasonable time limits. The multi-fluid model is found to represent a trade-off between accuracy and computational efforts for practical applications.

Unfortunately, the present models are still on a level aiming at reasonable solutions with several model parameters tuned to known flow fields. For predictive purposes, these models are hardly able to predict unknown flow fields with reasonable degree of accuracy. It appears that the CFD evaluations of bubble columns by use of multi-dimensional multi-fluid models still have very limited inherent capabilities to fully replace the empirical based analysis (i.e., in the framework of axial dispersion models) in use today [68]. After two decades performing fluid dynamic modeling of bubble columns, it has been realized that there is a limit for how accurate one will be able to formulate closure laws adopting the Eulerian framework. In the subsequent sections a survey of the present status on bubble column modeling is given.

### 8.4.1 Fluid Dynamic Modeling

Considering modeling in further details the general picture from the literature is that the forces acting on the dispersed phase are [67]: Inertia-, gravity-, buoyancy-, viscous-, pressure-, lift-, wall-, turbulent stress-, turbulent dispersion-, steady drag- and added mass forces. In the latest papers performing 3D simulations, the force balances in vertical bubbly flows are found to be determined by only a few of these forces. The axial component of the momentum equation for the gas phase is dominated by the pressure- and steady drag forces only indicating that algebraic slip models may be sufficient [21, 118, 157], whereas most multi-fluid models also retain the inertia- and gravity (buoyancy) terms. The axial momentum balance for the liquid phase considers the inertia-, turbulent stress-, pressure-, steady drag- and gravity forces. Only pressure and buoyancy forces are acting on a motionless bubble in a liquid at rest. In the radial- and azimuthal directions the force balances generally includes the steady drag force, i.e., a force that is opposing motion, while the pertinent forces causing motion are more difficult to define. In a very short inlet zone the wall friction is likely to induce a radial pressure gradient that pushes the gas bubbles away from the wall, whereas a few column diameters above the inlet the radial pressure gradient vanishes. It is still an open question whether or not this pressure gradient is sufficient to determine the phase distribution observed in these systems. It is expected that the presence of the wall induce forces that act on the dispersed particles further away

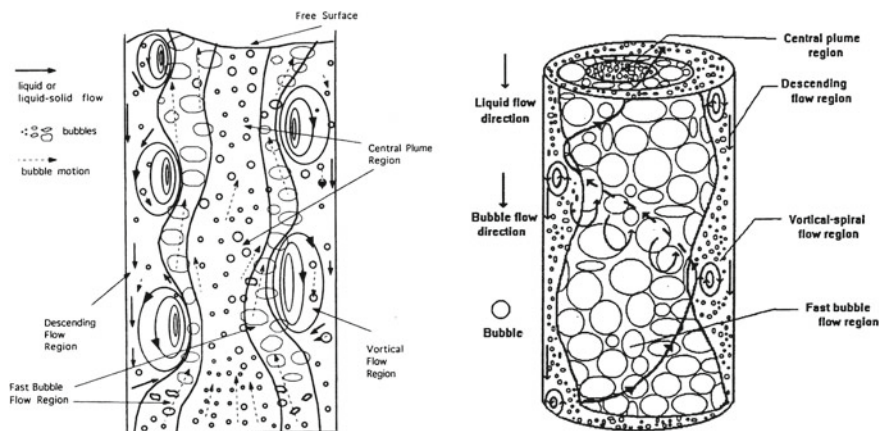

from the inlet, but there is no general acceptance on the physical mechanisms and formulations of these forces. It is also a matter of discussion whether this wall effect should be taken into account indirectly through the liquid wall friction, or in view of the model averaging performed directly as a force in the gas phase equations.

In the generalized drag formulation the interfacial coupling is expressed as a linear sum of independent forces, this point of view is probably not valid when the void fraction exceeds a few percent. Moreover, the parameterizations used for the coefficients occurring in the interfacial closures vary significantly, especially at higher void fractions. Single particle drag-, added mass- and lift coefficients are most frequently used, whereas swarm corrections have been included in some codes. For higher void fractions other rather empirical corrections have been introduced as well [10]. Likewise, considering the multi-fluid model, the average interfacial momentum transfer terms containing the interfacial average pressure and viscous stresses (discussed in Sect. 3.3) are strictly not consistent with the fundamental singlephase forces presented in Sect. 5.1. The interfacial coupling and wall forces are difficult to parameterize with sufficient accuracy. The steady drag component part of the generalized drag is the dominant interfacial force. In a few papers fair agreement with the available experimental data on the dynamic large scale circulating flow pattern in bubble columns have been achieved using this interfacial force solely [71, 82]. A variety of different formulations of this force, and especially on the drag coefficient, are reported in the literature valid for deformable and rigid spherical particles, extended for different flow regimes, swarm effects and pure and contaminated fluid systems. In several papers on bubble column flow modeling [13, 118] the drag coefficient correlations valid for non-deformable spheres [110, 140] have been adopted. For typical heterogeneous flow conditions these relations give rise to drag force coefficient values which are typically about 25 % of the standard values for cap bubbles given by the parameterizations suggested by Tomiyama et al. [168] (see Sect. 5.1.4). Jakobsen et al. [71] did assess these spherical particle coefficient correlations in their 2D code and obtained completely flat profiles (i.e., no variation in the radial direction) for the axial velocities and the volume fraction. There was thus no circulation cells created in the column, which is in accordance with the experiments reported by Harteveld [57]. On the other hand, other 2D and 3D simulations reported in the literature employing the drag coefficient correlations for spherical particles always give the anticipated dynamic circulating flow pattern that has become standard in the recent papers. It should be mentioned that in most of the latter simulations an additional wall friction force [103] acting on the gas phase is implemented (to be discussed shortly). Implementing the added mass force has barely any influence on the steady state solution [31, 71]. Deen et al. [31] explained this to some extent surprising result by the fact that the simulations soon reach a quasi-stationary state where there is only minor acceleration. The bubble jets observed close to the distributor plate are then disregarded. However, the convergence rate and thus the computational costs are often significantly improved implementing this force. The primary effect of the transversal lift force is to push the gas bubbles radially inwards or outwards in the column depending on the sign of the lift coefficient. The force is usually modeled as though it is induced by a velocity gradient, and can therefore only reinforce or smooth

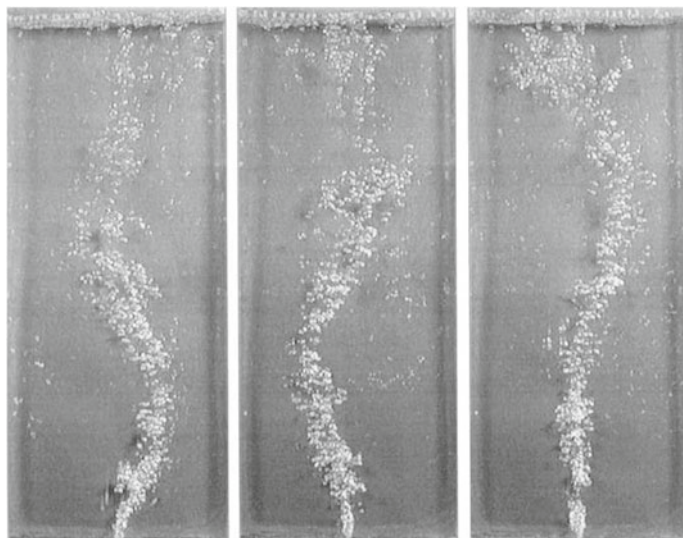

out the existing gradients in the flow fields. For this reason other forces are important in the initial phase of the flow pattern development. Moreover, in the two-fluid model with a single average bubble size this force alone can not change a center peak flow pattern to a wall peak pattern or vice versa. However, using a multi-fluid model with a bubble size distribution the lift force might change a center peak flow pattern to a wall peak pattern or vice versa. Nevertheless, any interactions between the onset of the dynamic large-scale circulation flow pattern and the bubble coalescence and breakage mechanisms have not been demonstrated yet. Effects similar to those of the lift force are observed when implementing the turbulent dispersion force using the gradient diffusion model. This dispersion force closure smooths out sharp velocity gradients in the domain. If the model overestimates the diffusive effect, the velocity profiles may become completely flat over the column cross section. The radial wall lift force proposed by Antal et al. [2] requires a certain minimum resolution of the grid close to the wall. The values of the model coefficients are crucial for the development of the profiles since these parameters determine the magnitude of the force as well as the operative distance from the wall. The magnitude of the force is highest for larger bubbles, and the force is very sensitive to the bubble size. However, the force does not alter the flow development significantly except very close to the wall. To ensure that the gas in upward bubbly flow migrates away from a triangular duct wall Lopez de Bertodano [103] introduced an axial friction force acting on the gas in the vicinity of the wall. Under bubble column flow conditions this friction force may significantly affect the radial phase distribution provided that a sufficiently small steady drag force is employed [71]. The addition of the gas wall friction may for example alter a uniform or wall peaking flow regime into a center peaking behavior. In several reports on bubble column modeling a constant gas density is employed. This assumption is not consistent for tall columns that are operated at ambient outlet pressure. Similar inconsistency problems arise when reactive systems are simulated, as the gas density vary in accordance with the chemical process behavior. Moreover, interfacial mass transfer fluxes and chemical reactions often induce numerical stability problems and no proper convergence. The flow of the continuous phase is considered to be initiated by a balance between the interfacial particle-fluid coupling- and wall friction forces, whereas the fluid phase turbulence damps the macroscale dynamics of the bubble swarms smoothing the velocity- and volume fraction fields. Temporal instabilities induced by the fluid inertia terms create non-homogeneity's in the force balances. Unfortunately, proper modeling of turbulence is still one of the main open questions in gas-liquid bubbly flows, and this flow property may significantly affect both the stresses and the bubble dispersion [157].

It has been shown by Svendsen et al. [161], among others, that the time averaged experimental data on the flow pattern in cylindrical bubble columns is close to axi-symmetric. Fair agreement between experimental- and simulated results are generally obtained for the steady velocity fields in both phases, whereas the steady phase distribution is still a problem. Therefore, it was anticipated that the 2D axi-symmetric simulations capture the pertinent time-averaged flow pattern that is needed for the analysis of many (not all) mechanisms of interest for chemical engineers. Sanyal et al. [137] and Krishna and van Baten [81] for example stated that the 2D models

**Fig. 8.7** Classification of regions accounting for the macroscopic flow structures: *left* 2D bubble column [172]; *right* 3D bubble column [23]. Reproduced with permission from John Wiley and Sons. Copyright 1993 and 1994 American Institute of Chemical Engineers (AIChE)

provide good engineering descriptions, although they are not able to capture the high frequency unsteady behavior of the flow, and can be used for approximately predicting the low frequency time-averaged flow and void patterns in bubble columns. The early 2D steady-state model proposed by Jakobsen [64] (outlined in app F) was able to capture the global flow pattern fairly well provided that a large negative lift force was included. However, after the first elaborated experimental studies on 2D rectangular bubble columns were published by Tzeng et al. [172] and Lin et al. [98], it was commonly accepted that time-average computations cannot provide a rational explanation of the transport processes of mass, momentum, and energy between the bubbles and liquid. The experimental data obtained was analyzed and sketches of their interpretations of the dynamic flow patterns in both 2D and 3D columns were given, as shown in Fig. 8.7. It was concluded that a proper bubble column model should consider the transient flow behavior. A few years later Sokolichin and Eigenberger [154], Sokolichin et al. [155], Sokolichin and Eigenberger [156] and Borchers et al. [15] claimed that dynamic 3D models were needed to provide sufficient representations of the high frequency unsteady behavior of these flows. Very different dynamic flow patterns may result in quantitatively similar long-time averaged flow profiles. This limits the use of long-time averaged flow profiles for validation of bubbly flow models. van den Akker [175], among others, questioned the early turbulence modeling performed (or rather the lack of any) in these studies and argued that the apparently realistic simulations of the transient flow characteristics could be numerical modes rather than physical ones (see also Sokolichin et al. [157]). Insufficiently fine grids may have been used in the simulations resulting in numerical instabilities that could be erroneously interpreted as physical ones. However, after the observation of Sokolichin and Eigenberger was reported, intensive focus on these instability issues were put forward, mainly by researchers from the fluid dynamics community. The experimental data provided by Becker et al. [8, 9],

**Fig. 8.8** Lateral movement of the bubble hose in a flat bubble column [9]. Reprinted with permission from Elsevier

see Fig. 8.8, still serve as a benchmark test and is often used for validation of dynamic flow models. The numerical investigations were restricted to bubbly flow hydrodynamics (i.e., no reactive systems were analyzed), where additional simplifications were made; isothermal conditions, no interfacial mass transfer, constant liquid density, gas density constant or depending on local pressure as described by the ideal gas law, neglecting bubble coalescence and breakage.

However, after the dynamic flow structures were observed bubble columns have generally been simulated using either 2D- or 3D dynamic models both for cylindrical [13, 82, 83, 96, 97, 120, 121, 125, 137] and rectangular 2D and 3D column geometries [13, 16, 18, 19, 31, 82, 111, 113, 118, 124, 157]. The gas is introduced both adopting uniform and localized feedings at the bottom of the column. Modeling of systems uniformly gassed at the bottom is more difficult than the modeling of partly aerated ones. Simulating systems with continuous liquid flow is also more difficult than keeping the liquid in batch mode. Finally, it is also noted that the different research groups applied both commercial codes (e.g., CFX, FLUENT, PHOENICS, ASTRID, NPHASE) and several in-house codes where the inherent choice of numerical methods, discretizations, grid arrangements and boundary implementations varies quite a lot. These numerical differences alter the solutions to some extent, so it should not be expected that the corresponding simulations will provide identical results. An open and unified research code available for all research groups could assist eliminating any misinterpretations of numerical modes as physical mechanisms, and vice versa.

Considering the interfacial- and turbulent closures for vertical bubble driven flows, no extensive progress has been observed in the later publications. However, two

diverging modeling trends seem to emerge due to the lack of understanding of the phenomena involved and on how to deal with these phenomena within an average modeling framework. One group of papers considers only phenomena that can be validated with the existing experimental techniques and thus contains a minimum number of terms and effects. The other group of papers include a large number of weakly founded theoretical hypothesis and relations intending to resolve the missing mechanisms.

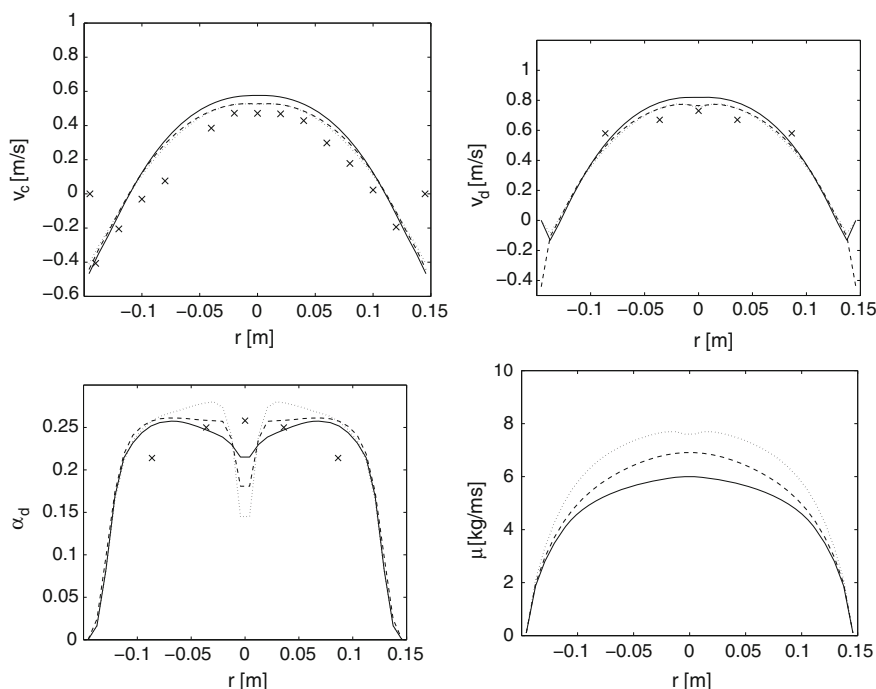

#### 8.4.1.1 Steady-State or Dynamic Simulations, Closures, and Numerical Grid Arrangements

Not only dynamic models have been adopted investigating these phenomena. Lopez de Bertodano [103] for example used a 3D steady finite volume method (FVM) (PHOENICS) with a staggered grid arrangement to simulate turbulent bubbly two-phase flow in a triangular duct. In this study the lift-, the turbulent dispersion- and the steady drag forces were assumed dominant. Standard literature expressions were adopted for the drag- and lift forces, whereas a crude model for the turbulent dispersion force was developed. An extended  $k - \varepsilon$  model, considering bubble induced turbulence, was also developed for the liquid phase turbulence. It was proposed that the shear-induced turbulence and the bubble-induced turbulence could be superposed. The lift force was found essential to reproduce the experimentally observed wall void peaks satisfactorily. Anglart et al. [1] adopted many of the same closures within a 2D steady version of the same code (PHOENICS) predicting low void bubbly flow between two parallel plates. They found satisfactory agreements with experimental data when applying drag-, added mass-, lift-, wall (lubrication)- and turbulent diffusion forces in their study. The extended  $k - \varepsilon$  model of Lopez de Bertodano [103] was applied for the liquid phase turbulence. In a more recent paper Antal et al. [4] adopted very similar closures for 3D steady-state bubble column simulations using the NPHASE code. The NPHASE CMFD code employs a FVM on a collocated grid. A three field multi-fluid model formulation was used to simulate two-phase flow in a bubble column operating in the churn-turbulent flow regime. The gas phase was subdivided into two fields (i.e., small and large bubbles) to more accurately describe the interfacial momentum transfer fluxes. The third field was used for the liquid phase. The model results were validated against a few time averaged data sets for the liquid axial velocity and the gas volume fraction. Global flow patterns for all three fields and overall gas volume fractions were shown. The simulations were in fair agreement with the experimental observations. Using a 2D in-house FVM code with a staggered grid arrangement Dhotre and Joshi [32] predicted the flow pattern, pressure drop and heat transfer coefficient in bubble column reactors. The model used contained steady drag-, added mass- and lift forces, as well as a reduced pressure gradient formulated as an apparent form drag. Turbulent dispersion was accounted for by use of mass diffusion terms in the continuity equations. A low Reynolds number  $k - \varepsilon$  model was incorporated, broadly speaking constituting a standard  $k - \varepsilon$  model with modified treatment of the near-wall region. The turbulence model used contained an additional

production term accounting for the large scale turbulence produced within the liquid flow field due to the movement of the bubbles. A semi-empirical mechanical energy balance for the gas–liquid system was required fulfilled. The simulated results were in very good agreement with experimental literature data on the axial liquid velocity, gas volume fraction, friction multiplier and heat transfer coefficient.

In a recent study Jakobsen et al. [71] examined the capabilities and limitations of a dynamic 2D axi-symmetric two-fluid model for simulating cylindrical bubble column reactor flows. In their in-house code all the relevant force terms consisting of the steady drag, bulk lift, added mass, turbulence dispersion and wall lift were considered. Sensitivity studies disregarding one of the secondary forces like lift, added mass and turbulent dispersion at the time in otherwise equivalent simulations were performed. Additional simulations were run with three different turbulence closures for the liquid phase, and no shear stress terms for the gas phase. A standard  $k - \epsilon$  model [95] was used to examine the effect of shear induced turbulence, case (a). In an alternative case (b), both shear- and bubble induced turbulence were accounted for by linearly superposing the turbulent viscosities obtained from the  $k - \epsilon$  model and the model of Sato and Sekoguchi [138]. A third approach, case (c), is similar to case (b) in that both shear and bubble induce turbulence contributions are considered. However, in this model formulation, case (c), the bubble induced turbulence contribution was included through an extra source term in the turbulence model equations [64, 67, 71]. The relevant theory is summarized in Sect. 8.4.4.

A comparison between the steady state profiles at axial levels  $z = 2.0$  and  $z = 0.3$  m in the column employing the three turbulence closures (a), (b) and (c) was given as shown in Figs. 8.9 and 8.10, respectively. The most important conclusion drawn from this investigation is that the assumption of cylindrical axi-symmetry in the computations prevents lateral motion of the dispersed gas phase and leads to an unrealistic radial phase distribution wherein the maximum void is away from the center-line, which is also reported by other authors [82, 137]. It is also worth noting that imposing the axi-symmetry boundary condition causes the liquid flow to develop very quickly and the long-time circulating pattern is reached within a few seconds (typically less than 5 s of real time) after the first gas has been flowing through the column. In contrast, the experimental data reported by Sanyal et al. [137] and Pfleger and Becker [125] is characterized by a highly dynamic flow, with 3D vortical bubble swarms. For  $z = 2.0$  m all the model versions gave reasonable velocities compared to the experimental data. For  $z = 0.3$  m there were larger discrepancies between the simulated results and the experimental data. The voidage profiles observed in the experiments are lower than at  $z = 2.0$  m, while the profiles from the simulations are approximately the same. The discrepancy indicates that the physics in the bottom of the column is not sufficiently captured by the 2D model. At the axial level 0.3 m above the inlet, Fig. 8.10, the cross-sectional averaged void was over-estimated by about 25–35 %, thus the corresponding cross-sectional averaged gas velocity was underestimated. This is a strong indication that 3D effects are important at least in the inlet section. However, studies reported in the literature show that it can be very difficult to obtain reasonable time averaged radial void profiles even in 3D simulations [71]. Nevertheless, the deviation between the experimental data and

the simulated results may also indicate that the inlet boundary conditions used, the phase distribution and the interfacial coupling are inaccurate and not in agreement with the real system.

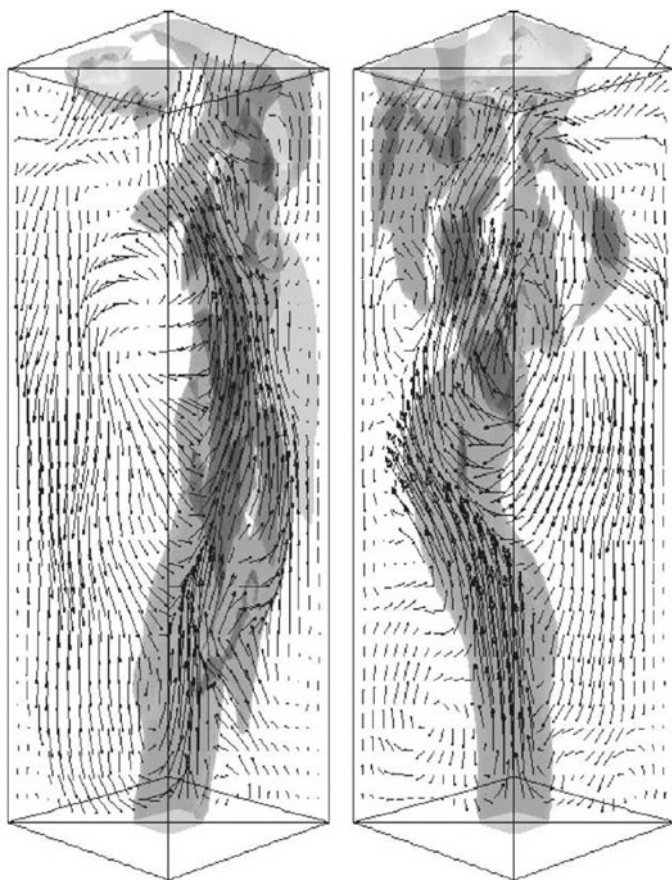

Deen et al. [31] used the lift force in addition to the steady drag- and added mass forces in their dynamic 3D-model to obtain the transversal spreading of the bubble plume which is observed in experiments. A prescribed zero void wall boundary was used forcing the gas to migrate away from the wall. The continuous phase turbulence was incorporated in two different ways, using either a standard  $k - \varepsilon$ - or a VLES model. The effective viscosity of the liquid phase was composed of three contributions, the molecular-, shear induced turbulent- and bubble induced turbulence viscosities. The calculation of the turbulent gas viscosity is based on the turbulent liquid viscosity as proposed by Jakobsen et al. [67]. These simulations were performed using the commercial code CFX, thus a FVM on a collocated grid was employed. Sample results simulating a square 3D column at low void fractions using the 3D VLES model of Deen et al. [31] are shown in Fig. 8.11. Krishna and van Baten [82, 83] used a steady drag force as the only interfacial momentum coupling in their

transient 2D- and 3D three fluid models with an inherent prescribed and fixed bi-modal distribution of the gas bubble sizes. The two bubble classes are denoted small and large bubbles. The small bubbles are in the range of 1–6 mm, whereas the large bubbles are typically in the range of 20–80 mm. A simplification made in the model is that there are no interactions or exchanges between the small and large bubble populations. A FVM on a non-staggered grid was used discretizing the equations (i.e., in CFX). No-slip conditions at the wall were used for both phases. A  $k - \varepsilon$  model was applied for the liquid phase turbulence, whereas no turbulence model was used for the dispersed phases. To prevent a circulation pattern in which the liquid flows up near the wall and comes down in the core, the large bubble gas was injected on the inner 75 % of the radius. The time averaged volume fraction- and velocity profiles calculated from the predicted 3D flow field were in reasonable agreement with experimental data. Lehr et al. [97] used a similar three-fluid model (implemented in CFX), combined with a simplified population balance model for the bubble-size distribution. The simplified population balance relation used contained semi-empirical parameterizations for the bubble coalescence and breakage phenomena. It was concluded that the

calculated long time average volume fractions, velocities, and also the interfacial area density were in good agreement with experimental data. Pfleger et al. [124] applied a two-fluid model using the same code (CFX) to a 2D rectangular column with localized spargers. It was concluded that a 3D model including the steady drag force and a standard  $k - \varepsilon$  model is sufficient to correctly capture the unsteady behavior of bubbly flow with very low gas void fractions. The bubble swarm began its swinging motion after a certain time delay. Pfleger and Becker [125] and Bertola et al. [13] used similar two-fluid models and FVMs on collocated grid arrangements (CFX and FLUENT, respectively) simulating both cylindrical and rectangular columns, confirming the results found by Pfleger et al. [124]. It should be noted, however, that Bertola et al. [13] solved the  $k - \varepsilon$  turbulence model for both phases, whereas in the work of Pfleger and co-workers [124, 125] the dispersed phase was considered laminar. Mudde and Simonin [113] performed both dynamic 2D- and 3D simulations of a 2D

rectangular column using a similar FVM on a collocated grid arrangement (ASTRID). Their two-fluid model contained an extended  $k - \epsilon$  turbulence model formulation for the liquid phase turbulence, and drag- and added mass forces. The dispersed phase turbulence was assumed steady and homogeneous and described by an extended Tchen's theory approach [151, 152, 163, 181]. This code predicted reasonable high frequency oscillating flows only when the added mass force was included, without this force low frequency almost steady flows were obtained. Using a FD algorithm Tomiyama et al. [166] reported that the transient transversal migration of bubble plumes in vessels can be well predicted including steady drag-, added mass- and lift forces in their two-fluid model describing laminar flows containing very low void fractions (i.e., below 0.5 %). Later, Tomiyama [167] and Tomiyama and Shimada [169] used the bubble induced turbulence model of Sato and Sekoguchi [138] and Sato et al. [139] and an extended  $k - \epsilon$  model in their work on turbulent flows. In a recent paper Sokolichin et al. [157] concluded that the model by Sato and Sekoguchi [138] for bubble induced turbulence overestimates the turbulent viscosity parameter and thus strongly underestimates the turbulence level in a number of test cases. Another disadvantage of this approach is associated with the local nature of the model, because it considers the increase of the turbulence intensity only locally in the reactor where the gas phase is actually present. In reality, the turbulence induced by the bubbles at some given point can spread and affect regions further away from the turbulence source. Oey et al. [118] applied a 3D two-fluid model containing the steady drag-, added mass- and turbulent dispersion forces together with an extra source term in the  $k - \epsilon$  turbulence model accounting for the effects of the interface in their in-house staggered FVM code (ESTEEM). Due to the controversy in the literature regarding disperse phase turbulence, both laminar and turbulent gas simulations were made. In the turbulence case, the extended Tchen's theory approach was adopted. The liquid tangential velocity components close to the wall were found using wall functions, while no wall friction was taken into account for the dispersed phase. They found that in 3D the steady drag force was sufficient to capture the global dynamics of the bubble plume while the other forces moreover have secondary effects only. Most of the studies mentioned above adopted a kind of  $k - \epsilon$  model to describe the liquid turbulence in the system, whereas there is less consensus regarding whether the dispersed phase should be considered turbulent or laminar, or even whether any deviating stress terms at all should remain in the dispersed phase equations. However, even the  $k - \epsilon$  model predictions are questioned by Deen et al. [31] and Bove et al. [16]. This group showed that only low frequency unsteady flow is obtained using the  $k - \epsilon$  model due to overestimation of the turbulent viscosity. These model predictions were found not to be in satisfactory agreement with the more high frequent experimental results. On the other hand, when using a 3D Smagorinsky LES (Large Eddy Simulation) model instead, the strong transient movements of the bubble plume which are observed in experiments were captured. Similarly, the majority of the investigations reported conclude that for both rectangular and cylindrical columns the high frequency instabilities are 3D and have to be resolved by the use of 3D models. Nevertheless, in a few recent papers [6, 7, 22] it has been shown that 2D mixture model formulations can be used to reproduce the time-dependent

flow behavior of 2D bubble columns. It has been found that the crucial physics can be captured by 2D models if suitable turbulence models are used. The predictions reported by Bech [6, 7] rely on the inclusion of a mass diffusion term in the dispersed phase continuity equation together with a appropriate zero- or two-equation turbulence model, while Cartland Glover and Generalis'[22] predictions rely on the inclusion of a Reynolds stress model. In the work of Bech [7] the  $k - \omega$  turbulence model gave a better qualitative prediction of the bubble plume than the standard  $k - \varepsilon$  model, due to the low-Reynolds number treatment of the former model. A simple mixing length turbulence model gave the best prediction of the meandering plume, even without any dispersion term.

A conclusion drawn in several papers investigating the fluid dynamics of the reactors is that the flow have to be about perfect before the chemistry related topics should be considered. Such an invidious statement may have been of severe hindrance for the development of integrated fluid dynamic reactor models of interest for chemical reaction engineers. However, there are several indications that the local high frequency dynamics and coherent structures of the flow are important determining the conversion in chemical reacting systems [19, 57, 111, 157, 176]. The mixing times predicted by steady flow codes are for example found not to be in accordance with experimental data, whereas mixing times predicted by high frequent transient flow codes are in fair agreement with the corresponding measurements. Nevertheless, the main limitation associated with these advanced reactor models is the tremendous CPU demands needed for the high frequency instabilities, making such 3D simulations not feasible for most research groups. The interfacial and turbulence closures suggested in the literature also differ considering the anticipated importance of the bubble size distributions. It thus seemed obvious for many researchers that further progress on the flow pattern description was difficult to obtain without a proper description of the interfacial coupling terms, and especially on the contact area or projected area for the drag forces. The bubble column research thus turned towards the development of a dynamic multi-fluid model that is extended with a population balance module for the bubble size distribution. However, the existing models are still restricted in some way or another due to the large cpu demands required by 3D multi-fluid simulations.

#### 8.4.1.2 Multi-Fluid Models and Bubble Size Distributions

To gain insight on the capability of the present models to capture physical responses to changes in the bubble size distributions, a few preliminary analyzes have been performed adopting the multi-fluid modeling framework.

Lo [100–102] developed the extended two-fluid model named the MUSIG (Multiple-SIze-Group) model in which the dispersed phase is divided into multiple groups. In the original two-fluid MUSIG model only one set of continuity and momentum equations are considered for the dispersed phase. The model describes the dynamic evolution of a number of bubble size groups in space (typically  $\sim 15$ – $20$  groups) and from the resulting size distribution a mean bubble size is determined.

The mean bubble size, which is varying locally in the column, is used to calculate an improved estimate of the contact area and thus the momentum transfer terms (steady drag). However, since the two-fluid model is employed, the single gas velocity field limits the applicability of the model. In particular, effects such as segregation by size are difficult to describe. The performance of the original MUSIG model is thus limited to convection dominated bubbly flows, since it is based on the assumption that a single velocity field can be applied for all bubble size groups [80].

To remove this model limitation entirely a complete multi-fluid model is required. For gas–liquid systems Reyes [135] and Lafi and Reyes [86] presented a detailed derivation of the mass, momentum and energy conservation equations for poly-dispersed systems following an approach analogous to the Boltzmann’s transport equation. They derived a set of fluid particle conservation equations for the distribution of chemically non-reacting, spherical fluid particles dispersed in a continuous medium. Kocamustafaogullari and Ishii [79], following a similar approach, extended the application of the model to a general two-phase flow. An analogous modeling framework for dense gas–solid reactive mixtures in fluidized beds has been presented by Goldman and Sirovich [48], Simonin [153], Valiveti and Koch [177] and Lathouwers and Bellan [90–94]. In this case the governing transport equations are derived using kinetic theory concepts similar to those of dense gases. Important differences from classical kinetic theory are the in-elasticity of collisions between macroscopic particles leading to dissipation, and the presence of an interstitial gas exerting drag on the particles, which leads to interaction terms in the averaged transport equations.

Based on these generalized theories the research group at FZ Rossendorf in Dresden [42, 150] developed a useful alternative to the original MUSIG model by extending the two-fluid model to a multi-fluid model with a limited number both of size ( $M$ ) and velocity ( $N$ ) phases (sometimes referred to as the  $N \times M$  MUSIG model). The dispersed phases can thus move with different velocities and the novel multi-fluid model might be capable of handling more complex flow situations. In particular, in the extended MUSIG model approach the dispersed phase is divided into a number of  $N$  velocity phases (or groups), where each of the velocity groups is characterized by its own velocity field. Moreover, the overall particle size distribution is represented by dividing the particle diameter range within each of the velocity groups into a number of  $M$  bubble size phases (or classes). The subdivision into groups and classes should preferably be based on the different physics of the particle motion. Considering bubbly flows with bubbles of different sizes, the different behavior with respect to the lift or turbulent dispersion forces could be a suitable split up criterion for the velocity groups. Shi et al. [150] assumed that for most cases 3 or 4 velocity groups are sufficient in order to capture the main phenomena in bubbly and slug flows. For simplicity the number of particle diameter classes within each of the velocity groups was equal and fixed to a predefined value. The first numerical simulations were therefore performed using  $N = 3$  velocity phases and  $M = 7$  bubble size classes in each velocity group. An overall number of 21 bubble size classes was thus applied for the representation of the local bubble size distribution. This bubble size resolution was found to be appropriate for many bubbly flow problems.

Sha et al. [146, 147] developed a similar multi-fluid model for the simulation of gas-liquid bubbly flow. To guarantee the conservation of mass the population balance part of the model was solved by the discrete solution method presented by Hagesæther et al. [56]. The 3D transient simulations of a rectangular column with dimensions  $150 \times 30 \times 2000$  mm and the gas evenly distributed at the bottom were run using the commercial software CFX4.4. For the same bubble size distribution and feed rate at the inlet, the simulations were carried out as two, three, six and eleven phase flows. The number of population balance equations solved was 10 in all the simulations. It was stated that the higher the number of phases used, the more accurate are the results.

Carrica et al. [21] developed a simplified multi-fluid model for the description of bubbly two-phase flow around a surface ship. In the momentum equations for the gas bubble phases or groups the inertia and shear stress terms were assumed to be negligible. The interfacial momentum transfer terms included for the different bubble groups are steady-drag, added mass, lift and turbulent dispersion forces. Algebraic turbulence models were used both for the liquid phase contributions and the for the bubble-induced turbulence. The two-fluid model was solved using a FVM on a staggered grid. In the population balance part of the model the inter-group transfer mechanisms included were bubble breakage, coalescence and the dissolution of air into the ocean. 15 size groups were used with bubble radius at normal pressure between 10 and  $1000 \mu\text{m}$ . It was found that inter-group transfer is very important in these flows both for determining a reasonable two-phase flow field and the bubble size distribution. The population balance was discretized using the multi-group approach. It was pointed out that the lack of validated kernels for bubble coalescence and breakage was limiting the accuracy of the model predictions. Politano et al. [126] adapted the population balance model of Carrica et al. [21] for the purpose of 3D steady-state simulation of bubble column flows. However, no details regarding the necessary model modifications were provided. In a later study by Politano et al. [127] a 2D steady-state version of this model was applied for the simulation of poly-disperse two-phase flow in vertical channels. The two-fluid model was modified using an extended  $k - \varepsilon$  model for the description of liquid phase turbulence. A two-phase logarithmic wall law was developed to improve on the boundary treatment of the  $k - \varepsilon$  model. The interfacial momentum transfer terms included for the different bubble groups are steady-drag, added mass, lift, turbulent dispersion and wall forces. The two-fluid model equations were discretized using a finite difference (FD) method. The bubble mass was discretized in three groups. The effect of bubble size on the radial phase distribution in vertical upward channels was investigated. Comparing the model predictions with experimental data it was concluded that the model is able to predict the transition from the near-wall gas volume fraction peaking to the core peaking beyond a critical bubble size.

Tomiya [167] and Tomiyama and Shimada [169] adopted a  $(N + 1)$ -fluid model for the prediction of 3D unsteady turbulent bubbly flows with non-uniform bubble sizes. Among the  $(N + 1)$ -fluids, one fluid corresponds to the liquid phase and the  $N$  fluids to gas bubbles. To demonstrate the potential of the proposed method, unsteady bubble plumes in a water filled vessel were simulated using both

(3 + 1)-fluid and two-fluid models. The gas bubbles were classified and fixed in three groups only, thus a (3 + 1)- or four-fluid model was used. The dispersions investigated were very dilute thus the bubble coalescence and breakage phenomena were neglected, whereas the inertia terms were retained in the 3 bubble phase momentum equations. No population balance model was then needed, and the phase continuity equations were solved for all phases. It was confirmed that the (3 + 1)-fluid model gave better predictions than the two-fluid model for bubble plumes with non-uniform bubble sizes.

As mentioned earlier, three-fluid models have also been used by a few groups [82, 97]. Krishna and van Baten [82] solved the Eulerian volume-averaged mass- and momentum equations for all three phases. However, no interchange between the small and large bubble phases were included thus each of the dispersed bubble phases exchanges momentum only with the liquid phase. No population balance model was used as the bubble coalescence and breakage phenomena were neglected. Lehr et al. [97] extended the basic three-fluid model including a simplified population balance model for the bubble-size distribution.

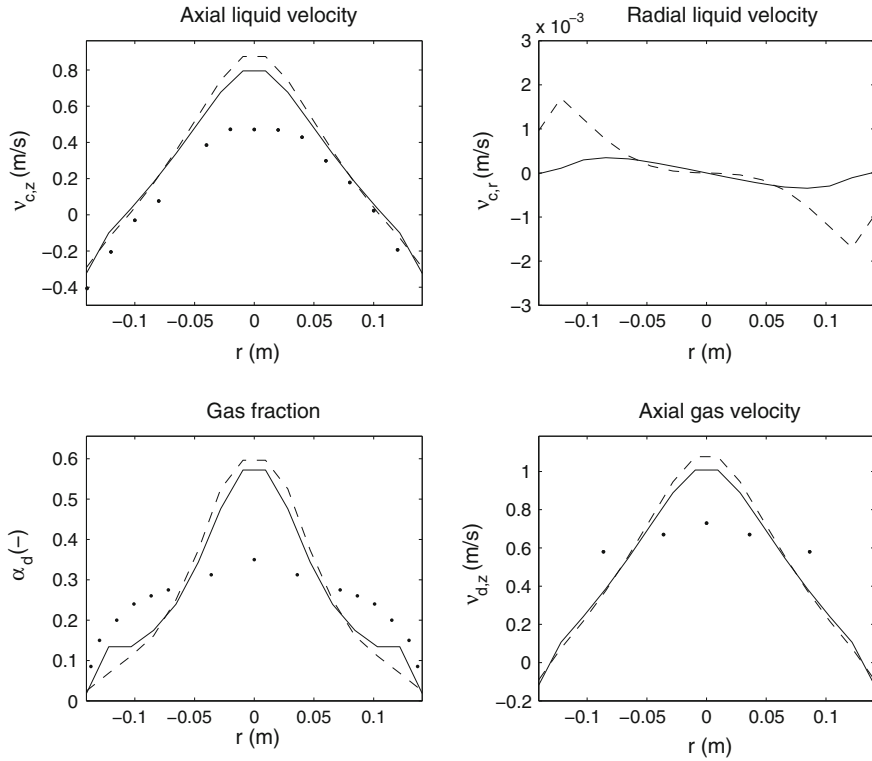

In most studies reported so far two-fluid models are used [18, 21, 100–102, 120, 121, 126], assuming that all the particles have the same average velocities. In other words, the possible particle collisions due to buoyancy effects are neglected even though these contributions have not been proven insignificant. This means that the two momentum equations for the two phases are solved together with the continuity equation of the liquid phase and the  $N$  population balance equations for the dispersed phases [21]. An alternative, often used adopting commercial CFD codes due to limited access to the solver routines, is to solve the full two-fluid model in the common way using the dispersed phase continuity equation together with the two momentum equations and the liquid phase continuity. Within the IPSA-like calculation loop the  $N - 1$  population balance equations are solved in another step considering additional transport equations for scalar variables. Unfortunately, using this approach it may be difficult to ensure mass conservation for the dispersed phase, and/or the last class can get negative concentrations. From the solution of the size distribution of the dispersed phase, the Sauter mean diameter is calculated. This diameter is then used computing the contact area, thus the two-way interaction between the flow and the bubble size distribution is established. When dilute dispersions are considered, the interfacial momentum transfer fluxes due to particle collisions, coalescence and breakage phenomena are normally neglected. Politano et al. [126] are the only ones that considered the interfacial momentum transfer fluxes between the bubble groups induced by bubble coalescence and breakage, but still the bubble collisions resulting in rebound were not taken into consideration.

Several recent studies indicate that algebraic slip models are sufficient modeling the flow pattern in bubble columns [14, 21, 118, 157], as the pressure and steady drag forces only dominate the axial component of the gas momentum balance. Therefore, the population balance model can be merged with an algebraic slip model to reduce the computational cost required for preliminary analysis [14]. Furthermore, adopting this concept the restriction used in the two-fluid model assuming that all the particles have the same velocity can be avoided. This means that only one set

of momentum- and continuity equations for the mixture is solved together with the  $N$  population balance equations for the dispersed phases. The individual phase- and bubble class velocities are calculated from the mixture ones using algebraic relations. Even simpler approaches are used solving a single transport equation for one moment of the population balance only, determining a locally varying mean particle size or the interfacial area density [79, 96, 109, 183].

The main contribution from the work of Luo [105, 106] was a closure model for binary breakage of fluid particles in fully developed turbulence flows based on isotropic turbulence- and probability theories. The author(s) also claimed that this model contains no adjustable parameters, a better phrase may be no additional adjustable parameters as both the isotropic turbulence- and the probability theories involved contain adjustable parameters and distribution functions. Hagesæther et al. [53–56] continued the population balance model development of Luo within the framework of an idealized plug flow model, whereas Bertola et al. [14] combined the extended population balance module with a 2D algebraic slip mixture model for the flow pattern. Bertola et al. [14] studied the effect of the bubble size distribution on the flow fields in bubble columns. An extended  $k - \varepsilon$  model was used describing turbulence of the mixture flow. Two sets of simulations were performed, i.e., both with and without the population balance involved. Four different superficial gas velocities, i.e., 2, 4, 6 and 8 cm/s were used, and the superficial liquid velocity was set to 1 cm/s in all the cases. The population balance contained six prescribed bubble classes with diameters set to  $d_1 = 0.0038$ ,  $d_1 = 0.0048$ ,  $d_1 = 0.0060$ ,  $d_1 = 0.0076$ ,  $d_1 = 0.0095$  and  $d_1 = 0.0120$  m. Figures 8.12 and 8.13 show simulated and experimental results with superficial gas velocity,  $v_g^s = 8$  cm/s. Figure 8.12 shows the axial and radial liquid velocity components, the axial gas velocity component and the gas fraction 2.0 m above the column inlet. Figure 8.13 shows the number density in each class 2.0 m above the inlet. The results from the two simulations (i.e., with and without the population balance) are nearly identical. In both cases the simulated results are in fair agreement with the experimental data, but in the center of the reactor the deviation between the simulated and experimental velocity and void fraction profiles are rather large. The number density 2.0 m above the inlet is shown in Fig. 8.13. In general, it was found that the initial bubble size was not stable and further determined by break-up and coalescence mechanisms. The simulation provides results in fair agreement with the experimental data for the classes 3–6 where the bubble number density is at the same order of magnitude as the experimental data. In bubble classes 1 and 2 the experimental bubble number densities are considerably underestimated in the simulations compared to the measured data.

However, in other cases the model predictions deviate much more from each other and were in poor agreement the experimental data considering the measurable quantities like phase velocities, gas volume fractions and bubble size distributions. An obvious reason for this discrepancy is that the breakage and coalescence kernels rely on ad-hoc empiricism determining the particle-particle and particle-turbulence interaction phenomena. The existing parameterizations developed for turbulent flows are high order functions of the local turbulent energy dissipation rate that is often determined by the  $k - \varepsilon$  turbulence model. This approach is not accurate enough [97,

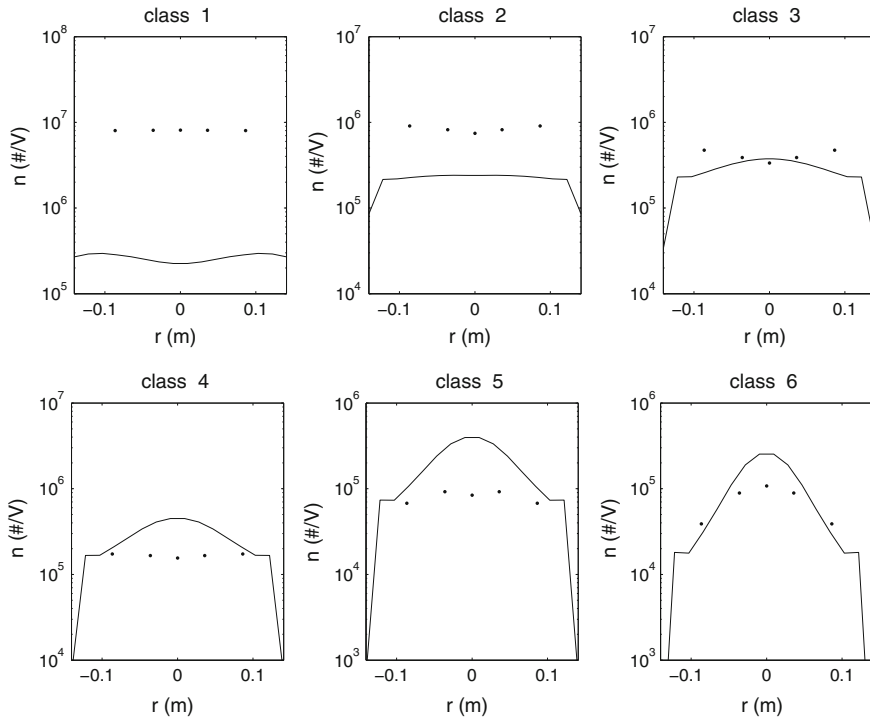

**Fig. 8.12** Simulated results obtained with (continuous line—) and without (dashed line- -) the population balance at the axial level 2 m above the column inlet. (·) is experimental data [66].  $v_d^s = 8$  cm/s. Reprinted from [14], Copyright 2005, with permission from Begell House, Inc

[121, 130], as this model variable (i.e.,  $\varepsilon$ ) merely represents a closure for the turbulence integral length scale with model parameters fitted to experimental data of idealized single phase flows. The population balance kernels are also difficult to validate on the meso scale level as the physical mechanisms involved (e.g., considering eddies and eddy- particle interactions) are vague and not clearly defined. If possible, the coalescence and breakage closures should be re-parameterized in terms of measurable quantities. Well planned experimental analysis of the meso scale phenomena are then required providing data for proper model validation.

#### 8.4.1.3 Initial- and Boundary Conditions

Initial- and boundary conditions are very important parts of any model formulation. However, there is still very limited knowledge regarding the formulation of proper boundary conditions even for simple bubble columns [68, 71, 175].

**Fig. 8.13** The calculated bubble number density at axial level 2 m above the column inlet. (·) is experimental data [66].  $v_d^s = 8$  cm/s. Reprinted from [14], Copyright 2005, with permission from Begell House, Inc

For implicit solutions and steady state problems the initial guess of the unknown fields are given physical values, as close to the expected solution as possible. For very simple flow problems a uniform flow field may suffice in which some of the velocity components are set to zero.

For dynamic simulations initial values are specified for all the variable fields. For bubble column flows there is generally no gas in the column initially and thus no flow before the valves are opened ( $\alpha_c = 1$ ,  $\mathbf{v}_k = 0$ ). Using the  $k - \varepsilon$  model the turbulent energy and dissipation rates are given low but non-zero values.

Inlet boundary conditions for the local gas volume fraction, bubble size distribution as well as the local gas velocity components are difficult to determine but numerous approximate conditions have been proposed in the literature [13, 16, 133]. For example, when the gas starts entering the column, uniform void- and velocity profiles for both phases might be specified at the inlet [71]. The inlet conditions for  $\alpha_k$  and  $v_{k,z}$  may also be determined using a 1D mass balance over the inlet plane, requiring that the relative velocity inside the column is determined by prescribed terminal velocities and a known (empirical) bubble size distribution. Superficial velocities for the liquid and dispersed phases are normally prescribed. This approach neglects

the complex bubble trajectories, added mass- and turbulent production mechanisms within a short but important inlet zone [14]. Experimental investigations of the complex flows in the inlet zone of the column have been performed by several research groups [45, 57, 132]. Nevertheless, there is clearly a need for further studies as Hartevelde et al. [57] demonstrated important discrepancies between their experimental observations and the model predictions reported in the literature regarding the onset of the important flow instabilities. A uniform aeration at the inlet did create a very small entrance region, and no large-scale circulation or coherent structures [57]. On the other hand, the general purpose flow simulators normally give a dynamic large-scale circulation flow pattern even with uniform distribution of gas at the inlet, because the current models are tuned to known flow fields and thus reveal insufficient predictive capabilities.

The specification of proper outlet boundary conditions is also a problem for these flows, as the recirculating motion of the liquid phase continues as long as gas bubbles are present at sufficiently high fluxes. Consistent formulations of such boundaries have not been reported so far [49]. When the liquid is operated in a continuous mode, Neumann conditions are frequently used for the scalar variables. For the velocity components Neumann conditions can be used as well, or a prescribed pressure boundary is preferred. However, at higher gas fluxes no inflow of gas can be allowed at the outlet boundary because the inflow fluxes are then generally unknown. If the column is operated in the heterogeneous flow regime, the recirculation motion is so strong that this boundary treatment often breaks down. This limitation restricts the use of explicit discretization schemes to situations with low gas fractions, or cases where the local recirculating flux contains very little gas. For implicit solution methods other approximate and rather crude outlet conditions are sometimes used for the flow variables. In the commercial flow codes the boundary is often idealized considering the liquid phase in batch mode only [133]. Following the experimental laboratory practice of keeping the height of the gas–liquid dispersion smaller than the actual column height, the top surface of the column can be modeled as an outlet for both the gas and liquid phases. It is anticipated that the solution of the model equations will determine the actual height of the gas–liquid dispersion and only gas will exit from the column outlet. Adopting this approach one has to ensure that the modeling closures are well posed and that the discretization scheme applied to the governing equations as well as the iterative solver used are capable of handling the steep gradients in the volume fraction and density profiles (discontinuities) that occur when the continuous phase change from being liquid below the gas–liquid interface and gas above it. Due to the large density difference between these phases, such an attempt very often leads to non-physical pressure and velocity values close to the interface and encounters severe convergence difficulties. In order to enhance the convergence behavior in the interface region, empirically adjusted and smoothed profiles of the continuous phase density profile and/or on the void fraction profile may help to maintain a fairly stable solution [123]. For incompressible flows this numerical approach could enforce mass conservation, whereas for reactive- and other density varying system's mass conservation may be a severe problem thus this boundary treatment should be avoided. As numerical instabilities and inaccurate mass conservation are

frequent solving problems containing sharp interfaces within the calculation domain, the solution domain is often restricted to the height of the gas–liquid dispersion. In this case the local liquid velocity components normal to the outlet plane are fixed at zero as there is no net fluxes through the column outlet cross section. The top surface of the solution domain is assumed to coincide with the free surface of the dispersion that may or may not be assumed flat. This assumption is rather crude as an exact value of the gas–liquid dispersion height is not known a priori. In order to induce apparently physical flow characteristics at the outlet, approximate boundaries are required for the other flow variables. The tangential shear stress and the normal fluxes of all scalar variables are set to zero at the free surface. The gas bubbles are free to escape from the top surface. In commercial codes this implementation may not be possible and further approximations have been proposed. In some cases the top surface of the dispersion is defined as an artificial inlet where the normal liquid velocity is set to zero and the normal gas velocity is set to an approximate terminal rise velocity. In other cases the top surface of the dispersion is modeled as a *no shear wall*. This boundary set both the gas and liquid velocities to zero. In order to represent escaping gas bubbles, an artificial gas sink is defined for all the grid cells attached to the top surface. A similar approach was used by Lehr et al. [97]. The free surface, which was assumed to be located at the top of the column, was approximated by an apparent semi-permeable wall. In this way the gas could leave the system, whereas the liquid surface acts as a frictionless wall for the liquid. The liquid was considered to leave the system through an outflow at the periphery of the column. Bove et al. [16] specified an outlet pressure boundary instead, and the axial liquid velocity components were determined in accordance with a global mass balance. This approach is strictly only valid when the changes in liquid density due to interfacial mass transfer or temperature changes are negligible, as the local changes are not known a priori. Furthermore, in many industrial systems the liquid phase is not operated in batch mode, a continuous flow of the liquid phase has to be allowed. However, due to numerical problems most reports on bubble column modeling introduce the simplifying assumption that the continuous phase is operated in batch mode. Further work is needed on the continuous mode boundary condition.

At an axi-symmetric boundary Neumann conditions are used for all the fields, except for the normal velocity component which is zero because the flow direction turns at this point. The assumption of cylindrical axi-symmetry in the computations prevents lateral motion of the dispersed gas phase and leads to an unrealistic radial phase distribution [71, 82]. Krishna and van Baten [82] obtained better agreement with experiments when a 3D model was applied. However, experience showed that it is very difficult to obtain reasonable time averaged radial void profiles even in 3D simulations.

To implement a wall boundary when a  $k - \varepsilon$  turbulence model closure is adopted for bubble driven flows in bubble columns, the conventional wall function approach used for the single phase flow is employed. The liquid velocity profile near the wall is thus assumed to be similar to the single phase flow profile and approximated by the classical logarithmic law of the wall, as described in Sect. 1.3.5. However, Troshko and Hassan [170, 171] claimed that this assumption is reasonable for dilute

and downward bubbly flows, but not recommended for upwards bubble driven flows as found in bubble columns. A corresponding two-phase logarithmic wall law was derived intending to be in better agreement with experimental data on homogeneous bubbly flows. It is noted that when other turbulence closures are adopted, a variety of model specific wall boundary conditions have been designed.

### 8.4.2 Numerical Schemes and Algorithms

Significant improvements of the numerical methods have been obtained during the last decade, but the present algorithms are still far from being sufficiently robust and efficient. Further work on the numerical solution methods in the framework of FVMs should proceed along the paths sketched in the sequel.

Several schemes and algorithms for solving the fluid dynamic part of the model have been published. This work has been concentrated on several items. Most important, one avoids using the very diffusive first order upwind schemes discretizing the convective terms in the multi-fluid transport equations. Instead higher order schemes that are more accurate have been implemented into the codes [67, 70, 71, 118, 155, 156]. The numerical truncation errors induced by the discretization scheme employed for the convective terms may severely alter the numerical solution and this can destroy the physics reflected by the model equations. Oey et al. [118] and Jakobsen et al. [71], for example, stated that accurate discretization schemes for the dispersed phase continuity equation and for the convection terms within the fluid momentum equations are crucial for accurate predictions of the dynamic flow development in bubble columns [71, 118]. Large discretization errors may change the flow developing from center to wall peaking or vice versa. This finding reflects an important aspect of any multi-phase flow modeling, the numerical and modeling issues cannot be investigated (completely) separately as their interplay is of considerable importance [67, 68, 70, 71]. It is also well known that the strong coupling between the phasic equations prevents efficient and robust convergence for the implicit iteration process [119]. Exchanging the well known partial elimination algorithm (PEA) of Spalding [158, 159], reducing the interaction between the phasic velocities in the drag terms of the momentum equations, with a coupled solver [3, 4, 78, 84, 85, 88, 89, 165] that simultaneously iterates on one velocity component of all phases at the time seems to improve the numerical stability and the overall convergence rate [179]. In addition, the discretization schemes together with the solution algorithms lead to large sparse linear systems of algebraic equations that need to be solved. Previously the TDMA algorithm was applied to multi-dimensional problems determining a line-wise Gauss-Seidel approach. During the last decade there have been developments in full-field solvers along the lines of Krylov subspace methods and in the field of multigrid schemes [88, 89, 99, 178, 179]. These methods make effective use of sparsity and are efficient methods for the solution of large linear systems [99]. Furthermore, the original inter-phase-slip-algorithm (IPSA) of Spalding [158] was developed to introduce an implicit coupling between pressure and volume

fractions. The algorithm contains an attempt to approximate the simultaneous change of volume fraction and velocity with pressure. However, most versions of the IPSA algorithm were merely extensions of the single phase SIMPLE approach, thus the pressure was computed by assuming that all the velocity components, but not the volume fraction variable, depend upon pressure changes. The pressure-volume fraction relationship was not considered in a satisfactory implicit manner. Therefore, the extension of the single phase pressure-velocity coupling to multi-fluid models leads to low convergence rates and pure robustness of the iterating procedure [64]. Another issue that makes the implication of multiphase reactor models difficult is that the conventional algorithms for incompressible flow are not applicable as for reactive flow systems the density is highly variable. Moreover, the overall solution strategy might also be re-designed to ensure that the algorithm conserves mass for all the phases and not only for the total mixture. Lately, numerical methods originally intended for multiphase models, rather than being extended single phase approaches, have been investigated [3, 4, 71, 84, 85, 89, 165]. A fully implicit coupling of the phase continuity and compatibility equations within the framework of pressure-volume fraction-velocity correction schemes seems to have potentials if the resulting set of algebraic equations could be solved by an efficient and robust parallel solver [85]. However, so far, severe stability problems have been identified within the iterative solution process. The numerical properties of the resulting set of algebraic equations are not optimized for robust solutions.

The capabilities of alternative methods like FEMs (e.g., [20]) and fully spectral methods (e.g., [33]) are still rarely explored.

### ***8.4.3 Chemical Reaction Engineering***

Based on the experimental and numerical analyzes discussed in the previous sections, it may seem evident that the current bubble column models have very limited inherent capabilities of predicting industrial bubble column flows with sufficient accuracy. However, after tedious adjustments of model parameters, boundary conditions, time and space resolutions, numerical implementations, and solution algorithms it is often possible to reproduce known flow fields to a certain extent. Dynamic and 3D flow patterns that upon averaging give profiles in fair agreement with experimental data can be achieved. The global liquid flow pattern is usually captured fairly well, whereas the corresponding gas fields are more questionable and difficult to evaluate due to the lack of reliable experimental data. Unfortunately, the possibility of achieving a completely erroneous steady-state flow pattern where the liquid flows up along the wall and down in the core of the column is present. Moreover, it is often difficult to reproduce the gas volume fraction fields with sufficient accuracy. The latter limitation would severely affect the contact areas, the interfacial heat- and mass transfer fluxes, the projected areas as well as the interfacial momentum transfer fluxes preventing reliable predictions of the performance of chemical processes. It can thus be concluded that a true predictive fluid dynamic model is not imminent. However, even though there are obviously many open questions and shortcomings

related to the fluid dynamic modeling of bubble columns, preliminary attempts have been performed predicting chemical reactive systems. For example, the early 2D models that were developed by Jakobsen [64, 161] to describe the global steady flow pattern were tested aiming at predicting chemical conversion of a reactive system operated in a bubble column [64, 69]. The system investigated was  $CO_2$  absorption in a methyldiethanolamine (MDEA) solution. The starting point for the numerical investigation was a steady two-fluid flow model tuned to the air/water system. This air/water model was then applied to the reactive system without re-tuning any model parameters but updating the physical properties in accordance with the reactive system. It was found that with this advanced reactor model both the global flow pattern, the interfacial mass transfer fluxes as well as the conversion were still difficult to predict due to the limited accuracy reflected by the interfacial coupling models and especially the relations used for the contact area (and the projected area). Several semi-empirical models for the locally varying mean bubble size and contact areas were suggested [64, 65] with limited success. The accuracy of the experimental data used for model validation was also questioned. According to Dudukovic et al. [36], still no fundamental models for the interfacial heat- and mass transfer fluxes have been coupled successfully to the flow models and reliable reactor performance predictions based on these models are not imminent. The mechanisms of coalescence and breakage are far from being sufficiently understood yet. The physicochemical hydrodynamics determining the bubble coalescence and breakage phenomena may not be captured by any continuum model formulation. Therefore, the use of advanced fluid dynamic models might not significantly improve on the prediction of the interfacial transfer fluxes and thus the chemical conversion, as the pertinent physics on bubble, interface and molecular scales still have to be considered using empirical parameterizations. In summary, one of the weakest links in modeling reactive systems operated in bubble columns is the fluid dynamic part considering multi-phase turbulence modeling, interfacial closures, and especially the impact and descriptions of bubble size and shape distributions. For reactive systems the estimates of the contact areas and thus the interfacial mass transfer rates are likely to contain large uncertainties.

#### 8.4.4 Multi-fluid Modeling Framework

The combined multifluid-population balance models with approximate bubble coalescence and breakage rate closures have been found to represent a trade-off between accuracy and computational efforts for practical applications. The multi-fluid model represents an extension of the well known two-fluid model and is described in detail by Reyes [135], Lafi and Reyes [86], Carrica et al. [21], Pfleger et al. [125], Lathouwers and Bellan [94], Pfleger et al. [124], Tomiyama and Shimada [169], Fan et al. [41] and Jakobsen et al. [71]. To determine the multiphase flow solely (i.e., not including any reactive chemical processes) the governing equations consist of the continuity- and momentum equations for  $N + 1$  phases, one phase corresponds to the liquid phase and the remaining  $N$  phases are gas bubble size phases. In most

resent papers ensemble average models are used. Population balance modeling is examined in Chap. 9.

The average multi-fluid model equations are outlined in the following together with the conventional interfacial closures that are frequently adopted in gas–liquid bubbly flow analyzes. The average multi-fluid continuity equation for phase  $k$  reads:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k) = \sum_{l=1}^N \Gamma_{k,l} \quad (8.10)$$

where the novel term on the right hand side describes the net mass transfer flux to phase  $k$  from all the other  $l$  phases. For simplicity, the averaging symbols are omitted.

The phasic volume fractions must also satisfy the compatibility condition:

$$\sum_{k=1}^{N+1} \alpha_k = 1 \quad (8.11)$$

In a consistent manner the momentum balance for phase  $k$  yields:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k \mathbf{v}_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k \mathbf{v}_k) = -\alpha_k \nabla p - \nabla \cdot (\alpha_k \boldsymbol{\sigma}_k) + \alpha_k \rho_k \mathbf{g} + \sum_{l=1}^N \mathbf{M}_{k,l} \quad (8.12)$$

where the novel interfacial momentum transfer terms account for all the momentum transfer fluxes between phase  $k$  and the other  $N$  phases.

The limiting steps in the model development are the formulation of closure relations or closure laws determining the interfacial transfer fluxes, the bubble coalescence and breakage processes, and turbulence effects.

#### 8.4.4.1 Forces Acting on Bubbles

When sufficiently dilute dispersions are considered, only particle-fluid interactions are significant and the two-fluid closures can be employed. In these particular cases, only the interaction between each of the dispersed gas phases ( $d$ ) and the continuous liquid phase ( $c$ ) is considered parameterizing the last term on the RHS of (8.12):

$$\begin{aligned} \sum_{l=1}^N \mathbf{M}_{d,l} &\approx \mathbf{M}_{d,c} = \alpha_c \mathbf{F}_d = -\alpha_c \mathbf{F}_c \\ &= \alpha_c \mathbf{F}_{D,d} + \alpha_c \mathbf{F}_{V,d} + \alpha_c \mathbf{F}_{L,d} + \alpha_c \mathbf{F}_{TD,d} + \alpha_c \mathbf{F}_{W,d} \end{aligned} \quad (8.13)$$

The steady drag-, added mass-, lift-, turbulent diffusion- and wall forces, respectively, are presented in Sect. 5.1. Moreover, the force terms for dilute dispersions

are multiplied by the liquid fraction due to the reduced liquid volume available for considerable gas loadings [64].

The Lagrangian steady drag force on a single particle is commonly expressed by (5.28). For Eulerian model formulations one normally employs (5.14), hence for the multi-fluid models the standard steady drag force parameterization yields:

$$\mathbf{F}_{D,d} = -F_{D,d}(\mathbf{v}_d - \mathbf{v}_c) = -\frac{3}{4d_{s,d}}\alpha_d\rho_c C_{D,d}|\mathbf{v}_d - \mathbf{v}_c|(\mathbf{v}_d - \mathbf{v}_c) \quad (8.14)$$

The drag coefficient is frequently estimated using the relation suggested by Tomiyama et al. [168], as described in Sect. 5.1.4.

The acceleration of the liquid in the wake of the bubbles can be taken into account through the added mass force given by (5.92), whereas the Eulerian lift force acting on the dispersed phase is normally expressed on the form (5.45).

In near-homogeneous, stationary flows, the turbulence in the continuous phase might cause the particles in the dispersed phases to be transported from regions of high concentration to regions of low concentration. This mechanism is often modeled as a gradient diffusion process. However, the particle motion in free shear layers is rather governed by the large-scale, rotating structures which represent a quasi-orderly, not stochastic, motion. In this particular case the turbulent particle dispersion cannot be regarded as a gradient diffusion process. In any case, the turbulence in the continuous phase may affect the migration of the dispersed phase particles. These turbulence-particle interaction mechanisms are collectively referred to as *turbulent dispersion*. The mechanisms and models for particle dispersion in turbulent flows have been reviewed by several researchers [17, 24, 25, 39, 71, 134]. Still there is no generally accepted model which is applicable to all flow conditions. Nevertheless, the turbulent dispersion force acting on bubbles in turbulent liquid flow is commonly modeled using the gradient hypothesis (e.g., [21]):

$$\mathbf{F}_{TD,d} = -\frac{\nu_{c,t}}{\alpha_d Sc_b} F_{D,d} \nabla \alpha_d = -\frac{3}{4d_{s,d}} \rho_c C_{D,d} |\mathbf{v}_d - \mathbf{v}_c| \frac{\nu_{c,t}}{Sc_b} \nabla \alpha_d \quad (8.15)$$

where the bubble Schmidt number is defined as:  $Sc_b = \frac{\nu_{c,t}}{\nu_b}$ , in which  $\nu_b (\approx \nu_{d,t})$  is interpreted as a bubble diffusivity.

An additional wall lift force that pushes the dispersed phase away from the wall was suggested by Antal et al. [2]. Recently, the defect in the original model that a bubble located far from the wall is attracted to the wall, has been removed by Politano et al. [127]. The modified wall lift force model used by Jakobsen et al. [71] is given by (5.75). The wall might also exert a friction force on the bubbles [107]. A wall boundary condition for the gas momentum equations that was formulated by Lopez de Bertodano [103] is thus sometimes used:

$$F_{d,w} = -C_{wb,d} \frac{\alpha_d \rho_c}{100d_{s,d}} |\mathbf{v}_c| v_{d,z} A_w \quad (8.16)$$

where  $C_{wb,d} = 1.0$  is a common value.

### 8.4.4.2 Multiphase Turbulence Modeling

The averaged multiphase equations do not contain enough information about the average of products to form a solvable set of equations. The statistical manipulations of the equations always lead to a situation in which there are more unknowns than equations. This is a *closure* problem similar to that of single phase turbulence theory. In both the single phase and multiphase flow situations one has to make ad hoc assumptions to make the number of equations equal to the number of unknowns.

In most multiphase modeling approaches the standard single phase  $k - \epsilon$  model formulation is adopted, with only minor modifications to account for the turbulence production and dissipation due to the existence of the dispersed phase. Only a few papers consider the consistent multiphase  $k - \epsilon$  models that can be formulated based on the multiphase equations following a procedure corresponding to the one we applied in Sect. 1.2.7 for single phase flows. It is noted that the various averaging procedures that might be applied formulating the governing multiphase equations can in specific cases give rise to different terms in the resulting  $k - \epsilon$  model equations, so the turbulence closures derived by use of the different averaging methods do not necessarily coincide (in particular comparing single- and multiple averaging operators).

For convenience a summary of a few important features of the single phase  $k - \epsilon$  model is repeated before the multiphase model extensions are introduced. It is stressed that the conventional form of the single phase  $k$ -equation is defined by (1.407). The corresponding transport equation for the dissipation rate  $\epsilon$  (1.410) is normally formulated empirically based on an analogy to the equation for turbulent kinetic energy (1.407). The latter equation possesses production and dissipation terms that are similar to those in the kinetic energy transport equation but are divided by the turbulence time scale of the energy containing eddies,  $\tau_t = \frac{k}{\epsilon}$  (i.e., the turbulent kinetic energy accumulated at the integral length scale of turbulence is approximated by an averaged  $k$  value for the whole spectrum of turbulence). Moreover, the turbulent kinetic energy production term is modeled based on the eddy viscosity hypothesis (1.386) which is an *isotropic* model for the Reynolds stress assuming that all the normal stresses are equal. In addition, the effective turbulent viscosity (1.412) is approximated by analogy with the kinetic theory of dilute gases (see, e.g., [103], pp. 159–160; [128], pp. 361–373; [180], pp. 18–19). The dissipation rate  $\epsilon$  is estimated based on dimensional analysis (1.435). There is, however, experimental evidence that the flow in bubble columns is highly anisotropic (e.g., see [108]). Nevertheless, complete Reynolds stress models are used in rare cases only due to their numerical stability limitations.

A non-isotropic version of the eddy viscosity hypothesis is sometimes used in situations where such effects are essential and the particular flow in question is expected to be far from isotropic [104]. That is, when the turbulent kinetic energy is calculated, the Reynolds stresses can be approximated by:

$$\overline{\mathbf{v}'\mathbf{v}'} = \frac{2}{3}\mathbf{A}k - \nu_t(\nabla\bar{\mathbf{v}} + (\nabla\bar{\mathbf{v}})^T) \quad (8.17)$$

where  $\mathbf{A}$  is a turbulence anisotropy tensor which may be calculated by one of the various algebraic stress models available [117]. Naturally, for the case of isotropic turbulence  $\mathbf{A} = \mathbf{e}$ .

#### *A $k - \epsilon$ Model for Bubbly Flows: Bubble Induced Turbulence*

The mere presence of dispersed phases within a continuous phase can also affect turbulence within the continuous phase [26]. These effects are often named *turbulence modulation*. Large particles tend to increase the turbulence levels in the continuous phase, due to enhanced shear production in their wakes. However, large concentrations of small particles tend to decrease turbulence in the continuous phase. There is still no generally accepted model which is applicable to all flow conditions.

To enable simulations of two-phase bubbly flows [64, 72] the single phase  $k - \epsilon$  model has been extended by including a semi-empirical production term to take into account the additional turbulence production induced by the bubbles' motion relative to the liquid (i.e., based on the idea of [138, 139]). In this approach it was assumed that the internal flow inside the dispersed phase (gas bubbles) does not affect the liquid phase turbulence. The shear work performed on the liquid by a single bubble, representing the additional turbulence production due to the bubble, was thus assumed to be equal to the product of the drag force and the relative velocity.

In vector notation the two-phase  $k - \epsilon$  model equations for incompressible flows (time averaged) were formulated as follows:

$$\frac{\partial}{\partial t}(\alpha_l \rho_l k) + \nabla \cdot (\alpha_l \rho_l \bar{\mathbf{v}}_l k) = \nabla \cdot (\alpha_l \frac{\nu_{l,t}}{\sigma_k} \nabla k) + \alpha_l (P_k + P_b - \rho_l \epsilon) \quad (8.18)$$

$$\frac{\partial}{\partial t}(\alpha_l \rho_l \epsilon) + \nabla \cdot (\alpha_l \rho_l \bar{\mathbf{v}}_l \epsilon) = \nabla \cdot (\alpha_l \frac{\nu_{l,t}}{\sigma_\epsilon} \nabla \epsilon) + \alpha_l \frac{\epsilon}{k} (C_1 (P_k + P_b) - C_2 \rho_l \epsilon) \quad (8.19)$$

in which  $P_k$  denotes the production of turbulence due to fluid shear and  $P_b$  represents the production of turbulence due to the relative bubble-liquid motion.

The turbulence production term due to the relative bubble-liquid motion per unit volume was expressed as:

$$P_b = C_b \bar{\mathbf{F}}_l \cdot (\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g) \quad (8.20)$$

In Cartesian index notation this term becomes:

$$P_b = C_b \sum_i \bar{F}_{l,i} (\bar{v}_{l,i} - \bar{v}_{g,i}) \quad (8.21)$$

where  $0 \leq C_b \leq 1$  is a parameter to be empirically determined. This parameter is expected to be related to bubble size and shape as well as the local turbulent length scale. Note, however, that only the steady drag force part of the generalized drag force formulation has been included so far.

The fluid shear production term is usually expressed as:

$$P_k = \mu_{l,t} (\nabla \bar{\mathbf{v}}_l + (\nabla \bar{\mathbf{v}}_l)^T) : \nabla \bar{\mathbf{v}}_l \quad (8.22)$$

However, we recollect from the derivation of the single phase  $k$ -equation in Sect. 1.2.7 that the rigorous definition of this production term can be approximated by the generalized Boussinesq hypothesis, in the following manner (conveniently written in tensor notation):

$$P_k = -\overline{\rho_l v'_{l,i} v'_{l,j}} \frac{\partial \bar{v}_{l,i}}{\partial x_j} \approx -\left( \frac{2}{3} \rho_l k \delta_{ij} - \mu_{l,t} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) \right) \frac{\partial \bar{v}_{l,i}}{\partial x_j} \quad (8.23)$$

This relation is usually further simplified by neglecting the normal stresses due to the assumption of a non-existing inverse cascade of turbulence. The shear production term is thus approximated by:

$$P_k \approx \mu_{l,t} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) \frac{\partial \bar{v}_{l,i}}{\partial x_j} \quad (8.24)$$

The two production terms  $P_k$  and  $P_b$  are normally added linearly in the turbulence model, because these mechanisms are assumed to be independent.

For steady-state simulations using Reynolds averaged models the turbulent kinetic energy variable  $k$  denotes a measure of the mean energy considering all time scales (i.e., for the whole energy spectrum). For a typical energy spectrum we know that most of the energy is accumulated on the larger scales of turbulence and very little on the smaller scales. Therefore, the  $k$ -quantity is sometimes used as a measure of the energy level on the integral scales (i.e., the larger energy containing scales).

Unsteady turbulent flow simulations using Reynolds averaged models have been discussed by [141] (Chap. 21) and [164] (Chap. 6). The physical interpretation of the quantities used in these models has been a matter of discussion. Schlichting and Gersten [141] (Chap. 21) stated that these flow variables are interpreted as time average quantities whereby the time interval used in the averaging operator has been chosen large enough to include all turbulent fluctuations, but still small enough to contain no effect from the transient, or periodic, part. This concept is based on the assumption that the transient process occurs very slowly, or that the frequency of the oscillation is very small and lies outside the turbulent spectrum. Telionis [164] (Chap. 6) discussed an extension of this approach, the triple decomposition, where the instantaneous quantities are decomposed into three parts. Note that in the standard Reynolds decomposition we split the instantaneous velocities into a time independent time average (mean) and a fluctuation, whereas in the triple decomposition approach the mean motion is also dependent on time. The mean is thus generally made up of a time independent part and a time dependent ordered part.

In other cases the application of this concept has been further extended simulating faster turbulent fluctuations that are within the turbulence spectrum. For such dynamic simulations, using Reynolds averaged models, the  $k$ -quantity represents the turbulent kinetic energy accumulated on the fraction of the spectrum that is represented by the modeled scales. Therefore, to compare the simulated results obtained with this type

of models with experimental data, that is averaged over a sufficient time period to give steady-state data (representing the whole spectrum of turbulence), both the modeled and the resolved scales have to be considered [73]. Similarly, in our analysis of the dynamic multiphase flow pattern within chemical reactors we may need information on the size of eddies and on the scales of the coherent structures that can be observed within the flow. Unfortunately, in practice it is difficult to create a snapshot picture of the flow pattern in the reactors. Instead of observing a large region of space at an instant in time, we find it easier to make measurements at one point in space over a long time period. This approach is in accordance with the hypothesis of Taylor [162], as mentioned in Sect. 1.2.7. Taylor suggested that for quasi-steady single phase turbulent flows (i.e., homogeneous turbulence with respect to time), turbulence might be considered to be *frozen* as it advects past a sensor. Thus, the fluid velocity could be used to translate turbulence measurements determined as a function of time to their corresponding measurements in space. However, the approximate hypothesis is valid for the homogeneous fields only in which a constant mean velocity prevails, say  $\bar{v}_z$  in the  $z$ -direction. From Sect. 1.2.7 we reiterate that Taylor's simplification is useful for flow situations where the turbulent eddies evolve with a time scale longer than the time it takes an eddy to be advected past a fixed spatial point (e.g., the location of a sensor). If an eddy of diameter  $\lambda$  is advected at a mean velocity of magnitude,  $|\bar{v}|$ , (i.e., considering a uniform flow with mean velocity,  $\bar{v}$ , of low intensity, so that  $\bar{v} \gg \sqrt{v'^2}$ ) the time period,  $P$ , for it to pass by a stationary sensor is given by:

$$P = \frac{\lambda}{|\bar{v}|} \quad (8.25)$$

The Taylor hypothesis can also be stated in terms of a wavenumber,  $\kappa$ , and frequency,  $f$ :

$$\kappa = \frac{f}{|\bar{v}|} \quad (8.26)$$

where  $\kappa = \frac{2\pi}{\lambda}$ , and  $f = \frac{2\pi}{P}$ , for wavelength  $\lambda$  and wave period  $P$ . The dimensions of  $\kappa$  are radians per unit length, while  $f$  has dimensions of radians per unit time.

To satisfy the requirement that the turbulent properties of the flow within the eddy will not change significantly as the eddy advects past a sensor, the following criterion should be fulfilled:

$$\sigma_M \left( \frac{|\bar{v}|}{2} \right) \quad (8.27)$$

where  $\sigma_M$ , the standard deviation of the magnitude of the velocity, is a measure of the intensity of turbulence. Thus, Taylor's hypothesis should be satisfactory when the turbulence intensity is small relative to the magnitude of the velocity.

The Taylor hypothesis has been further discussed by [160] (pp 5–7) and [62] (pp 31–81) considering theories of double correlations between turbulence-velocity components, the features of the double longitudinal and lateral correlations in

homogeneous turbulence, integral scales of turbulence, and Eulerian, Lagrangian and mixed Eulerian-Lagrangian correlations.

In this case it is usually assumed that [62] (p 46):

$$\frac{\partial}{\partial t} = -\bar{v}_z \frac{\partial}{\partial z} \quad (8.28)$$

Thus, Taylor's hypothesis is valid only if all terms on the right hand side of the  $z$ -component of the momentum equation (i.e., considering a homogeneous flow field that has a constant mean velocity given as  $\bar{v}_z$ ) are very small compared with the terms on the left hand side. For steady-state simulations, considering the turbulence spectrum in terms of eddy size (length scale), the scales predicted by the  $k - \epsilon$  model is thus much larger than the particle size. The inclusion of turbulence production due to the bubbles' relative motion is therefore based on the assumption of an inverse cascade of turbulence. For dynamic simulations the  $k$ -quantity may represent scales less than or at the same order of magnitude as the particle size. In the cases where the extra turbulence production mechanisms represent scales larger than the ones represented by the modeled part of turbulence, no extra terms should be included in the turbulence model. The physical interpretation that the particles may introduce a inverse cascade of turbulence has been confirmed numerically by [40] who used direct numerical simulations of arrays of bubbles (12 by 12 and 18 by 18) in 2D low Reynolds number bubbly flows to investigate the relative motion of several bubbles. They found that the bubbles produced eddies much larger than the bubble size. Those eddies kept growing until they were of the same size as the computational domain for the small (12 by 12) array. (For the 18 by 18 array the computation was stopped while the eddies were still growing, and not reached the size of the computational domain). Later studies on the the inverse energy cascade structure of turbulence in bubbly flows and on turbulence structures induced by bubble buoyancy by [115, 116] confirmed the findings of [40].

The given  $k - \epsilon$  turbulence model formulation has been used to determine the turbulence of the continuous phase in two-phase bubbly flow by several investigators on bubble columns (e.g., [64, 136]) and on stirred tank reactors (e.g., [43]).

#### *A $k - \epsilon$ Turbulence Model for Bubbly Flows: Two Time Scales*

Lopez de Bertodano et al. [104] proposed a similar extension of the standard single-phase  $k - \epsilon$  model considering two time scales of turbulence to enable simulations of bubbly two-phase flows. The basis for their model development was an analysis of the asymptotic behavior of both the modified single-phase  $k - \epsilon$  model described above, and a two-phase  $k - \epsilon$  model developed from the time averaged two-fluid model equations (i.e., by use of the time averaging operator outlined in Sect. 3.4.2 or alternatively by use of the generalized single averaging operator procedure discussed in Sect. 3.4.3). Two physical flows were analyzed: Bubbles rising in a still tank of liquid, and homogeneous decay of grid generated turbulence in bubbly flow. The two-phase  $k - \epsilon$  model analyzed was based on the Favre averaged transport equation for turbulent kinetic energy developed by [76, 77]. The resulting transport

equation for kinetic energy is similar to the one obtained from the single phase model (8.18), supporting the semi-empirical modification introduced in that model. The formulation of a proper  $\epsilon$ -equation for the case of bubbly flow was found to be more severe. As a first approach they adopted the above equation developed from the single phase transport equations (8.19). However, analyzing the two physical situations mentioned above, they found that this model formulation fails to produce both the asymptotic value and the time constant of homogeneous decay of grid generated bubbly flow turbulence. That is, the modified single-phase model did not break down, but it gave rise to unphysical solutions for such cases. Based on these observations [104] proposed a modified model containing two time constants, one for the liquid shear induced turbulence and a second one for the bubble induced turbulence. The basic assumption made in this model development is that the shear-induced turbulent kinetic energy and the bubble-induced turbulent kinetic energy may be linearly superposed in accordance with the hypothesis of [138, 139]. Note, however, that [87] observed experimentally that this assumption is only valid for void fractions less than 1 %, whereas for higher values there is an amplification in the turbulence attributed to the interactions between the bubbles. The application of this model to the high void fraction flows occurring in operating multiphase chemical reactors like stirred tanks and bubble columns is thus questionable.

Nevertheless, in the first step in the model derivation a transport equation for the bubble induced turbulent kinetic energy was postulated:

$$\frac{\partial}{\partial t}(\alpha_l \rho_l k_{BI}) + \nabla \cdot (\alpha_l \rho_l \bar{\mathbf{v}}_l k_{BI}) = \nabla \cdot (\alpha_l \frac{\nu_{l,t}}{\sigma_k} \nabla k_{BI}) + \frac{1}{\tau_b} (k_{BIa} - k_{BI}) \quad (8.29)$$

where  $k_{BIa}$  denotes the asymptotic value of bubble induced turbulent kinetic energy,  $k_{BI}$  denotes the turbulence generated by the bubbles, and  $\tau_b$  denotes the time constant of the bubble.

Secondly, the standard single phase  $k$ -equation was adopted to describe the shear induced turbulence. Third, by adding these two transport equations, assuming that the bubble and shear induced turbulent kinetic energy contributions can be linearly superimposed, they obtained the following  $k$ -equation for the liquid phase:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_l \rho_l k) + \nabla \cdot (\alpha_l \rho_l \bar{\mathbf{v}}_l k) = & \nabla \cdot (\alpha_l \frac{\nu_{l,t}}{\sigma_k} \nabla k) + \alpha_l (P_{k,SI} - \rho_l \epsilon_{SI}) \\ & + \frac{1}{\tau_b} (k_{BIa} - k_{BI}) \end{aligned} \quad (8.30)$$

To parametrize the new quantities occurring in these equations a few semi-empirical relations from the literature were adopted. The asymptotic value of bubble induced turbulent kinetic energy,  $k_{BIa}$ , is estimated based on the work of [5]. By use of the so-called *cell model* assumed valid for dilute dispersions, an average relation for the pseudo-turbulent stresses around a group of spheres in potential flow has been formulated. From this relation an expression for the turbulent normal stresses determining the asymptotic value for bubble induced turbulent energy was derived:

$$k_{\text{BIa}} = \alpha_g \frac{1}{2} C_V |\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g|^2 \quad (8.31)$$

Lopez de Bertodano [103] defined a time constant for the bubbles by:

$$\tau_b = \frac{d_b}{|\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g|} \quad (8.32)$$

Lopez de Bertodano et al. [104] redefined this definition to make the model consistent with the two-phase model of [77]:

$$\tau_b = \left( \frac{2}{3} \frac{C_V}{C_D} \right) \frac{d_b}{(\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g)} \quad (8.33)$$

This relation was obtained using the well-known expression for steady interfacial drag and the two formulations for bubble induced turbulence production (i.e., the one given by [77], and the other one defined by [104]).

At this point it is important to notice that the interfacial source and dissipation terms occurring in the  $k$ -equation above are consistent with the source and sink terms in the two-phase  $k$ -equation developed by [77]. Lopez de Bertodano et al. [104] recognized that the terms  $\rho_l \epsilon_{\text{SI}} + \frac{k_{\text{BI}}}{\tau_b}$  are a linear superposition of shear and bubble induced dissipation. Similarly, the terms  $P_{k,\text{SI}} + \frac{k_{\text{BIa}}}{\tau_b}$  were found to denote the linear superposition of the shear and bubble induced sources of turbulence. Note that the latter term, i.e., by introducing the suggested parameterizations, is identical to the bubble induced source of turbulence ( $P_b$ ) which was taken to be proportional to the work done on the liquid by the bubbles as shown in Eq. (8.19). The  $k$ -equation used by [104] is thus identical to Eq. (8.19). The only modification introduced into the modified single phase  $k - \epsilon$  model is that the production of bubble induced dissipation used in the  $\epsilon$ -equation, i.e.,  $\alpha_l \frac{\epsilon}{k} C_1 P_b$ , has been replaced by a bubble induced dissipation term arising from the above derivation,  $\epsilon_{\text{BI}} = -\frac{k_{\text{BIa}}}{\tau_b}$ . The  $\epsilon$ -equation used by Lopez de Bertodano et al. [104] is then given by:

$$\frac{\partial}{\partial t} (\alpha_l \rho_l \epsilon) + \nabla \cdot (\alpha_l \rho_l \bar{\mathbf{v}}_l \epsilon) = \nabla \cdot (\alpha_l \frac{\nu_{l,t}}{\sigma_\epsilon} \nabla \epsilon) + \alpha_l \frac{\epsilon}{k} (C_1 P_k - C_2 \rho_l \epsilon) - \epsilon_{\text{BI}} \quad (8.34)$$

Lopez de Bertodano [103] stated that this simple modification has a big effect on the dynamic and the asymptotic behavior of the model. At a later stage, [104] also stated that the bubble induced time constant, which is proportional to the residence time of a bubble, is usually very short compared to the time constant of the shear induced turbulence. They concluded that for most practical cases the transport equation for bubble induced turbulence (8.29) can be reduced to  $k_{\text{BI}} = k_{\text{BIa}}$ .

Another important modification implemented is that [103] and [104] assumed that the idea of linear superposition may also be used for the viscosity. Sato et al. [139] proposed that for bubbly flow the turbulent viscosity should be the sum of the single phase shear induced turbulent viscosity ( $\nu_{\text{SI}}$ ) and the bubble induced turbulent

viscosity ( $\nu_{\text{BI}}$ ):

$$\nu_t = \nu_{\text{SI}} + \nu_{\text{BI}} \quad (8.35)$$

The bubble induced viscosity is given by [139]:

$$\nu_{\text{BI}} = 1.2 \frac{d_b}{2} \alpha_g |\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g| \quad (8.36)$$

This simple model for bubble induced viscosity is a Prandtl mixing length model with the bubble radius as the mixing length and  $1.2\alpha_g|\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g|$  as the mean eddy fluctuation (i.e.,  $\nu_{\text{BI}} = l_m \sqrt{v'^2}$ ). The shear induced turbulent viscosity is still given by (1.412).

A few attempts to apply this model for the description of bubble column operation have been reported in the literature (e.g., [43]). However, no notable improvements were obtained compared to the single time-scale model.

#### *A Fairly Rigorous $k - \epsilon$ Model for Two-phase Flows*

Elghobashi and Abou-Arab [38] did develop a modeled  $k - \epsilon$  turbulence model for two-phase flows. As basis the fairly rigorous instantaneous volume averaged momentum equation for the continuous phase was adopted (i.e., neglecting the spatial covariance terms), derived beforehand in accordance with the time-after volume averaging procedure described in Sect. 3.4.4. The conventional Reynolds averaging procedure was adopted for the time averaging process. Constitutive equations for the resulting time-averaged equations were suggested for the turbulent covariances up to third order. However, to the author's knowledge, this model has not been applied for the prediction of multiphase reactors mostly due to the complexity of the suggested closure relations. On the other hand, this paper serves as a useful reference as the exact derivation of the  $k - \epsilon$  model equations are given and discussed. Parts of this modeling work have been adopted in many papers.

## Chapter 9

# The Population Balance Equation

The chemical engineering community began the first efforts that can be associated with the concepts of the population balance in the early 1960s. The familiar application of population balance principles to the modeling of flow and mixing characteristics in vessels was formally organized by Danckwerts [18]. Certain distribution functions were then defined for the residence times of fluid elements in a process vessel. The residence time distribution function give information about the fraction of the fluid that spends a certain time in a process vessel. Himmelblau and Bishoff [37] describe how the residence time and other age distributions are defined, how they can be measured, and how they can be interpreted. This chapter focuses on the derivation and use of the general population balance equation (PBE) to describe the evolution of the fluid particle distribution due to the advection, growth, coalescence and breakage processes.

The historical derivation of the general population balance equation for countable entities is outlined. Two fundamental modeling frameworks emerge formulating the early population balances, in quite the same way as the kinetic theory of dilute gases and the continuum mechanical theory were proposed deriving the governing conservation equations in fluid mechanics. A third less rigorous approach is also used formulating the population balance directly on the macroscopic averaging scales, an analogue to the multiphase mixture models. A fourth less computationally demanding approach is to formulate a moment form of the population balance equation.

Considering dispersed two-phase flows, a few research groups adopted a statistical Boltzmann-type equation determining the rate of change of a suitable defined distribution function. Performing the Maxwellian averaging integrating all terms over the whole velocity space to eliminate the velocity dependence, one obtains the generic population balance equation. Rigorous closures are required for the unknown terms resulting from the averaging process. However, by employing the conventional Chapman–Enskog approximate expansion method solving the Boltzmann-type equation this theory provides rational means of understanding for the one way coupling between microscopic particle physics and the average macroscopic continuum properties. Moreover, to represent complex problem physics an optimized choice of

distribution function definition considering multiple internal coordinates in an environment of a particular state may be necessary, and novel closure required, making the approach rather demanding theoretically. The procedure sketched above has much in common with the granular theory of solid particles, outlined in Chap. 4. However, the majority of research groups within the chemical engineering community adopted an alternative approach based on a generalization of the classical continuum mechanical theory developing the population balance equation. On the other hand, the continuum theory gives only an average representation of the dispersed phase considering macroscopic scales several orders of magnitude larger than the microscopic particle dimensions and does not provide any information on the unresolved mechanisms that can be utilized formulating the population balance closures. In most cases, the balance principle is applied formulating a transport equation for the distribution function on the integral form. Generalized versions of the Leibnitz- and Gauss theorems are then required transferring the integral balance to the differential form. Thereafter, the governing local instantaneous continuum mechanical equations on the differential form are averaged to obtain a model formulation representing tractable volume and time resolutions. However, the averaging process also give rise to additional closure requirements. In the past, the time after volume averaging procedure was frequently used, being consistent with the time- after volume averaged multi-fluid model formulation discussed in Sect. 3.4.4. The third group of population balances are formulated on integral form directly on the averaging scales and then converted to the differential form employing the extended Leibnitz- and Gauss theorems. In this formulation, the closures are purely empirical parameterizations based on intuitive relationships rather than sound scientific principles.

The population balance concept was first presented by Hulburt and Katz [39]. Rather than adopting the standard continuum mechanical framework, the model derivation was based on the alternative Boltzmann-type equation familiar from classical statistical mechanics. The main problems investigated stem from solid particle nucleation, growth, and agglomeration.

Randolph [105] and Randolph and Larson [106], on the other hand, formulated a generic population balance model based on the generalized continuum mechanical framework. Their main concern was solid particle crystallization, nucleation, growth, agglomeration/aggregation and breakage.

Ramkrishna [103, 104] adopted the generalized continuum mechanical concepts of Randolph [105] and Randolph and Larson [106] to derive the population balance equation. Moreover, Ramkrishna [104] also discussed a more general stochastic theory to inquire into the statistical foundation of the population balance equation. In this statistical analysis Ramkrishna [104] used statistical concepts such as probabilities and expectancies to derive a set of product density equations. In this framework the PBE is seen as one of the product density equations in the given set. Since this theory is not common background among engineers, this route is not further explored in this book. Ramkrishna [103, 104] did investigate biological populations as well as numerous studies of chemical engineering problems have been reported.

Similar PBE modeling approaches have also been used in the theory of aerosols in which the gas is the continuous phase [27, 136], in chemical-, mechanical- and

nuclear engineering describing multi-phase droplet flow dynamics [47, 48] and to incompressible bubbly two-phase flows [28]. The origin of the PBE has been further examined by Sporleder et al. [125].

In chemical engineering Coualaloglou and Tavlarides [17] were among the first to introduce the simpler macroscopic formulation, describing the interaction processes in agitated liquid–liquid dispersions. However, the prior closures were frequently deduced from a model on integral form and approximated numerically into the discrete formulas employed in the program codes. Unfortunately, the fundamental kernel models on the integral form were generally not provided. Hence, there was no clear split between the numerical scheme and the physical closure laws. In order to use more accurate numerical schemes approximating the kernel integrals, the discrete kernel formulas provided must be transformed back to the fundamental integral form. For long it was not considered trivial to reformulate the discrete kernel formulas into the original integral form. Nevertheless, in a very useful review by Lasheras et al. [60], several of the former breakage kernels were presented on integral form providing a clear split between the numerical scheme and the physical closure law. By use of the same modeling ideas, similar reformulations of the early breakage kernels were examined by Liao and Lucas [73, 74] and Solsvik et al. [122].

Lee et al. [69] and Prince and Blanch [102] adopted the basic ideas of Coualaloglou and Tavlarides [17] formulating the population balance source terms directly on the averaging scales performing analysis of bubble breakage and coalescence in turbulent gas–liquid dispersions. However, by use of the modeling ideas of Lasheras et al. [60], the breakage kernel can be reformulated into the fundamental integral form. The source term closures were originally completely integrated parts of the discrete numerical scheme adopted. The number densities of the bubbles were thus defined as the number of bubbles per unit mixture volume and not as a probability density in accordance with the kinetic theory of gases.

Luo [79] and Luo and Svendsen [80] extended the work of Coualaloglou and Tavlarides [17], Lee et al. [69] and Prince and Blanch [102] formulating the population balance directly on the macroscopic scales where the closure laws for the source terms were originally integrated parts of the discrete numerical scheme used solving the model equations. However, by employing the modeling ideas of Lasheras et al. [60], the breakage kernel has been rewritten into the fundamental integral form.

Hagesæther et al. [31, 32] and Wang et al. [133] extended the breakage model of Luo and Svendsen [80] removing an internal limitation that the kernel was not taking into consideration that there is a physical lower limit for the particle size for which the breakage rate diminishes. Some of the shortcomings were removed from the original kernels by taking into account the energy distribution of the turbulent eddies, the effect of capillary pressure and the surface energy increase during bubble/droplet breakup.

Carica et al. [11] investigated compressible bubbly two-phase flow around a surface ship. They developed a population balance from kinetic theory using the particle mass as internal coordinate or property, whereas most earlier work on solid particle analysis used particle volume (or diameter). In flows where compressibility effects in the gas are important (as in the case of laboratory bubble columns operated

at atmospheric conditions) the use of mass as an internal coordinate was found to be advantageous because this quantity is conserved under pressure changes. The use of a mass density form of the population balance derived based on the kinetic theory approach (i.e., instead of the more common number density) has also been discussed, having several advantages in reactor technology [100]. Millies and Mewes [89], Lehr and Mewes [70], Lehr et al. [71], Pilon et al. [97] and Lasheras [60] sketched a possible alternative formulation using particle volume (diameter) as the internal coordinate within the number density form of the population balance equation. In their approach several growth terms have to be considered expressing the effects of gas expansion due to changes in gas density in accordance with a suitable EOS. Both formulations are equivalent in the case of incompressible fluids.

In the work of Fleischer et al. [24] and Hagesæther et al. [30] one dimensional population balance formulations and closure laws very similar to those of Luo and Svendsen [80] were employed. In the bubbly flow simulations by Hagesæther et al. [31, 32] and Wang et al. [133, 134] the macroscopic population balance formulation of Luo and Svendsen [80] was still adopted (no fluid dynamic calculations were performed) but with extended versions of the kernel functions.

Venneker et al. [132] made an off-line simulation of the underlying flow and the local gas fractions and bubble size distributions for turbulent gas dispersions in a stirred vessel. The transport of bubbles throughout the vessel was estimated from a single-phase steady-state flow field, whereas literature kernels for coalescence and breakage were adopted to close the population balance equation predicting the gas fractions and bubble size distributions.

Several extensions of the two-fluid model have been developed and reported in the literature. Generally, the two-fluid model solve the continuity and momentum equations for the continuous liquid phase and one single dispersed gas phase. In order to describe the local size distribution of the bubbles, the population balance equations for the different size groups are solved. The coalescence and breakage processes are frequently modeled in accordance with the work of Luo and Svendsen [80] and Prince and Blanch [102].

Lehr and Mewes [70] included a model for a varying local bubble size in their 3D dynamic two-fluid calculations of bubble column flows performed by use of a commercial CFD code. A transport equation for the interfacial area density in bubbly flow was adopted from Millies and Mewes [89]. In deriving the simplified population balance equation it was assumed that a dynamic equilibrium between coalescence and breakage was reached, so that the relative volume fraction of large and small bubbles remain constant. The population balance was then integrated analytically in an approximate manner.

Extended two-fluid models have also been employed by Lo [76–78] developing the MUSIG model in the CFX-4 software, Buwa and Ranade [10] using the FLUENT software, Olmos et al. [92, 93] using CFX4-3 with 10 bubble size classes, Chen et al. [13] running 2D simulations using the FLUENT software with 16 bubble size classes, Chen et al. [12] performed 3D simulations using the FLUENT software with nine bubble size classes. Moreover, Laakkonen et al. [57] simulated a laboratory

scale stirred tank using the two-fluid MUSIG model in CFX5.7. Laakkonen et al. adopted the simplified kernels of Lehr et al. [71].

Chen et al. [12] and Bertola et al. [8] simulated mixtures consisting of  $N + 1$  phases by use of algebraic slip mixture models (ASMMs) which have been combined with a population balance equation. Each bubble size group did have individual local velocities which were calculated from appropriate algebraic slip velocity parameterizations. In order to close the system of equations, the mixture velocity was expressed in terms of the individual phase velocities. The average gas phase velocity was then determined from a volume weighted slip velocity superposed on the continuous phase velocity. Chen et al. [12] also did run a few simulations with the ASMM model with the same velocity for all the bubble phases.

In order to improve the accuracy of the flow field simulation, a three-phase model was introduced by Krishna et al. [51–54]. In the three-phase models, the gas phase is divided into two bubble size groups. The momentum equations are employed for the two bubble groups and the liquid. For the two different bubble size groups, the drag coefficients are different. However, Krishna et al. [51–54] did not include any population balance model to estimate the bubble coalescence and breakage phenomena, hence the size of the small and large bubbles was constant. Motivated by the work of Krishna et al. [51–54], Lehr et al. [71] combined the three-fluid model in CFD 4.2 with the simplified population balance of Millies and Mewes [89] and Lehr and Mewes [70]. In this case the bubble size distribution is bimodal and the solutions of the balance equation for high superficial gas velocities result in two-fractions, one for the fraction with small and the other for the fraction with large bubble diameters. The flow field accuracy in cylindrical columns is considered better with a three phase model than that obtained by a two-fluid model [71]. However, the assumption of equilibrium between the coalescence and break-up processes may not be appropriate in bubble columns because of significant influence of convection.

To remove the two-fluid model limitations entirely a complete multi-fluid model is required. For gas–liquid systems Reyes [107] and Lafi and Reyes [59] presented a detailed derivation of the mass, momentum and energy conservation equations for poly-dispersed systems following an approach analogous to the Boltzmann’s transport equation. They derived a set of fluid particle conservation equations for the distribution of chemically non-reacting, spherical fluid particles dispersed in a continuous medium. Kocamustafaogullari and Ishii [45], following a similar approach, extended the application of the model to a general two-phase flow. An analogous modeling framework for dense gas–solid reactive mixtures in fluidized beds has been developed by Simonin [118] and Lathouwers and Bellan [61–65].

Based on these generalized theories Shi et al. [117] and Frank et al. [26] developed a useful alternative to the original MUSIG model by extending the two-fluid model to a multi-fluid model with a finite number of size ( $M$ ) and velocity ( $N$ ) phases. This multi-fluid model is sometimes called the  $N \times M$  MUSIG model. In the extended MUSIG model approach the dispersed phase is divided into  $N$  velocity phases (or groups), where each of the velocity groups is characterized by its own velocity field. Moreover, the overall particle size distribution is represented by dividing the particle

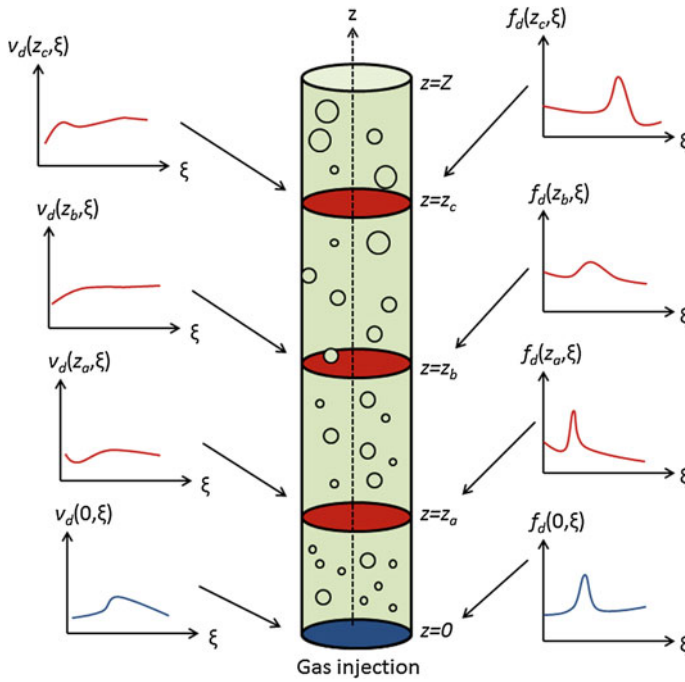

diameter range within each of the velocity groups into a number of  $M$  bubble size phases (or classes). The  $N \times M$  MUSIG model was built into CFX-10.

Sha et al. [114, 115] developed a similar multi-fluid model for simulating gas-liquid bubbly flows in CFX4.4. However, slightly different distributions of the velocity fields and the particle size classes were allowed in these two codes. To guarantee the conservation of mass the population balance solution method presented by Hagesaether et al. [31, 32] was adopted. For the same bubble size distribution and feed rate at the inlet, the simulations were run as two, three, six, and eleven phase flow. The number of the discrete population balance equations was ten for all the simulations.

A natural further development of the combined multifluid-population balance modeling framework for poly-dispersed flows might be to apply a set of model equations with resolution intermediate between the Boltzmann type of equation and the moment equations (i.e., corresponding to the governing fluid dynamic equations), in which the velocity coordinates in phase space are treated using moments (integrated quantities), whereas the dispersed phase properties (e.g., particle size, composition, temperature, etc) is resolved. Such a multi-fluid modeling concept was proposed by Laurent and Massot [66] for describing laminar poly-dispersed spray flames. They were able to derive Tambour's sectional equations from the kinetic level. This type of modeling framework has also been investigated by Jakobsen et al. [19, 91, 96, 123–125, 137] in order to derive a general set of balance equations for the dispersed phase populations. Starting out from a Boltzmann-type equation, a set of consistent PBE, mass, momentum, species mass and enthalpy (temperature) equations were derived for the dispersed phase and expressed in terms of a probability density function. Moreover, in this research group the rigorous model framework was solved by high order weighted residual methods such as the collocation, Galerkin, tau and least-squares methods providing a continuum functional representation instead of the typical discrete group discretization approach used in the MUSIG type of models. In this framework, as distinct from the MUSIG type of models, all the dispersed phase governing equations are expressed in terms of the inner coordinates so that further details of the dispersed flow and chemical process behavior can be resolved and described directly and not only the moments of the dispersed phase properties, as illustrated in Fig 9.1. Figure 9.2 illustrates the main differences between the MUSIG and  $N \times M$  MUSIG models, and the continuous functional approach.

## 9.1 Four Alternative Population Balance Frameworks

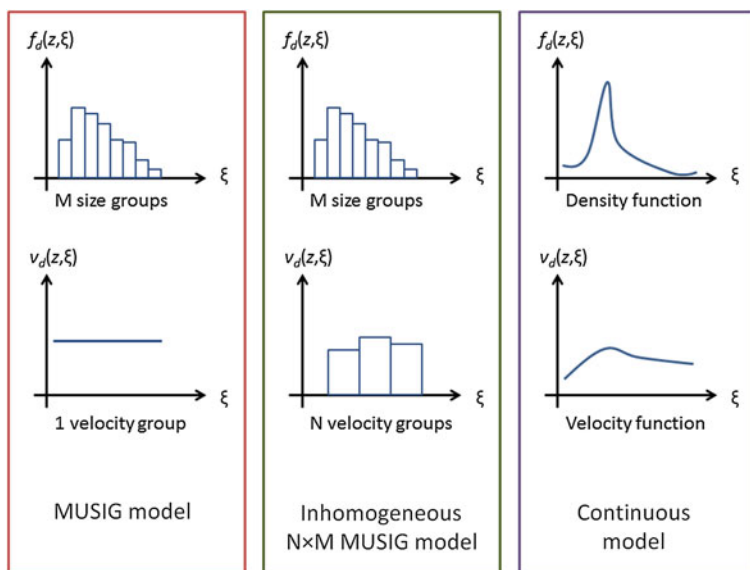

In the following sections four alternative approaches for deriving population balance equations are outlined. The four types of PBEs comprise a macroscopic PBE, a local instantaneous PBE, a microscopic PBE, and a PBE on the moment form. Two of these population balance forms are formulated in accordance with the conventional continuum mechanical theory.

**Fig. 9.1** Illustration of a bubble column.  $\xi$  is a characteristic property of the bubble, e.g. the bubble diameter. The distribution of bubbles,  $f_d(z, \xi)$ , and the corresponding dispersed phase velocity,  $v_d(z, \xi)$ , evolve due to the different interaction processes [19]

In a *first* modeling approach, a macroscopic population balance is formulated directly on the averaging scales in terms of number density functions [80, 102]. A corresponding set of macroscopic source term closures are presented as well. Reviews of numerous fluid particle breakage and coalescence kernels on macroscopic scales can be found elsewhere [60, 73, 74, 122]. This modeling framework resembles the mixture model concept.

In a *second* modeling approach, a more fundamental local instantaneous continuum mechanical population balance is formulated on the local scales in terms of number probability densities [37, 104–106]. A few source term closures for the bubble coalescence and breakage processes are then outlined. The kernels given are frequently adopted describing the bubble size- and phase distributions in both two-phase bubble column- and stirred tank reactors. Several fluid particle breakage and coalescence kernel models for the local models, and adaptations of the macroscopic models, can also be found in the literature [60, 73, 74, 122]. The local instantaneous population balance is subsequently averaged using the familiar time after volume averaging procedure. In this approach the fairly general form of the constitutive relations adopted for the bubble coalescence and breakage phenomena are formulated based on physical reasoning and intuitive interpretations of the anticipated

**Fig. 9.2** Illustrations of the MUSIG model, the  $N \times M$  inhomogeneous MUSIG model, and the continuous approach [19]

mechanisms involved. Further, links to the discrete particle scale phenomena are usually expressed on the averaging scales extrapolating relationships and concepts from the kinetic theory of gases. The fundamental kinetic theory concept allows for the introduction of external forces determining the interaction between the fluid and the dispersed particles.

In the *third* modeling approach the generic population balance equation is derived by Maxwellian averaging a statistical Boltzmann-type of equation in terms of number probability densities, in line with the work of Reyes [107], Lafi and Reyes [59], Carrica et al. [11], Lasheras et al. [60], and Jakobsen et al. [19, 91, 96, 123–125, 137]. In this framework, a Boltzmann type equation is Maxwellian averaged over the entire particle velocity space only thus the resulting dispersed phase governing equations are expressed explicitly in terms of the inner coordinates, the external physical space coordinates and time so that further details of the dispersed flow and chemical process behavior can be resolved and described directly and not only the moments of the dispersed phase properties. The fundamental derivation of the population balance equation is considered general and not limited to describe gas–liquid dispersions. However, to employ the general population balance framework to model other particulate systems like solid particles and droplets appropriate kernels are required for the particle growth, agglomeration/aggregation/coalescence and breakage processes. Many droplet and solid particle closures are presented elsewhere [27, 48, 60, 73, 74, 81, 82, 106, 122, 131, 136].

In the *fourth* modeling approach the general local instantaneous- and microscopic forms of the PBE are written in terms of the moments of the number density function. The moment form of the PBE might be providing sufficient information for many applications and reduces greatly the computational costs.

### 9.1.1 Macroscopic Continuum Mechanical Population Balance

The formulations of the population balance equation based on the continuum mechanical approach can be split into two categories, the macroscopic- and the local instantaneous population balance equation formulations. The macroscopic approach consists in describing the evolution of a number density in time and space of several groups or classes of the dispersed phase properties.

In this section the macroscopic population balance formulation of Prince and Blanch [102], Luo [79] and Luo and Svendsen [80] is outlined. In the work of Luo [79] no growth terms were considered, the balance equation thus contains a transient term, a convection term and four source terms due to binary bubble coalescence and breakage.

The population equation was expressed as:

$$\frac{\partial n_i}{\partial t} + \nabla \cdot (\mathbf{v}_i n_i) = B_{B,i} - D_{B,i} + B_{C,i} - D_{C,i} \left( \frac{1}{\text{sm}^3} \right) \quad (9.1)$$

where  $n_i$  is the number density with units ( $\text{m}^{-3}$ ),  $\mathbf{v}_i$  is the mass average velocity vector, and the source terms express the bubble number birth and death rates per unit dispersion volume for bubbles of size  $d_i$  at time  $t$  due to coalescence and breakage, respectively.

The number density variable can be related to the fundamental number density distribution function  $f$  by the following definition:

$$n_i(\mathbf{r}, t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} f(\mathbf{r}, \xi, t) d\xi \left( \frac{1}{\text{m}^3} \right) \quad (9.2)$$

The source terms are assumed to be functions of bubble size  $d_i$ , bubble number density  $n_i$  and time  $t$ . The birth of bubbles of size  $d_i$  due to coalescence stems from the coalescence between all bubbles of size smaller than  $d_i$ . Hence, the birth rate for bubbles of size  $d_i$ ,  $B_{C,i}$ , can be obtained by summing all coalescence events that form a bubble of size  $d_i$ . This gives:

$$B_C(i) = \sum_{d_j = d_{\min}}^{d_i/2} \Omega_C(d_j : d_i - d_j) \left( \frac{1}{\text{s m}^3} \right) \quad (9.3)$$

where  $d_{\min}$  is the minimum bubble size and depends on the minimum eddy size in the system. The source term definition implies that bubbles of size  $d_j$  coalesce with bubbles of size  $(d_i - d_j)$  to form bubbles of size  $d_i$ . The upper limit of the sum stems from symmetry considerations or to avoid counting the coalescence between the same pair of bubble sizes twice.

Similarly, the death of bubbles of size  $d_i$  due to coalescence stems from coalescence between two bubbles in class  $d_i$  or between one bubble in class  $d_i$  and other bubbles. Hence, the bubble death rate for bubbles of size  $d_i$ ,  $D_C$ , can be calculated by:

$$D_C(i) = \sum_{d_j=d_{\min}}^{d_{\max}-d_i} \Omega_C(d_j : d_i) \left( \frac{1}{\text{s m}^3} \right) \quad (9.4)$$

where  $d_{\max}$  is the maximum bubble size in the system. The upper limit indicates that the bubble size formed by coalescence will not exceed  $d_{\max}$ .

The birth of bubbles of size  $d_i$  due to breakage stems from the breakage of all bubbles larger than  $d_i$ . The breakage birth rate,  $B_B$ , can be obtained by summing all the breakage events that form the bubbles of size  $d_i$ :

$$B_B(i) = \sum_{d_j=d_i}^{d_{\max}} \Omega_B(d_j : d_i) \left( \frac{1}{\text{s m}^3} \right) \quad (9.5)$$

The death of bubbles of size  $d_i$  due to breakage stems from breakage of the bubbles within this class, thus:

$$D_B(i) = \Omega_B(d_i) \left( \frac{1}{\text{s m}^3} \right) \quad (9.6)$$

The local gas volume fraction can be calculated by:

$$\alpha_g = \sum_{i=1}^N n_i \frac{\pi}{6} d_i^3 \quad (-) \quad (9.7)$$

Hagesæther et al. [30–32] extended the model by Luo and Svendsen [80], but the resulting breakage model was still not completely conservative. To ensure number and mass conservation they thus adopted a numerical procedure redistributing the bubbles on pivot points in accordance with the discrete solution method [104].

### 9.1.1.1 Macroscopic Source Term Closures

In accordance with the work of Coualoglou and Tavlarides [17] and Prince and Blanch [102], Luo [79] assumed that all the macroscopic source terms determining the death and birth rates could be defined as the product of a collision density and a probability. Thus modeling of bubble coalescence means modeling of a

bubble–bubble collision density and a coalescence probability, whereas modeling of bubble breakage means modeling of an eddy–bubble collision density and a breakage probability. Models for the collision densities were derived assuming that the mechanisms of the bubble–bubble and eddy–bubble collisions are analogous to collisions between molecules as in the kinetic theory of gases [17].

### 9.1.1.2 Models for the Binary Bubble Coalescence Rate Sink, $\Omega_C(d_i : d_j)$

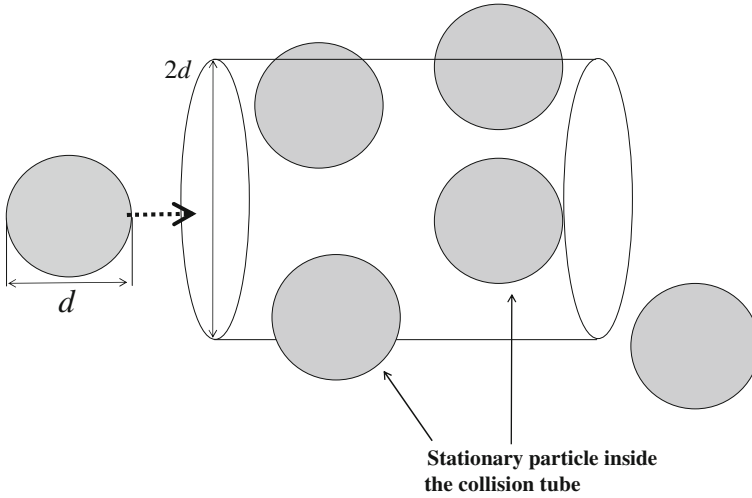

For the coalescence between bubbles of class,  $d_i$ , and bubbles of class,  $d_j$ , the binary coalescence rate sink is expressed as:

$$\Omega_C(d_i : d_j) = \omega_C(d_i : d_j) p_C(d_i : d_j) \left( \frac{1}{\text{s m}^3} \right). \quad (9.8)$$

### 9.1.1.3 Models for the Bubble–Bubble Collision Density, $\omega_C(d_i : d_j)$

Although not necessary valid for bubble columns, the dispersions are considered sufficiently dilute so that only binary collisions need to be considered. A collision of two bubbles can occur when the bubbles are brought together by the surrounding liquid flow or by body forces like gravity. At least three sources of relative motion can be distinguished; motion induced by turbulence in the continuous phase, motion induced by mean velocity gradients, and buoyancy (or, more generally, body forces)- induced motion, arising from different bubble slip velocities, wake interactions or helical/zigzag trajectories [42]. However, most studies on bubble columns has been restricted considering only models for the contribution of turbulence to coalescence, the contributions from mean-velocity gradients and body forces are generally neglected without proper validation. The two last mentioned collision mechanisms are generally both significant, which greatly complicates the construction and validation of coalescence models. The parameterization of the particle collision densities was obviously performed employing elementary concepts from the kinetic theory of gases, thus the derivation of the source term closures at the microscopic level have been followed by some kind of averaging and numerical discretization by a discrete numerical scheme [17, 102, 132]. Adopting elementary concepts from kinetic theory to derive a simple expression for the particle collision density one may consider a particle as it travels in a straight path from one collision to the next in a mono-disperse dispersion, as illustrated in Fig. 9.3. Its speed and direction of motion changes with each collision. Further imagine that at a given instant all particles, but the one in question are frozen in position and this particle moves with an average speed,  $|\mathbf{v}_p|$ . At the instant of collision, the center to center distance of the two particles is  $d$ . Considering the relatively large bubbles in industrial bubble columns the total collision cross section of the target area of the spherical fluid particle<sup>1</sup> is  $\sigma_{A_T} = \pi d^2$ .

<sup>1</sup> Smoluchowski [121], Williams and Loyalka [136], Friedlander [27] and Kolev [48] (p. 170), among others, considered very small particles and interpreted the cross sectional area in a slightly different way representing an extrapolation of the concepts in kinetic theory of gases. In these

**Fig. 9.3** A sketch of a collision tube of a entering bubble moving through the tube with speed  $|\mathbf{v}_p|$ . The bubbles within the tube are assumed to be frozen or stationary. Reprinted with permission from [41]. Copyright 2005 American Chemical Society

In time  $\Delta t$  the moving particle sweeps out a cylindrical volume of length  $|\mathbf{v}_p| \Delta t$  and cross section  $\pi d^2$ . Any particle whose center is in this cylinder will be struck by the moving particle. The number of collisions in the time  $\Delta t$  is  $f^{(1)} \pi d^2 |\mathbf{v}_p| \Delta t$ , where  $f^{(1)}$  is assumed to be locally uniformly distributed in space.

The volume integrated coalescence frequency, sometimes denoted the effective swept volume rate,<sup>2</sup>  $h_C(d)$  is given by:

$$h_C(d) = \sigma_{A_T} \mathbf{v}_p = \pi d^2 \mathbf{v}_p \left( \frac{\text{m}^3}{\text{s}} \right) \quad (9.9)$$

where  $\sigma_{A_T} = \pi d^2$  is the total cross-sectional area of the collision tube.

In kinetic theory the collision density of a single particle is defined as the number of collisions per unit time and length (diameter):

$$\omega_f(d) = f^{(1)}(d) h_C(d) = f^{(1)}(d, t) \pi d^2 |\mathbf{v}_p| \left( \frac{1}{\text{s}[\text{m}]} \right) \quad (9.10)$$

(Footnote 1 continued)

analyzes the traveling particle is treated as a point in space without cross sectional area, thus the effective area becomes equal to the cross sectional area of the stagnant particle. This alternative cross sectional area approximation becomes:  $\sigma'_{A_T} = \frac{1}{4} \pi d^2$ .

<sup>2</sup> The collision tube concept is familiar from the kinetic theory of gases. Consider a particle in such a cube, moving with a relative speed with respect to the other particles which are fixed. The particle in the tube sweeps a volume per unit time ( $\text{m}^3 \text{s}^{-1}$ ). Venneker [132] named the rate of volume swept by the particle for the *effective swept volume rate*. Henceforth this name is used referring to this quantity.

This relation represents a rough collision density model for a dispersion containing only one type of particles.

Sometimes the collision density representing the number of collisions per unit mixture volume and per unit time and length<sup>2</sup> (diameter<sup>2</sup>) is a more convenient quantity. Multiplying the collision density of a single particle with the particle number density the modified collision density yields:

$$\omega_{ff}(d) = h_C(d)f^{(1)}f^{(1)} = \frac{1}{2}f^{(1)}f^{(1)}\pi d^2|\mathbf{v}_p| \left( \frac{1}{\text{m}^3 \text{ s} [\text{m}] [\text{m}]} \right) \quad (9.11)$$

The factor  $\frac{1}{2}$  appears due to the fact that  $h(d)$  represents twice the number of collisions.

In accordance with the pioneering work of Smoluchowski [121], similar considerations can be repeated for dispersions containing two types of particles having diameters  $d, d'$  and particle densities  $f^{(1)}, f'^{(1)}$ . The resulting collision density yields:

$$\omega_C(d, d') = h_C(d, d')f^{(1)}f'^{(1)} = f^{(1)}f'^{(1)}\pi \left( \frac{d + d'}{2} \right)^2 |\mathbf{v}_{\text{rel}, d, d'}| \left( \frac{1}{\text{m}^3 \text{ s} [\text{m}] [\text{m}]} \right) \quad (9.12)$$

where the collision frequency is calculated using the mean collision diameter  $d_{dd'} \equiv (d + d')/2$ . Note that in this case the  $\frac{1}{2}$  factor is not included.

Kolev [48] discussed the validity of these relations for fluid particle collisions considering the obvious discrepancies resulting from the different nature of the fluid particle collisions compared with the random molecular collisions. The basic assumptions in kinetic theory that the molecules are hard spheres and that the collisions are perfectly elastic and obey the classical conservation laws do not hold for real fluid particles because these particles are deformable, elastic and may agglomerate or even coalesce after random collisions. The collision density is thus not really an independent function of the coalescence probability. For bubbly flow Colella et al. [16] also found the basic kinetic theory assumption that the particles are interacting only during collision violated, as the bubbles influence each other by means of their wakes.

Prince and Blanch [102] modeled bubble coalescence in bubble columns considering bubble collisions due to turbulence, buoyancy, and laminar shear, and by analysis of the coalescence probability (efficiency) of collisions. It was assumed that the collisions from the various mechanisms are cumulative. The collision density resulting from turbulent motion was expressed as a function of bubble size, concentration and velocity in accordance with the work of Smoluchowski [121]:

$$\omega^T(d, d') \approx f^{(1)}f'^{(1)}\frac{\pi}{4} \left( \frac{d + d'}{2} \right)^2 \left( \bar{v}_{t,d}^2 + \bar{v}_{t,d'}^2 \right)^{1/2} \left( \frac{1}{\text{m}^3 \text{ s} [\text{m}] [\text{m}]} \right) \quad (9.13)$$

where the collision cross-sectional area is defined by:  $\sigma'_{A_T} = \frac{\pi}{4}(\frac{d+d'}{2})^2$ .

To calculate the collision density an estimate of the length of the relative velocity between a pair of unlike particles, taking into account the distribution of particle velocities, is required. From kinetic theory of gases, we know that  $\bar{v}_{\text{rel},1,2} = (\bar{v}_1^2 + \bar{v}_2^2)^{1/2}$  can be justified by a detailed calculation with the Maxwell distribution function (See Present [101], p. 53 and p. 79). However, this relation is not generally valid for bubble, drops and particles. The approximation:

$$|\bar{v}_{\text{rel},t,d,d'}| \approx (\bar{v}_{t,d}^2 + \bar{v}_{t,d'}^2)^{1/2} \quad (9.14)$$

is questionable.

Estimates of the turbulent fluid particle velocities have been obtained using certain relations developed in the classical theory on isotropic turbulence due to Kolmogorov [49]. It is noted that the derivation of the population balance kernel closures are only approximate as the application of the classical turbulence relations, which were developed for continuous fluid velocity fluctuations or vortices, to describe discrete fluid particle flows are not always in accordance with the classical turbulence theory restrictions. The theory of Kolmogorov [49] states that within the inertial subrange of turbulence, where the distance  $\lambda$  between two points in the flow field is much smaller than the turbulence integral-scale  $L$  but much larger than the Kolmogorov micro-scale  $\eta$ , the second order velocity structure function is only a function of the turbulent energy dissipation rate  $\varepsilon$  and the distance  $\lambda$ ,

$$\overline{\delta v^2(\lambda)} = \overline{[v_z(z + \lambda) - v_z(z)]^2} = C(\varepsilon\lambda)^{2/3}. \quad (9.15)$$

This turbulence quantity is defined as the covariance of the difference in velocity between two points in physical space. The two-point velocity structure function should not be confused with the normal component of the Reynolds stresses, which is a one-point, one time, covariance of the velocity.

To estimate the average turbulent fluid particle velocity, the second-order structure function (9.15) is interpreted as an absolute particle velocity squared and defined for two points in the fluid separated by a distance equal to the bubble diameter  $d$ . The structure function is then given as  $\overline{\delta v^2(d)} = \overline{[v_z(z + d) - v_z(z)]^2}$ . If the magnitude of the diameter  $d$  lies within the inertial subrange of turbulence, the structure function can be calculated as  $\overline{\delta v^2(d)} = C(\varepsilon d)^{2/3}$ . The discrete absolute mean velocity of bubbles with diameter  $d_i$  is thus approximated as:

$$\bar{v}_{t,d_i}^2 \approx \overline{\delta v^2(d_i)} = C(\varepsilon d_i)^{2/3} \quad (9.16)$$

where  $C \approx \frac{27}{55} \Gamma(\frac{1}{3}) C_k \approx \frac{27}{55} \times 2.6789 \times 1.5 \approx 1.973$ . This relationship between the constant  $C$  and the Kolmogorov constant  $C_k$  (i.e., the parameter in the energy spectrum function for the inertial subrange) has been deduced from the power-law spectrum and the second-order structure function [99] (Chapter 6 and App. G).

In this model approximation it is assumed that the eddy motion on the size of the bubble is primarily responsible for the relative motion between bubbles. Very small eddies do not contain sufficient energy to significantly affect the bubble motion, while eddies much larger than the bubbles transport groups of bubbles by fluid advection without leading to significant relative motion. Moreover, to make the problem feasible it is customary to assume that the turbulence is isotropic and that the bubble size lies in the inertial subrange of turbulence. However, the validity of using the Kolmogorov hypotheses describing bubbly flows is strictly not verified yet. The relationships from classical turbulence theory have simply been interpreted and extrapolated in a convenient manner. The Kolmogorov velocity second-order structure function  $\overline{\delta v^2}(d)$  might for example appear as an estimate for an absolute turbulent bubble velocity in the inertial subrange of isotropic turbulence [102], in other cases the same structure function might be considered a relative bubble velocity in turbulent flow, or even employed as a measure of intra-bubble oscillations.

The collision density relation proposed by Prince and Blanch [102] for use in the framework of a discrete solution method was deduced from (9.13) and given as,<sup>3</sup>

$$\begin{aligned}\omega_C^T(d_i : d_j) &\approx n_i n_j \frac{\pi}{4} \left( \frac{d_i + d_j}{2} \right)^2 \left( \bar{v}_{t,d_i}^2 + \bar{v}_{t,d_j}^2 \right)^{1/2} \\ &\approx 0.088 \pi n_i n_j (d_i + d_j)^2 \varepsilon^{1/3} (d_i^{2/3} + d_j^{2/3})^{1/2} \left( \frac{1}{s \text{ m}^3} \right)\end{aligned}\quad (9.17)$$

The collision density formula was written in a discrete form consistent with the numerical scheme adopted. The number densities of the bubbles were thus defined as the number of bubbles per unit mixture volume and not as a probability density in accordance with the kinetic theory concept.

The buoyancy collision density  $\omega_C^B(d_i : d_j)$  has been expressed by (e.g., [79, 102]; [136], p. 164):

$$\omega_C^B(d_i : d_j) \approx n_i n_j \frac{\pi}{4} \left( \frac{d_i + d_j}{2} \right)^2 |\bar{v}_{r,d_i} - \bar{v}_{r,d_j}| \left( \frac{1}{s \text{ m}^3} \right) \quad (9.18)$$

where  $\bar{v}_{r,d_i}$  is the rise velocity of the particle.

The functional form of the collision rate due to laminar shear is expressed by (e.g., [27], p. 200; [136], p. 170):

$$\omega_C^{LS}(d_i : d_j) \approx n_i n_j \frac{4}{3} \left( \frac{d_i + d_j}{2} \right)^3 \left( \frac{\overline{dv_c}}{dr} \right) \left( \frac{1}{s \text{ m}^3} \right) \quad (9.19)$$

---

<sup>3</sup> Note that the parameter value used by Luo [79] is a factor of 4 larger than the one in (9.17). The reason for this deviation is that Luo used a different definition of the effective total cross-sectional area  $\sigma_{AT}$ .

where  $\bar{v}_c$  is the continuous phase circulation velocity. The term  $(\frac{d\bar{v}_c}{dr})$  is the average shear rate.

The net coalescence frequency of bubbles of diameter  $d_i$  and  $d_j$  was then calculated superposing the different bubble collisions mechanisms as a linear sum of contributions multiplied by a common efficiency [102]:

$$\Omega_C(d_i : d_j) = \left[ \omega_C^T(d_i : d_j) + \omega_C^B(d_i : d_j) + \omega_C^{LS}(d_i : d_j) \right] p_C(d_i : d_j) \left( \frac{1}{s \, m^3} \right) \quad (9.20)$$

Hagesæther et al. [31, 32] adopted this approach modeling bubble column dispersions and found that with the choice of parameter values used in their analysis, the turbulent contribution dominated the collision rate for the bubbles in the system. However, the most important model parameter being the turbulent energy dissipation rate is difficult to compute and only crude estimates were obtained. To achieve approximate estimates for the macroscopic coalescence and breakage rates in bubble columns the macroscopic kernel values were calculated adopting a fixed global average value for the energy dissipation rate. The magnitude of the turbulent energy dissipation rate has been estimated by semi-empirical analysis of the kinetic energy transport in the column. Shah et al. [116], for example, postulated that the global energy dissipation rate per unit mass in bubble columns can be calculated from the pressure drop experienced by the gas flow rate. This relationship was derived from a macroscopic mechanical energy balance assuming that the global work done by the pressure of surroundings on the bubble volume element moving with a constant and uniform gas velocity is balanced by the global energy dissipation rate term. The global energy dissipation function was then approximated by:

$$\mu \Phi_{\text{eff}} V \approx (v_G p|_{\text{out}} - v_G p|_{\text{in}}) A \approx v_G A \Delta p|_{\text{global}} \approx v_G \rho_L g \alpha_L H_{GL} A \quad (\text{J/s}) \quad (9.21)$$

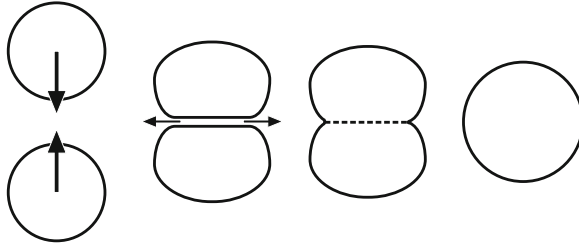

where  $H_{GL}$  is the dispersion height,  $A$  the column cross section area,  $V = H_{GL} A$  the dispersion volume, and  $\Delta p|_{\text{global}}$  the global pressure drop.

The global specific energy dissipation rate is then obtained by dividing the dissipation function by the liquid mass:

$$\langle \varepsilon_G \rangle_{\text{global}} \approx \frac{\mu \Phi_{\text{eff}} V}{m_L} \approx \frac{v_G \rho_L g \alpha_L H_{GL} A}{\rho_L \alpha_L H_{GL} A} = v_G g \quad (\text{J/kg s}) \quad (9.22)$$

Similar estimates of the turbulent energy dissipation rate per unit mass has been used by others as well [71, 79]. Nevertheless, the value of the energy dissipation rate has not been validated experimentally yet. For agitated vessels an analogous relation for the turbulent energy dissipation rate per unit mass has been reported by Prince and Blanch [102].

In addition, as distinct from the approach of Prince and Blanch [102], Kolev [48] (p. 174) argued that the frequency of coalescence of bubbles should rather be determined having individual efficiencies:

**Fig. 9.4** A sketch of the three consecutive stages of the binary coalescence process. Two bubbles are approaching each other. The bubble surfaces deform and a thin liquid film is created between them. The liquid drains thinning the film, and hydrodynamic instabilities cause film rupture. The final result of binary bubble coalescence is a new larger bubble

$$\begin{aligned} \Omega_C(d_i : d_j) = & \omega_C^T(d_i : d_j)p_C^T(d_i : d_j) + \omega_C^B(d_i : d_j)p_C^B(d_i : d_j) \\ & + \omega_C^{LS}(d_i : d_j)p_C^{LS}(d_i : d_j), \quad \left( \frac{1}{\text{s m}^3} \right) \end{aligned} \quad (9.23)$$

Kolev [48] (p. 173) further assumed that for the coalescence processes induced by buoyancy and non-uniform velocity fields the forces leading to collisions inevitably act towards coalescence for contracting particle free path length. Therefore, the probabilities must have the following values  $0 \leq p_C^T(d_i : d_j) \leq 1$  and  $p_C^B(d_i : d_j) = p_C^{LS}(d_i : d_j) \approx 1$ .

#### 9.1.1.4 Models for the Probability of Coalescence, $p_C(d_i : d_j)$

The expression for coalescence probability (sometimes named efficiency) of binary fluid particle collisions in dispersions is normally related to the physical phenomena that are considered to determine the overall coalescence process. The coalescence process in stagnant fluids is generally assumed to occur in three consecutive stages, as sketched in Fig. 9.4. First, bubbles collide, trapping a small amount of liquid between them under the action of the continuous phase. Second, this liquid drains over a period of time from an initial thickness until the liquid film separating the bubbles reaches a critical thickness, under the action of the film hydrodynamics. The hydrodynamics of the film depends on whether the film surface is mobile or immobile, and the mobility, in turn, depends on whether the continuous phase is pure or a solution. Third, at this point, film rupture occurs due to film instability resulting in instantaneous coalescence.

The duration of the actual particle–particle interactions taking place in real flow situations in process vessels is however limited and may vary considerably in time and space. The net force which compresses the fluid particle must thus act for a sufficient time to ensure that the intervening film drains to the critical thickness so that film rupture and coalescence take place. In an early view it was postulated that for

these processes to occur, the actual particle–particle collision (contact) time interval  $\Delta t_{\text{col}}$  must exceed the coalescence time interval  $\Delta t_{\text{coal}}$  of the coalescence processes,  $\Delta t_{\text{col}} > \Delta t_{\text{coal}}$ .

The probability of coalescence was thus generally defined as a function of the ratio of the collision time interval  $\Delta t_{\text{col}}$  and the coalescence time interval,  $\Delta t_{\text{coal}}$  (e.g., [48], p. 248):

$$p_C \propto f(\Delta t_{\text{col}}/\Delta t_{\text{coal}}) \quad (-) \quad (9.24)$$

The coalescence efficiency thus represents the fraction of particles that coalesce out of the total number of particles that have been colliding.

The functional relationship given by Ross and Curl [111] is often used modeling the fluid particle coalescence probability:

$$p_C \approx \exp(-\Delta t_{\text{coal}}/\Delta t_{\text{col}}) \quad (-) \quad (9.25)$$

The probability of oscillatory fluid particle coalescence which is induced by turbulent fluctuations, is generally expected to be determined by physical mechanisms on various scales. Coualaloglou and Tavlarides [17], Luo [79], Luo and Svendsen [80], Hagesæther et al. [30–32], among others, adopted the same functional relationship as presented above describing these processes, basically because no extended models were available. However, modified relations for estimating the collision and coalescence time intervals were derived for these problems.

The coalescence time is usually approximated and considered as the time required for film drainage between the fluid particles. In most cases the complexity of the film draining phenomena involved is a severe problem for the modelers and may be best illustrated discussing briefly an early modeling attempt. Oolman and Blanch [94] derived an expression for the coalescence times in stagnant fluids by examining the time required for the liquid film between bubbles to thin from an initial thickness to a critical value where rupture occurs. The original model considers the flow rate of fluid from the liquid film by capillary pressure, augmented by the Hamaker contribution (reflecting the mutual attraction of fluid molecules on opposite sides of the liquid film) at very low film thicknesses, bubble deformation, and the changes in the concentration of surfactant species.

The liquid film drainage model was given by [94]:

$$-\frac{dh}{dt} = \left\{ \frac{8}{R_d^2 \rho_c} \left[ \frac{-4c}{RT} \left( \frac{d\sigma_I}{dc} \right)^2 + h^2 \left( \frac{2\sigma_I}{r_b} + \frac{A}{6\pi h^3} \right) \right] \right\}^{1/2} \quad (\text{m/s}) \quad (9.26)$$

where  $h$  is the film thickness (m),  $R_d$  is the radius of the liquid disk between the coalescing bubbles (m),  $R$  is the gas constant,  $T$  is the temperature (K),  $A$  is the Hamaker constant (J),  $\sigma_I$  is the surface tension (N/m) and  $c$  is the concentration of a surfactant species (mol/m<sup>3</sup>).

To solve (9.26) sufficient initial conditions are required. In the work of Prince and Blanch [102] a rough estimate of the initial thickness of the films created in air–water

systems was given to be  $h_0 = 1 \times 10^{-4}$  (m). Likewise, the final film thickness was taken as  $h_f = 1 \times 10^{-8}$  (m). Prince and Blanch [102] thus obtained an estimate of the coalescence time for binary bubble collisions in bubble columns solving a simplified form of (9.26). They considered that in practice several of the effects included in (9.26) are very cumbersome to determine and no analytical solution of the resulting equation is available. Several simplifying assumptions were therefore employed (e.g., no Hamaker contributions, no surface impurities, simplified interface geometry, etc.) making an analytical solution possible. A typical coalescence time  $\Delta t_{coal,ij}$  was found by integration,

$$\Delta t_{coal,ij} = \left( \frac{r_{ij}^3 \rho_c}{16\sigma_I} \right)^{1/2} \ln \left( \frac{h_0}{h_f} \right) \quad (\text{s}) \quad (9.27)$$

where  $r_{ij} = (r_{b,i}^{-1} + r_{b,j}^{-1})^{-1/2}$  denotes the equivalent bubble radius.

For dispersed flows Chesters [15] derived an extended estimate for the coalescence time  $\Delta t_{coal}$  considering drainage between deformable and fully mobile interfaces. This model is assumed to be valid for systems where the viscosity of the dispersed phase is sufficiently small so that the film drainage is controlled by the resistance induced by the film to deformation and acceleration. When the film drainage is further caused by inertia forces like turbulence stresses, the parallel film model reduces to  $h = h_0 \exp(-t/\Delta t_{coal})$ . In this formula  $\Delta t_{coal} = \rho_c \bar{v}_{rel} r^2 / 8\sigma_I$ . Assuming that the relations governing film drainage between unequal particles are the same as those between equal particles of equivalent radius [15], the given coalescence time relation has been used both for unequal and equal sized fluid particle collisions. Therefore, although many bubble collisions encountered in practice involve partial-fully mobile interfaces, Luo [79] approximated the coalescence time for equal and unequal bubbles in bubble column flows by:

$$\Delta t_{coal,ij} \approx 0.5 \frac{\rho_c \bar{v}_{rel,t,ij} d_i^2}{(1 + \xi_{ij})^2 \sigma_I} \quad (9.28)$$

The length of the relative velocity between a pair of unlike bubbles is approximated by a mean velocity representative for bubbles with size corresponding to the inertial subrange of isotropic turbulence (9.14):

$$\bar{v}_{rel,t,ij} = (\bar{v}_{t,i}^2 + \bar{v}_{t,j}^2)^{1/2} = \bar{v}_{t,i} (1 + \xi_{ij}^{-2/3})^{1/2}, \quad (9.29)$$

where  $\bar{v}_{t,i}$  is the discrete mean velocity of bubbles with diameter  $d_i$  was calculated from (9.16).

In a turbulent flow field the collision time  $\Delta t_{col}$  is defined as the time two bubbles of size  $d$  and  $d'$  stay together before the turbulent fluctuations separate the bubbles again. Assuming that the collision time is proportional to the characteristic life time of an eddy with size in the inertial subrange of turbulence, Levich [72] determined the average collision time  $\Delta t_{col}$  between fluid particles in turbulent flow

from dimensional analysis. In the inertial range of turbulence the energy dissipation rate might be approximated by  $\varepsilon \sim v^3/l_e$ . The characteristic life time of eddies with a given size  $l_e$  about the size of the mean collision diameter of the bubbles  $l_e \approx (d + d')/2$  is then  $\tau_l \sim l_e/v \sim l_e^{2/3} \varepsilon^{-1/3}$ . The average contact time was thus approximated as:

$$\Delta t_{\text{col}} \approx (d + d')^{2/3} \varepsilon^{-1/3}. \quad (9.30)$$

The accuracy reflected by the contact time relation obtained solely from dimensional considerations is generally not considered sufficient given the sensitivity of the coalescence probability to small changes in the approximate contact time. Moreover, little or no experimental data is available for model validation.

For bubble column flow Luo [79] intended to derive a more reliable collision time relation valid both for two unequal and equal sized fluid particles by investigating the fluid particle approach process by use of a simplified kinetic energy balance. Based on a simple parallel film model which disregards all external forces, an expression for the collision time was obtained:

$$\Delta t_{\text{col}} = 2t_{\text{max}} \approx (1 + \xi_{ij}) \sqrt{\frac{(\rho_d/\rho_c + C_V) \frac{\rho_c d_i^3}{\sigma_l}}{3(1 + \xi_{ij}^2)(1 + \xi_{ij}^3)}} \quad (9.31)$$

where  $\xi_{ij} = d_i/d_j$ ,  $C_V$  is the added mass coefficient, and  $t_{\text{max}}$  is the time between the first contact and the time when the film area between the two colliding bubbles reaches its maximum value.

In order to determine the mean turbulent approach velocity of bubbles causing bubble–bubble collisions, a series of questionable assumptions were made by Luo and Svendsen [80]. First, in accordance with earlier work on fluid particle coalescence the colliding bubbles were assumed to take the velocity of the turbulent fluid eddies having the same size as the bubbles [17, 102]. Luo and Svendsen [80] further assumed that the turbulent eddies in liquid flows may have approximately the same velocity as neutrally buoyant droplets in the same flow. Utilizing the experimental results obtained in an investigation on turbulent motion of neutrally buoyant droplets in stirred tanks reported by Kuboi et al. [55, 56], the mean square droplet velocity was expressed by:

$$v_{\text{rms}}^2(d) = \overline{v^2}(d) = \beta(\varepsilon d)^{2/3} \text{ (m}^2/\text{s}^2\text{)} \quad (9.32)$$

where the parameter value  $\beta \approx 2.0$  was determined from the experimental data.

The experimental data also indicated that the turbulent velocity component distributions of droplets follow the Maxwellian distribution function, thus the mean droplet velocity was calculated as the mathematical average of the velocity distribution<sup>4</sup>:

<sup>4</sup> Luo and Svendsen [80] did not distinguish between the experimentally determined relation (9.32) and the Kolmogorov structure function (9.15). In their work the theoretical parameter value  $C$  was

$$\bar{v}_{\text{drops}} = \left( \frac{8v_{\text{rms}}^2(d)}{3\pi} \right)^{1/2} = \sqrt{\frac{16}{3\pi}}(\varepsilon d)^{1/3} = \sqrt{1.70}(\varepsilon d)^{1/3} \text{ (m/s)} \quad (9.33)$$

It was further noticed that the value of the coefficient was sensitive to the density ratio between the continuous and dispersed phases,  $(\rho_d/\rho_c)$ . Moreover, in a recent study Brenn et al. [9] investigated unsteady bubbly flow with very low void fractions and concluded that the velocity probability density functions of bubbles in liquid are better described using two superimposed Gaussian functions.

Hagesæther et al. [29] derived a model for film drainage in turbulent flows and studied its predictive capabilities. It was concluded that the film drainage models are not sufficiently accurate, and that adequate data on bubbly flows are not available for model validation. For droplet flows it was found that the pure drainage process (without interfacial mass transfer fluxes) was predicted with fair accuracy, whereas no reliable coalescence criterion was found (similar conclusions were made by Klaseboer et al. [43, 44]). Furthermore, it was concluded that a head on collisions are not representative for all possible impact parameters. Orme [95] and Havelka et al. [34], among others, noticed that the impact parameter is of great importance for the droplet–droplet collision outcome in gas flows. However, no collision outcome maps have been published yet for bubble–bubble collisions. Moreover, according to the experimental analysis of liquid films formed upon single bubble impact with a free surface as reported by Doublié [21], it is likely that a thin liquid film formed between two colliding bubbles ruptures after the collision when bubbles are actually already moving apart from each other. Millies and Mewes [89], Hagesæther [33], and Laari and Turunen [58] thus concluded that the film thinning time cannot be used to model the coalescence rate. Furthermore, Stewart [126] investigated experimentally bubble interaction in low-viscosity liquids and observed that the coalescence time is often much smaller than the contact time. Hence, the probabilistic hypotheses normally used for the calculation of the coalescence efficiency are questionable and presumably not valid. However, no complementary theory has been presented yet.

Saboni et al. [112, 113] developed drainage models for partially mobile plane-films to describe film drainage and rupture during coalescence in liquid–liquid dispersions taking into account the interfacial-tension gradients generated by interfacial mass transfer. The resulting Marangoni forces were accelerating the film drainage which in general corresponds to dispersed to continuous phase transfer and diminish film drainage in the negative case. Similar effects might be expected to occur for the gas–liquid systems operated in bubble columns, but no detailed experimental analysis on gas–liquid dispersions has been reported yet.

---

(Footnote 4 continued)

calculated as  $C = (3/5)\Gamma(1/3)C_k \approx (3/5) \times 2.6789 \times 1.5 = 2.41$ . It follows that their mean droplet velocity estimate is  $\bar{v}_{\text{drops}} \approx \left( \frac{8\delta v^2(d)}{3\pi} \right)^{1/2} = \sqrt{8 \times C/(3\pi)}(\varepsilon d)^{1/3} = \sqrt{2.046}(\varepsilon d)^{1/3}$ .

### 9.1.1.5 Models for the Macroscopic Breakage Rate Source, $\Omega_B(d_i, d_j)$

During the last decade considerable attention has been put on the macro-scale modeling of bubble breakage in gas–liquid dispersions (e.g., [45, 60, 102, 109, 133]). A brief outline of the important milestones are given in this sub-section.

The fluid particle breakage controls the maximum bubble size and can be greatly influenced by the continuous phase hydrodynamics and interfacial interactions. Therefore, a generalized breakage mechanism can be expressed as a balance between external stresses (dominating component),  $\sigma$ , that attempts to disrupt the bubble and the surface stress,  $\sigma_I/d$ , that resists the particle deformation. Thus, at the point of breakage, these forces must balance,  $\sigma \approx \frac{\sigma_I}{d/2}$ . This balance leads to the prediction of a critical Weber number, above which the fluid particle is no longer stable. It is defined by [38]:

$$We_{cr} = \frac{\sigma d_{max}}{2\sigma_I} \quad (9.34)$$

where  $d_{max}$  is the maximum stable fluid particle, and  $\sigma$  reflects the hydrodynamic conditions responsible for particle deformation and eventual breakage.

In the case of turbulent flow, particle breakage is caused by velocity fluctuations resulting in normal stress variations along the particle surface,  $We_{cr} = \rho_c \overline{v_c'^2} d_{max} / 2\sigma_I$ . In laminar flow, viscous shear in the continuous phase will elongate the particle and cause breakage,  $We_{cr} = \mu_c (\frac{\partial v_z}{\partial r}) d_{max} / 2\sigma_I$ . In the absence of net flow of the continuous phase such as rising bubbles in a liquid, the fluid particle breakage is caused by interfacial instabilities due to Raleigh–Taylor and Kelvin–Helmholtz instabilities [22]. In most bubble column analyzes the flow is considered turbulent and both the viscous- and interfacial instability effects are neglected basically without any further validation.

The fluid particle fragmentation phenomena in a highly turbulent flow are related to the fact that the velocity in a turbulent stream varies from one point to another (i.e., validated by two-point measurements [109]). Therefore, different dynamic normal stresses will be exerted at different points on the surface of the fluid particle. Under certain conditions, this will inevitably lead to deformation and breakage of the fluid particle.

According to Kocamustafaogullari and Ishii [45], the force due to the dynamic pressure may develop either through the local relative velocity around the particle, which appears because of inertial effects, or through the changes in eddy velocities over the length of the particle.

Most of the published literature on bubble breakage is derived from the theories of Kolmogorov [50] and Hinze [38]. In one phenomenological interpretation bubble breakage occurs through bubble interactions with turbulent eddies bombarding the bubble surface. If the energy of the incoming eddy is sufficiently high to overcome the surface energy, deformation of the surface results, which can finally lead to the formation of two or more daughter bubbles. For the bubble breakage to occur, the size of the bombarding eddies have to be smaller than or equal to the bubble size,

since larger eddies only transport the bubble. In order to model the breakup process, the following simplifications are generally made [80]:

1. The turbulence is isotropic,
2. Only binary breakage of a bubble is considered,
3. The breakage volume ratio is a stochastic variable,
4. The occurrence of breakage is determined by the energy level of the arriving eddy,
5. Only eddies of a size smaller than or equal to the bubble diameter can cause bubble breakage.

The fundament of the macroscopic theories is the engineering interpretation considering the velocity fluctuations as imaginary discrete entities denoted fluid slabs or eddies. Following this concept a large number of eddies exist in the flow having a size (diameter) distribution ranging from the Kolmogorov micro scale up to the vessel dimensions.

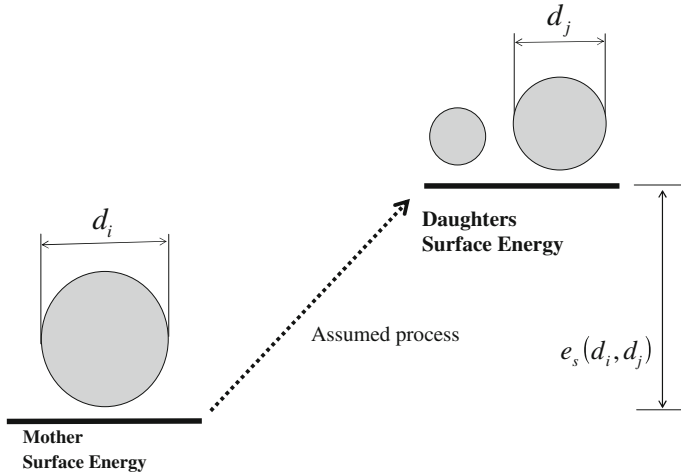

The basic ideas for the model development of Luo and Svendsen [80] was adopted from an earlier paper by Coulaloglou and Travlarides [17] considering droplet breakage in turbulent flows. In the model of Coulaloglou and Travlarides [17] the breakage density was expressed as a product of an integral or average breakage frequency ( $\propto 1/t_b$ ) and an integral (average) breakage efficiency determining the fraction of particles breaking. The breakage time ( $t_b$ ) was determined from isotropic turbulence theory and the breakage efficiency was determined from a probable fraction of turbulent eddies colliding with the droplets that have kinetic energy greater than the droplet surface energy.

Prince and Blanch [102] further postulated that bubble breakage is a result of collisions between particles and turbulent eddies, and that the collision rate can be calculated following arguments from the kinetic theory of gases. A total breakage rate  $\Omega_B(d_i)$  for particles of size  $d_i$ , with units ( $1/\text{sm}^3$ ), was thus expressed as a product of an eddy–bubble collision rate  $\omega_B(d_i : \lambda_j)$  and a breakage probability (efficiency)  $p_B(d_i : \lambda_j)$ , thus:

$$\Omega_B(d_i) = \sum_{\lambda} \omega_B(d_i : \lambda_j) p_B(d_i : \lambda_j) \quad (9.35)$$

This breakage rate model thus depends on a predefined daughter particle size distribution.

Luo and Svendsen [80] modified the eddy-particle collision concept using an eddy number density (instead of an eddy number concentration) and argued that for a bubble to be fragmented each of the colliding eddies must have sufficient turbulent kinetic energy to overcome the increase in bubble surface energy, as illustrated in Fig. 9.5. This is the so-called surface energy criterion for fluid particle breakage. Unlike the previous breakage models, the model by Luo and Svendsen [80] predicts the *partial breakage rate* for particles of size  $d_i$  breaking into the particular daughter particle sizes. In this way this breakage model does not require a predefined daughter particle size distribution function.

**Fig. 9.5** A sketch of the bubble breakage surface energy balance. The mean kinetic energy of an eddy of size  $\lambda$  breaking a bubble of size  $d_i$ ,  $\bar{e}(d_i, \lambda)$ , is assumed to be larger than the increase of the bubble surface energy required breaking the parent bubble  $d_i$  into a daughter bubble  $d_j$  and a second corresponding daughter bubble,  $e_s(d_i, d_j)$ . Reprinted with permission from [41]. Copyright 2005 American Chemical Society

Luo and Svendsen [80] also used a second criterion stating that the size of the colliding eddies must be of the same order of magnitude as the bubble diameter or less. It was assumed that larger eddies will give the fluid particle a translational velocity solely, whereas eddies of scales comparable to the fluid particle can cause breakage.

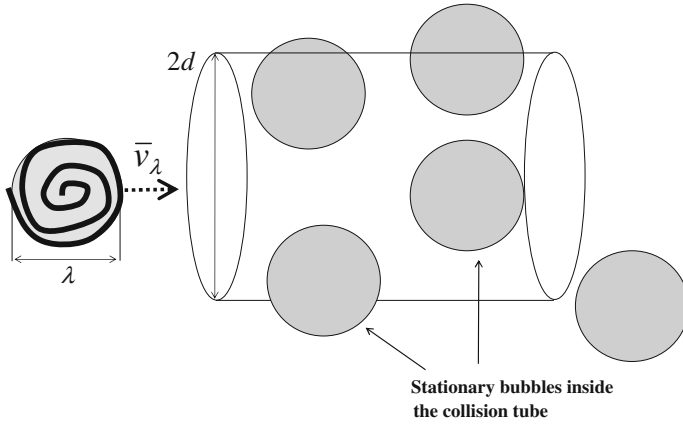

A differential breakage density was then defined as a product of an eddy–bubble collision probability density  $\omega_{B,\lambda}^T(d_i, \lambda)$  and a breakage efficiency  $p_B(d_i : d_j, \lambda)$ , which both depended on the eddy size ( $\lambda$ ). The total breakage rate source for a bubble of size  $d_i$  yields:

$$\Omega_B(d_i) = \sum_{d_j=d_{\min}}^{d_{\max}} \Omega_B(d_i : d_j) \left( \frac{1}{\text{s m}^3} \right) \quad (9.36)$$

The individual rate breaking a parent bubble of size  $d_i$  into the daughter size classes  $d_j$  is expressed as:

$$\Omega_B(d_i : d_j) = \int_{\lambda_{\min}}^d \omega_B^T(d_i, \lambda) p_B(d_i : d_j, \lambda) d\lambda \left( \frac{1}{\text{s m}^3} \right) \quad (9.37)$$

The eddy–bubble collision probability density  $\omega_B^T(d_i, \lambda)$  has units ( $1/\text{s m}^3[\text{m}]$ ). The upper integration limit for the eddy size is based on the model assumption that only

**Fig. 9.6** A sketch of a collision tube of an entering eddy moving through the tube with a velocity  $\bar{v}_\lambda$ . The bubbles within the tube are assumed to be frozen or stationary. Reprinted with permission from [41]. Copyright 2005 American Chemical Society

eddies of size smaller than or equal to the bubble diameter can cause bubble breakage. A bubble being dispersed in a large scale fluid eddy (larger than the bubble scale,  $d$ ) is assumed to be advected together with the eddies in the fluid. Unfortunately, the breakage frequency is found to be significantly sensitive to the choice of integration limits [31, 32, 60]. Note that no explicit breakage frequency was given.

Luo and Svendsen [80] considered the collision of eddies with a given velocity  $\bar{v}_\lambda$  bombarding a number  $n_i$  of locally frozen bubbles, as illustrated in Fig. 9.6. The eddy–bubble collision probability density was computed as<sup>5</sup>:

$$\omega_B^T(d_i, \lambda) = n_i f_\lambda h_C(d_i, \lambda) = n_i f_\lambda \frac{\pi}{4} (d_i + \lambda)^2 \bar{v}_\lambda \left( \frac{1}{\text{sm}^3[\text{m}]} \right) \quad (9.38)$$

where  $f_\lambda$  is the number of eddies of size between  $\lambda$  and  $\lambda + d\lambda$  with units  $(1/\text{m}^3[\text{m}])$ , and  $\bar{v}_\lambda$  is the turbulent velocity of eddies of size  $\lambda$ .

The mean turbulent velocity of eddies with size  $\lambda$  in the inertial subrange of isotropic turbulence was assumed equal to the velocity of the neutrally buoyant droplets measured by Kuboi et al. [55, 56]. Kuboi et al. [55, 56] found that the turbulent velocity of droplets could be expressed by the Maxwell distribution function (9.33), thus the mean eddy velocity was approximated by:

$$\bar{v}_\lambda \approx \left( \frac{8\beta}{3\pi} \right)^{1/2} (\varepsilon\lambda)^{1/3} = \sqrt{1.70} (\varepsilon\lambda)^{1/3} \quad (\text{m/s}) \quad (9.39)$$

<sup>5</sup> Politano et al. [98] adopted the kernel functionality of Luo and Svendsen but modified the definition of the effective collision cross-sectional area,  $\sigma_{A_T} = \frac{\pi}{4} \left( \frac{d_i + \lambda}{2} \right)^2$ , in accordance with other work in nuclear engineering (e.g., Kolev [48], p. 168).

The  $\beta$  coefficient value in the droplet rms velocity relation (9.32) obtained by Kuboi et al. [55, 56] is accidentally about the same as the  $C \approx \frac{27}{55} \Gamma(\frac{1}{3}) C_k$  value in the Kolmogorov structure function relation (9.15), that is  $\beta \approx C \approx 2.0$ . However, it was commented by Kuboi et al. [55, 56] that the comparison of these relations cannot be very decisive, in view of the fact that there is a large difference between the processes and kind of fluid used to obtain these relations. Kuboi et al. [55, 56] also investigated the particle-fluid density difference effect producing non-neutrally buoyant particle flows and concluded that the parameter value discussed above is very sensitive to the density ratio. Therefore, the application of the above relation as an approximation for the bubble velocity is highly questionable.

Furthermore, to employ (9.38), the number probability density of eddies of a particular size  $f_\lambda$  must be determined. Luo and Svendsen [80] assumed that the turbulence is isotropic and that the eddy size of interest lies in the inertial subrange. An expression for the number probability density of eddies as a function of wave length for these conditions were formulated adopting conceptual ideas from Azbel [2] (p. 85) and Azbel and Athanasios [3]. The turbulent energy spectrum function,  $E(k)$ , can be interpreted as the kinetic energy contained within eddies of wave numbers between  $k$  and  $k + dk$ , or equivalently, of size between  $\lambda$  and  $\lambda + d\lambda$ , per unit mass. A relationship between  $f_\lambda$  and  $E(k)$  can thus be obtained formulating an energy balance for eddies being interpreted both as discrete entities and as a wave function:

$$E_{\text{eddies}}(\lambda) = E_{\text{spectra}}(\lambda), \left( \frac{\text{J}}{\text{m}^3[\text{m}]} \right) \quad (9.40)$$

thus

$$f_\lambda \left[ \frac{1}{2} (\rho_L \frac{\pi}{6} \lambda^3) \bar{v}_\lambda^2 \right] = E(k) \rho_L (1 - \alpha_g) \left( -\frac{dk}{d\lambda} \right), \left( \frac{\text{J}}{\text{m}^3[\text{m}]} \right) \quad (9.41)$$

The functional form of the energy spectrum in the inertial subrange of turbulence is defined as (e.g., [99]):

$$E(k) = C_k \varepsilon^{2/3} k^{-5/3}, \left( \frac{\text{m}^2}{\text{s}^2} [\text{m}] \right) \quad (9.42)$$

where  $C_k \approx 1.5$ .

To enable computation of the number density of eddies we need to eliminate the wave number  $k$  from the energy balance. The necessary relationship between the wave number and the size of the eddy (wave length) is given by  $k = 2\pi/\lambda$ , hence  $\frac{dk}{d\lambda} = -2\pi\lambda^{-2}$ . To be consistent with the previous assumptions the eddy velocity must be estimated from the experimental relation (9.39). The number density of eddies  $f_\lambda$  is thus defined by<sup>6</sup>:

---

<sup>6</sup> Luo and Svendsen [80] did not distinguish between the value of the theoretical parameter  $C$  in the structure function relation (9.15) and the empirical parameter  $\beta = 2.0$  in the droplet rms velocity relation (9.32) when calculating the mean eddy velocity from (9.39). To reproduce the parameter

$$f_\lambda = (1 - \alpha_g) \frac{24C_k}{\beta(2\pi)^{5/3}} \frac{1}{\lambda^4} = \frac{0.841(1 - \alpha_g)}{\lambda^4} \left( \frac{1}{\text{m}^3[\text{m}]} \right), \quad (9.43)$$

where  $\alpha_g$  is the volume fraction of dispersed phase.

The determination of the structure function parameter value  $C$  may represent a severe problem as several authors report very different approximations of this value. For example, Luo [79] used  $C = \frac{3}{5} \Gamma(1/3) C_k = 2.41$ , Batchelor [7] (p. 123) defined  $C = \frac{9}{5} \Gamma(1/3) C_k = 7.23$ , Pope [99] (p. 232) obtained another value  $C \approx 1.973$ , Martínez-Bazán et al. [84] referred to Batchelor [6] and claimed that  $C \approx 8.2$ , Risso and Fabre [109] referred to Batchelor [5] (p. 120) and defined  $C = \frac{27}{55} \Gamma(1/3) C_k = 1.973$  which is the same value as given by Pope [99]. Lasheras et al. [60] reviewed several breakage models, and pointed out that the value of this parameter is ranging from about  $C = 8 \times 2.41/(3\pi) = 2.045$  to  $C = 8.2$ .

Substituting the expression for the number density of eddies (9.43) into (9.38), the collision density for the eddies of size between  $\lambda$  and  $d\lambda$  with particles of size  $d_i$  can be expressed as:

$$\omega_B^T(d_i, \lambda) = \frac{\pi}{4} (0.841) \sqrt{1.70} (1 - \alpha_g) n_i(\varepsilon\lambda)^{1/3} \frac{(d_i + \lambda)^2}{\lambda^4} \left( \frac{1}{\text{s m}^3 [\text{m}]} \right) \quad (9.44)$$

In dimensionless variables,<sup>7</sup>

$$\omega_B^T(\xi) = 0.861 (1 - \alpha_g) (\varepsilon d_i)^{1/3} n_i \frac{(1 + \xi)^2}{d_i^2 \xi^{11/3}}, \quad (9.45)$$

where  $\xi = \lambda/d_i$ .

To close the differential breakage density model (9.37) a *breakage probability* (efficiency) is needed. For each particular eddy hitting a particle, the probability for particle breakage was assumed to depend not only on the energy contained in the arriving eddy, but also on the minimum energy required to overcome the surface area increase due to particle fragmentation. The latter quantity was determined by the number and the sizes of the daughter particles formed in the breakage processes. In mathematical terms, the surface energy criterion was written:

$$e(d_i, \lambda) \geq e_s(d_i, d_j) \quad (9.46)$$

---

(Footnote 6 continued)

value in the eddy number density relation used by Luo and Svendsen, the value of the  $\beta$  parameter is computed using the structure function relation (9.15) instead of the empirical relation (9.32). That is, they let  $\beta = \frac{8C}{3\pi}$ , and  $C = \frac{3}{5} \Gamma(1/3) C_k \approx \frac{3}{5} \times 2.6789 \times 1.5 = 2.41$ . The parameter in the eddy number density of eddies was thus approximated as:  $\frac{9C_k}{C^{25/3} \pi^{2/3}} = 0.822$ .

<sup>7</sup> Luo and Svendsen used the parameter values  $C = \frac{3}{5} \Gamma(1/3) C_k = 2.41$ , and  $(8C/3\pi) \approx 2.045$ , hence their parameter value in (9.45) becomes  $\frac{\pi}{4} (0.822) \sqrt{2.045} \approx 0.923$ .

where  $e(d_i, \lambda)$  ( $J$ ) denotes the turbulent kinetic energy of an individual eddy of size  $\lambda$  breaking a bubble of size  $d_i$  and  $e_s(d_i, d_j)$  ( $J$ ) represents the increase of bubble surface energy required breaking the parent bubble  $d_i$  into a daughter bubble  $d_j$  and a second complement daughter bubble.

To determine the energy contained in eddies of different scales, a distribution function of the kinetic energy for eddies in turbulent flows is required. A Maxwellian distribution function may be a natural and consistent choice as the eddy velocity is assumed to follow this distribution [69], but Luo and Svendsen [80] preferred an empirical energy-distribution density function for fluid particles in liquid developed by Angelidou et al. [1]. The turbulent kinetic energy distribution of eddies with size  $\lambda$  is approximated as follows:

$$p_e(e(d_i, \lambda)) = \frac{1}{\bar{e}(d_i, \lambda)} \exp \left[ -\frac{e(d_i, \lambda)}{\bar{e}(d_i, \lambda)} \right] \quad (9.47)$$

The probability density for a fluid particle with size  $d_i$  breaking with the larger daughter bubble  $d_j$  when hit by an eddy with size  $\lambda$  was then assumed equal to the probability of the arriving eddy of size  $\lambda$  having a turbulent kinetic energy greater than or equal to the minimum energy required for the particle breakage (9.46).

The conditional breakage probability function used by Luo and Svendsen thus yields<sup>8</sup>:

$$\begin{aligned} p_B(d_i : d_j, \lambda) &= \int_{e_s(d_i, d_j)}^{\infty} \frac{1}{\bar{e}(d_i, \lambda)} \exp \left[ -\frac{e(d_i, \lambda)}{\bar{e}(d_i, \lambda)} \right] de' \\ &= 1 - \int_0^{e_s(d_i, d_j)} \frac{1}{\bar{e}(d_i, \lambda)} \exp \left[ -\frac{e(d_i, \lambda)}{\bar{e}(d_i, \lambda)} \right] de' \\ &= 1 - \int_0^{\chi_c} \exp(-\chi) d\chi' = \exp(-\chi_c) \end{aligned} \quad (9.48)$$

where  $\chi = \frac{e(d_i, \lambda)}{\bar{e}(d_i, \lambda)}$  is a dimensionless energy ratio. In this ratio  $\bar{e}(d_i, \lambda)$  is the mean turbulent kinetic energy for eddies of size  $\lambda$  and  $e(d_i, \lambda)$  is the kinetic energy for an individual eddy of size  $\lambda$ , respectively.

In accordance with (9.46) the critical energy ratio for particle breakage to occur, was calculated from:

---

<sup>8</sup> Notice that this efficiency function is not necessary volume or mass conservative as Luo and Svendsen [80] did consider the breakage efficiency function being equal to the kinetic energy distribution function. It would probably be better to consider the breakage distribution function purely proportional to the empirical kinetic energy distribution function, and determine the probability constant by requiring bubble volume or mass conservation within the breakage process.

$$\chi_{cr} = \left( \frac{e(d_i, \lambda)}{\bar{e}(d_i, \lambda)} \right)_{cr} = \frac{e_s(d_i, d_j)}{\bar{e}(d_i, \lambda)} = \frac{3C_f \pi \sigma_I}{2\beta \rho_c \varepsilon^{2/3} d_i^{5/3} \xi^{11/3}}. \quad (9.49)$$

By use of (9.39) the mean kinetic energy of an eddy with size  $\lambda$ , was determined by<sup>9</sup>:

$$\bar{e}(d_i, \lambda) = \rho_c \frac{\pi}{6} \lambda^3 \frac{\bar{v}_\lambda^2}{2} = \rho_c \frac{2\beta}{3} \lambda^{11/3} \varepsilon^{2/3} = \rho_c \frac{2\beta}{3} \xi^{11/3} d_i^{11/3} \varepsilon^{2/3} \quad (9.50)$$

When a fluid particle with diameter  $d_i$  is broken up into a particle of size  $d_j$  and the complement particle of size  $(d_i^3 - d_j^3)^{1/3}$ , the increase in surface energy was given by:

$$\begin{aligned} e_s(d_i, d_j) &= \pi \sigma_I [d_j^2 + (d_i^3 - d_j^3)^{1/3} - d_i^2] \\ &= \pi \sigma_I d_i^2 [f_{V_{ij}}^{2/3} + (1 - f_{V_{ij}})^{2/3} - 1] = C_f (f_{V_{ij}}) \pi \sigma_I d_i^2 \end{aligned} \quad (9.51)$$

where  $C_f(f_{V_{ij}})$  is defined as the increase coefficient of surface area which depends only on the breakage volume fraction,  $f_{V_{ij}} = d_j^3/d_i^3$ . The  $e_s(d_i, d_j)$  function is symmetrical about the breakage volume fraction,  $f_{V_{ij}} = 0.5$ .

Combining (9.37), (9.45) and (9.48), the breakage density of one particle of size  $d_i$  that breaks into particles of sizes  $d_j$  and  $(d_i^3 - d_j^3)^{1/3}$  is given by<sup>10</sup>:

$$\begin{aligned} \Omega_B(d_i : d_j) &= \int_{\lambda_{\min}}^d \omega_B^T(d_i, \lambda) p_B(d_i : d_j, \lambda) d\lambda \left( \frac{1}{\text{sm}^3} \right) \\ &= 0.861(1 - \alpha_g) n_i \left( \frac{\varepsilon}{d_i^2} \right)^{1/3} \int_{\xi_{\min}}^1 \frac{(1 + \xi)^2}{\xi^{11/3}} \exp\left(-\frac{3C_f \pi \sigma_I}{2\rho_c \beta \varepsilon^{2/3} d_i^{5/3} \xi^{11/3}}\right) d\xi \end{aligned} \quad (9.52)$$

where  $\xi_{\min} = \frac{\lambda_{\min}}{d}$ ,  $\frac{\lambda_{\min}}{\lambda_d} \approx 11.4 - 31.4$  and  $\eta$  is the Kolmogorov micro-scale.

A severe limitation of the original breakage density closure of Luo and Svendsen [80] is that the model produces too many very small particles whatever numerical size resolution used, the model is thus not well posed. That is, using the surface energy criterion solely a maximum breakage probability is predicted when the breakage fraction approaches zero. This is not in agreement to the real physical situation

<sup>9</sup> Luo [79] employed (9.16) with  $C \approx 2.41$  and obtained  $\bar{e}(d_i, \lambda) = \rho_c \frac{\pi}{6} \lambda^3 \frac{\bar{v}_\lambda^2}{2} = \rho_c \frac{C\pi}{12} \lambda^{11/3} \varepsilon^{2/3} = \rho_c \frac{C\pi}{12} \xi^{11/3} d_i^{11/3} \varepsilon^{2/3}$ . Moreover, with this parameter value and bubble velocity estimate the critical energy ratio becomes  $\chi_{cr} \approx e_s(d_i, d_j)/\bar{e}(d_i, \lambda) = 12C_f \sigma_I / (C\rho_c \varepsilon^{2/3} d_i^{5/3} \xi^{11/3})$ .

<sup>10</sup> Luo and Svendsen [80] employed the parameter value  $(8C/3\pi) \approx 2.045$  instead, hence the parameter in (9.52) becomes 0.923.

[133]. Several contributions have focused on the modification of the basic model of Luo and Svendsen [80] intending to avoid this limitation (e.g., [31, 71, 133]).

Hagesæther et al. [31] and Wang et al. [133] extended the basic breakage model of Luo and Svendsen [80] assuming that when a fluid particle with size  $d_i$  is hit by an eddy of size  $\lambda$  having turbulent kinetic energy  $e(d_i, \lambda)$ , the daughter particle size is limited by a minimum value due to the capillary pressure and by a maximum value due to the increase of the surface energy. The daughter bubble size is thus limited by two constraints. The capillary pressure constraint states that if the dynamic pressure of the turbulent eddy  $\frac{1}{2}\rho_c v_\lambda^2$  exceeds the capillary pressure  $\sigma_I/d''$ , the fluid particle is deformed and finally breaks up resulting in a minimum breakage fraction  $f_{V_{\min}}$  (or bubble size  $d_{j,\min}$ ) [72].  $d''$  denotes the diameter of the smaller daughter size (or two times the minimum radius of curvature). When breakage occurs, the dynamic pressure induced by the eddy turbulence kinetic energy satisfy the criterion:

$$\frac{1}{2}\rho_c v_\lambda^2 \geq \frac{\sigma_I}{d''} \quad (9.53)$$

The second constraint, often referred to as the surface area criterion [80], states that the eddy kinetic energy must be larger than the increase of the surface energy during the breakage as expressed by (9.46). This constraint results in a maximum breakage fraction  $f_{V_{\max}}$  (or bubble size  $d_{j,\max}$ ).

Lehr et al. [71] derived a similar breakage density function using only the capillary constraint and assumed that the interfacial force on the bubble surface and the initial force of the colliding eddy balance each other. Contrary, Hagesæther et al. [31] and Wang et al. [133] assumed that during breakage the inertial force of the colliding eddy is often larger than the interfacial force and bubble deformation is strengthened until breakage occurs. Therefore, the force balance of Lehr et al. [71] may not be satisfied during bubble breakage.

Politano et al. [98] studied the equilibrium between coalescence and breakage in homogeneous flows with isotropic turbulence using a population balance model. The population balance was solved using a multi-group approach. The daughter size distribution function was approximated by a uniform function, a delta function, and by the model proposed by Luo and Svendsen [80]. The breakage rate was calculated using either the model proposed by Luo and Svendsen [80] or the model proposed by Prince and Blance [102]. Significant differences in the resulting bubble breakage rate, and therefore in the bubble size distribution were observed comparing the model performance with experimental data on bubbly flows in an agitated tank. The model of Luo and Svendsen [80] was in very good agreement with the experimental data, whereas the model of Prince and Blanch [102] appears to over predict the bubble size.

Most of the macroscopic population balance kernels discussed are based on the eddy collision arguments that rely on the interpretation that turbulent flows consist of a collection of fluid slabs or eddies which are treated using relationships developed in the kinetic theory of gases. This engineering eddy concept is impossible to validate regarding eddy shape, the number densities and the breakage mechanisms discussed above. Further, the resulting breakage models require the specification of

the minimum and maximum eddy sizes that are capable of causing particle breakage, as well as a criterion for the minimum bubble size  $d_{\min}$ . Finally, the macroscopic formulation is considered less fundamental and less general than the average microscopic one. An unfortunate consequence of this modeling framework is that a discrete numerical scheme for the particle size is embedded within the source term closures, thus optimizing the numerical solution procedure is not a trivial task.

### ***9.1.2 Local Continuum Mechanical Population Balance Equation***

In the previous subsection it was mentioned that the formulations of the population balance equation based on the continuum mechanical approach might be split into two categories, the macroscopic- and the local instantaneous population balance equation formulations. The local instantaneous approach considers a continuum mechanical representation of a particle density function. This population balance equation is formulated from scratch on the continuum scales using generalized versions of the Leibnitz- and Gauss theorems.

In this section the population balance modeling approach established by Randolph [105], Randolph and Larson [106], and Himmelblau and Bischoff [37] is outlined. Ramkrishna [103, 104] employed the same continuum mechanical concepts. In this modeling approach the population balance model is considered a concept for describing the evolution of populations of countable entities like bubbles, drops and particles. In particular, in multiphase reactive flow the dispersed phase is treated as a population of particles distributed not only in physical space (i.e., in the ambient continuous phase) but also in an abstract property space [39, 105]. In the terminology of Hulburt and Katz [39], one refers to the spatial coordinates as external coordinates and the property coordinates as internal coordinates. The joint space of internal and external coordinates is referred to as the particle phase space. In this case the quantity of basic interest is a density function like the average number of particles per unit volume of the particle state space. The population balance may thus be considered an equation for the number density and regarded as a number balance for particles of a particular state.

A model describing the evolution of this density function must consider the various ways in which the particles of a specific state can either form or disappear from the system. The change of the density function with respect to the external coordinates refers to motion through physical space, and that of internal coordinates refers to motion through an abstract property space (e.g., particle growth). The physical processes that can be described by terms on this form are collectively referred to as convective processes since they result from motion in particle phase space. This group of physical processes, which cause convective motion in particle phase space, may contribute to the rates of formation and disappearance of the specific particle types. The number of particles of a particular type can also change by processes that create new particles (*birth* processes) and destroy existing particles (*death* processes). In bubbly flow birth of new particles can occur both due to breakage and coalescence processes. The bubble breakage and coalescence processes also contribute to death

processes, for a particle type that either breaks (into other particles) or coalesce with another particle no longer exists as such following the event. The phenomenological utility of population balance models lies in the convective processes as well as the birth and death processes. Following the notation of Ramkrishna [104] we let  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)$  be the number of particles per unit volume of the particle phase space at time  $t$ , at location  $\mathbf{x} \equiv (x_1, x_2, \dots, x_d)$  in property space ( $d$  representing the number of different quantities associated with the particle) and  $\mathbf{r} \equiv (r_1, r_2, r_3)$  in physical space. This number density function is considered a smooth function of its arguments  $\mathbf{x}$ ,  $\mathbf{r}$  and  $t$ , and  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)$  can be differentiated as many times as desired with respect to any of its arguments. To describe the different convective processes separate velocities are defined for the internal coordinates,  $\mathbf{v}_x(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$ , and for the external coordinates,  $\mathbf{v}_r(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$ . It is thus possible to identify particle (number) fluxes. In this representation  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)\mathbf{v}_r(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$  designates the particle flux through physical space and  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)\mathbf{v}_x(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$  denotes the particle flux through internal coordinate space. The continuous phase variables are represented by a vector  $\mathbf{Y}(\mathbf{r}, t) \equiv (\mathbf{v}_c, \mathbf{v}_d, \alpha_c, \alpha_d, p, \rho_c, \rho_d, \dots)$  which is calculated from the governing transport equations and the problem dependent boundary conditions.

If  $dV_x$  and  $dV_r$  denote infinitesimal volumes in property space and physical space respectively located at  $(\mathbf{x}, \mathbf{r})$ , then the number of particles in  $dV_x dV_r$  is given by  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)dV_x dV_r$ . The local (average) number density in physical space, that is, the total number of particles per unit volume of physical space, denoted  $N(\mathbf{r}, t)$ , is given by:

$$N(\mathbf{r}, t) = \int_{V_x} f^{(1)}(\mathbf{x}, \mathbf{r}, t) dV_x \quad (9.54)$$

For an arbitrary combined material volume element constituting a combined sub-volume  $V_{SV}(t)$  of the particle phase space the integral formulation of the population balance states that the only way in which the number of particles can change is by birth and death processes [37, 103–106].

The system balance is thus written on the form:

$$\left\{ \begin{array}{l} \text{The Time Rate of Change} \\ \text{of } f^{(1)} \text{ in the Sub-volume } V_{SV}(t) \end{array} \right\} = \left\{ \begin{array}{l} \text{The Net Generation of } f^{(1)} \\ \text{Within the Sub-volume } V_{SV}(t) \end{array} \right\}$$

This modeling approach thus considers the balance principle to the number density function  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)$  for an arbitrary combined material sub-volume  $V_{SV}(t)$  of the particle phase space  $V(t)$ :

$$\frac{D}{Dt} \int_{V_{SV}(t)} f^{(1)} dV' = \int_{V_{SV}(t)} (B - D) dV' \quad (9.55)$$

In this notation  $D/Dt$  represents a generalization of the substantial time derivative operator. The  $B - D$  terms are the net birth and death terms collectively representing

the net rate of production of particles of state  $(\mathbf{x}, \mathbf{r})$  at time  $t$  in an environment of state  $\mathbf{Y}$ .

In accordance with the standard approach in continuum fluid mechanics, the abstract system or material control volume description is converted into a combined Eulerian framework by use of a generalization of the conventional Reynolds theorem. For general vector spaces the Reynolds theorem is written as [103–106]:

$$\frac{D}{Dt} \int_{V_{SV}(t)} f^{(1)} dV' = \int_{V_{SV}} \frac{\partial f^{(1)}}{\partial t} dV' + \int_{A_{SA}} (\mathbf{v}f^{(1)}) \cdot \mathbf{n} dA' \quad (9.56)$$

where  $\mathbf{v}$  denotes the combined phase space velocity vector ( $\equiv \mathbf{v}_x + \mathbf{v}_r$ ) relative to a fixed combined control volume surface,  $dA' = dA'_x + dA'_r$  are local, infinitesimal surface areas in  $A = A_x + A_r$ , and  $\mathbf{n}$  denotes a combined normal unit vector ( $\equiv \mathbf{n}_x + \mathbf{n}_r$ ). Moreover,  $V$  is considered a combined abstract volume of a hypothetical continuous medium containing all the embedded particles within  $V_r$  and  $V_x$ . For convenience, we use the compact notation  $dV' = dV'_x dV'_r$ ,  $V = V_x \cup V_r$ , and  $\int_V = \int_{V_x} \int_{V_r}$ .

Likewise, one imagines that the surface integral in (9.56) can be rewritten in terms of a volume integral using a generalization of the conventional Gauss' theorem:

$$\int_{A_{SA}} (\mathbf{v}f^{(1)}) \cdot \mathbf{n} dA' = \int_{V_{SV}} \nabla \cdot (\mathbf{v}f^{(1)}) dV' \quad (9.57)$$

By use of (9.56) the system balance (9.55) can be rewritten as a volume integral for a fixed combined control volume in particle phase space:

$$\int_{V_{SV}} \left( \frac{\partial f^{(1)}}{\partial t} + \nabla \cdot (\mathbf{v}f^{(1)}) - (B - D) \right) dV' = 0 \quad (9.58)$$

Since  $V_{SV}$  was arbitrary, (9.58) must be satisfied for any  $V_{SV}$ , hence a necessary condition for (9.58) to be true is that the integrand vanishes identically. A differential population balance for the number density function  $f^{(1)}$  is thus achieved:

$$\frac{\partial f^{(1)}}{\partial t} + \nabla \cdot (\mathbf{v}f^{(1)}) - (B - D) = 0 \left( \frac{1}{\text{s m}^3[\mathbf{x}]} \right) \quad (9.59)$$

Considering the fluid particle coalescence and breakage phenomena only, the net source  $B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$  and sink  $D(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$  terms are given as:

$$B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) = B_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) + B_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) \left( \frac{1}{\text{s m}^3[\mathbf{x}]} \right) \quad (9.60)$$

$$D(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) = D_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) + D_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) \left( \frac{1}{s \text{ m}^3[\mathbf{x}]} \right) \quad (9.61)$$

The local instantaneous population balance becomes:

$$\begin{aligned} \frac{\partial f^{(1)}(\mathbf{x}, \mathbf{r}, t)}{\partial t} + \nabla_r \cdot (f^{(1)}(\mathbf{x}, \mathbf{r}, t) \mathbf{v}_r) + \nabla_x \cdot (f^{(1)}(\mathbf{x}, \mathbf{r}, t) \mathbf{v}_x) \\ = B_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) - D_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) + B_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) - D_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t). \end{aligned} \quad (9.62)$$

where  $f^{(1)}(\mathbf{x}, \mathbf{r}, t)$  is the bubble number probability density ( $1/\text{m}^3[\mathbf{x}]$ ), which varies with internal coordinates ( $\mathbf{x}$ ), spatial position ( $\mathbf{r}$ ) and time ( $t$ ).

The first term on the LHS of (9.62) describes the change of the particle number probability density with time. The second term designates the change in the particle number probability density due to convection. The third term represents the change in the bubble number probability density due to convection in the internal coordinates denoting several particle growth phenomena. Collectively the terms on the RHS denote a net source term, representing the change in the number probability density  $f^{(1)}$  due to particle breakup and coalescence. The  $B_B$  and  $D_B$  terms describe the birth and death rates of particles due to breakage, and the  $B_C$  and  $D_C$  terms account for the birth and death rates of particles due to coalescence.

To close this model formulation constitutive equations are required for both the growth and source term functions. This parameterization process is of great importance as it represents the weakest part of the population balance modeling. The detailed functionality of the closure relations and even the physical nature of these processes are generally unknown and require further attention. The complexity of the growth terms may also depend on the choice of internal coordinates or particle properties used characterizing the dispersed phase. In most bubbly flow investigations the particle diameter (volume) is used, thus the gas expansion due to pressure-, temperature- and composition changes as well as interfacial mass transfer fluxes has to be incorporated through some kind of growth terms. Contrary, using particle mass as the internal coordinate, only the interfacial mass transfer fluxes have to be incorporated through this term.

It is still not common to solve the local population balance equations derived above by direct numerical simulations, instead some kind of averaging is performed to enable solution with reasonable time and (physical) space resolutions. Another motivation for performing this averaging is to develop a PBE modeling framework that is consistent with the averaged multi-fluid model concept commonly used simulating multiphase flows. Adopting the conventional time after volume averaging procedure, the local transport equation is averaged over a physical averaging volume and thereafter in time. The result is:

$$\begin{aligned} \frac{\partial \langle f^{(1)}(\mathbf{x}, t) \rangle}{\partial t} + \nabla_r \cdot (\langle f^{(1)}(\mathbf{x}, t) \rangle \langle \mathbf{v}_r \rangle) + \nabla_x \cdot (\langle f^{(1)}(\mathbf{x}, t) \rangle \langle \mathbf{v}_x \rangle) \\ = \langle B_B(\mathbf{x}, \mathbf{Y}, t) \rangle - \langle D_B(\mathbf{x}, \mathbf{Y}, t) \rangle + \langle B_C(\mathbf{x}, \mathbf{Y}, t) \rangle - \langle D_C(\mathbf{x}, \mathbf{Y}, t) \rangle \end{aligned} \quad (9.63)$$

Number density weighted average velocities might then be introduced, thus:

$$\overline{\langle f^{(1)}(\mathbf{x}, t) \rangle \langle \mathbf{v}_r \rangle} = \overline{\langle f^{(1)}(\mathbf{x}, t) \rangle} \overline{\langle \mathbf{v}_r \rangle}^f \quad (9.64)$$

and

$$\overline{\langle f^{(1)}(\mathbf{x}, t) \rangle \langle \mathbf{v}_x \rangle} = \overline{\langle f^{(1)}(\mathbf{x}, t) \rangle} \overline{\langle \mathbf{v}_x \rangle}^f \quad (9.65)$$

This approach makes the velocities in the population balance different from the mass- or phase weighted average velocities obtained solving the two-fluid model. This discrepancy is an argument for the formulation of a mass density population balance instead of a number balance to achieve a consistently integrated population balance within the two-fluid modeling framework.

Standard Reynolds decomposition of the variables might be employed followed by time averaging of the equation. The typical low order turbulence modeling of the resulting covariance terms gives rise to diffusive terms in the balance equation [27]. The physics involved in these terms is, however, not understood making this modeling issue a challenging task:

$$\overline{\langle f^{(1)}(\mathbf{x}, t) \rangle \langle \mathbf{v}_r \rangle} = \overline{\langle f^{(1)}(\mathbf{x}, t) \rangle} \overline{\langle \mathbf{v}_r \rangle} + \overline{\langle f^{(1)}(\mathbf{x}, t) \rangle' \langle \mathbf{v}_r \rangle'} \quad (9.66)$$

and

$$\overline{\langle f^{(1)}(\mathbf{x}, t) \rangle \langle \mathbf{v}_x \rangle} = \overline{\langle f^{(1)}(\mathbf{x}, t) \rangle} \overline{\langle \mathbf{v}_x \rangle} + \overline{\langle f^{(1)}(\mathbf{x}, t) \rangle' \langle \mathbf{v}_x \rangle'} \quad (9.67)$$

Randolph and Larson [106], p. 74, claimed that evidence suggests that such random fluctuations in growth rate and the flow have been proven to exist in certain crystallization problems [40]. In problems in which such effects are significant, it might be proposed that these turbulent covariance terms can be approximated by use of the gradient hypothesis and a proportionality coefficient may be introduced in accordance with the Boussinesq hypothesis. In the work of Randolph and Larson [106], the associated proportionality coefficients were denoted the growth and flow diffusivities.

If an appropriate relation for the contact area as a function of the internal coordinates is available, the particle growth term due to interfacial mass transfer can be modeled in accordance with the well known film theory (although still of semi-empirical nature) and the ideal gas law [71]. The modeling of the source and sink terms due to fluid particle breakage and coalescence is less familiar and still on an early stage of development. Moreover, the existing theory is rather complex and not easily available. Further research is thus needed in order to derive consistent multifluid-population balance models.

### 9.1.2.1 Continuous Source Term Closures

In this subsection the conventional microscopic or local instantaneous continuum mechanical source term closures are presented and examined.

A fairly general framework has been formulated for the source terms considering fluid particle breakage, fluid particle coalescence, solid particle agglomeration/aggregation, solid particle breakage due to attrition etc and similar processes [27, 39, 45, 87, 88, 104, 106, 108, 119, 125, 128]. In this section emphasis is placed on fluid particle breakage and coalescence processes. Thorough reviews on the modeling of the fluid particle coalescence and breakage processes can be found elsewhere [73, 74, 122]. Detailed mathematical discussions of the solid particle breakage and coalescence modeling and the mathematical properties of the constitutive equations can be found in the papers by Barrow [4], Laurencot and Mischler [67, 68] and Rigopoulos [108]. Randolph and Larson [106] provides a more practical introduction to the application of the PBE in crystallization technology.

### *Breakage Death term*

Considering the breakage terms, the physical breakage of the different particles are assumed to be independent of each other. The average loss rate of particles of state  $(\mathbf{x}, \mathbf{r})$  per unit time by breakage is normally written as:

$$D_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) = b_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) f^{(1)}(\mathbf{x}, \mathbf{r}, t) \quad (9.68)$$

where  $b_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$  has the dimension of reciprocal time (1/s) and is called the breakage frequency. This breakage frequency function represents the fraction of particles of state  $(\mathbf{x}, \mathbf{r})$  breaking per unit time. The breakage processes are often considered of random nature, thus the modeling work usually adopts probabilistic theory.

### *Breakage Birth Term*

The average production rate for particles of state  $(\mathbf{x}, \mathbf{r})$  originating from breakage of particles of all other particles states, considering both internal and external coordinates is frequently given by [104, 125]:

$$B_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) = \int_{V_{x,SV}} \int_{V_{r,SV}} \nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) b_B(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) f^{(1)}(\mathbf{x}', \mathbf{r}', t) dV_{r'} dV_{x'} \quad (9.69)$$

where  $\nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  denotes the average number of particles formed from the breakage of a single particle of state  $(\mathbf{x}', \mathbf{r}')$  in an environment of  $\mathbf{Y}$  at time  $t$ .

$P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  designates the probability density function for creating daughter particles that have state  $(\mathbf{x}, \mathbf{r})$  from the breakage of a parent particle of state  $(\mathbf{x}', \mathbf{r}')$  in an environment of state  $\mathbf{Y}$  at time  $t$ . In the engineering literature this function is commonly referred to as the daughter particle size distribution function, being a probability density with units  $(1/m^3[\mathbf{x}])$ , denoting the size distribution of daughter particles that have  $(\mathbf{x}, \mathbf{r})$  produced upon breakage of a parent

particle of state  $(\mathbf{x}', \mathbf{r}')$ . The integrand on the RHS represents the rate of formation of daughter particles of state  $(\mathbf{x}, \mathbf{r})$  formed by breakage of parent particles of state  $(\mathbf{x}', \mathbf{r}')$ . That is, the number of particles of state  $(\mathbf{x}', \mathbf{r}')$  that breaks per unit time is  $b_B(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) f^{(1)}(\mathbf{x}', \mathbf{r}', t) dV_{r'} dV_{x'}$ . Multiplying the above expression by  $\nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  gives the number of daughter particles resulting from the breakage processes  $\nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) b_B(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) f^{(1)}(\mathbf{x}', \mathbf{r}', t) dV_{r'} dV_{x'}$  of which a fraction  $P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) dV_{r'} dV_{x'}$  represents daughter particles of state  $(\mathbf{x}, \mathbf{r})$ .

The probability density function,  $P_B$ , must satisfy the normalization condition (in the internal coordinates):

$$\int_{V_{x,SV}} P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) dV_{x'} = 1 \quad (9.70)$$

Often binary breakage is assumed under any operating conditions for which  $\nu = 2$ . However, experimental determination of this variable with the necessary adjustments of  $P_B$  is recommended. The function  $P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  must also be determined from experimental observations. Moreover, the  $\nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  and  $P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  functions are not really independent, thus it might be convenient to define a *breakage yield redistribution function* as follows:

$$H_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) = \nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) \quad (9.71)$$

Dorao [19], Dorao et al. [20], Martinez-Bazan et al. [86], Sporleder et al. [125] and Solsvik et al. [122] used this function and required that (9.71) must reflect the conservation property that:

$$\int_{\mathbf{x}'_{\min}}^{\mathbf{x}'} H_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) \mathbf{x}^N d\mathbf{x} = \mathbf{x}'^N \quad (9.72)$$

where  $N$  represents the order of the moment of the parent particle properties that is conserved.

A thorough analysis of the breakage birth term physical interpretation reveals that a major adjustment of the given breakage birth term formulation is required. In the generalized birth term formulation (9.69) the integral in physical space is strictly not appropriate for the physics of the current problem as the formulation corresponds to the assumption that a parent particle that is breaking at one location in physical space can produce daughter particles that occur elsewhere. Physically, it is obvious that in a local breakage event the birth place of the daughter particles should be at the same location as the parent particle did break. Ramkrishna [104] (p. 57) briefly mentioned this model limitation and that the given source term formulations have to be re-written for problems represented in the external coordinates. An appropriate modification can be obtained by introducing several assumptions about the physical space dependences of the functions in the integral argument in the given birth term definition.

The major assumption is that the breakage process is local in space so that the parent particle that breaks shears the same location as the daughter fragments from breakage immediately after the event. This assumption implies that all the processes comprising a breakage event occur in a particular differential volume  $dV_{r'}$  around  $\mathbf{r}'$  and containing  $\mathbf{r}$  and  $\tilde{\mathbf{r}}$ . Hence, it can be assumed that  $\nu(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) \approx \nu(\mathbf{x}', \mathbf{r}, \mathbf{Y}, t)$ ,  $b_B(\mathbf{x}', \mathbf{r}', \mathbf{Y}, t) \approx b_B(\mathbf{x}', \mathbf{r}, \mathbf{Y}, t)$  and  $f^{(1)}(\mathbf{x}', \mathbf{r}', t) \approx f^{(1)}(\mathbf{x}', \mathbf{r}, t)$ . These approximations thus allow the integration with respect to  $dV_{r'}$  in (9.69) to be carried out independently for  $P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  alone because these relaxations leave only the daughter size probability density function dependent on  $\mathbf{r}'$ . The volume integration thus becomes<sup>11</sup>:

$$P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) = \int_{V_{r,SV}} P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) dV_{r'} \quad (9.73)$$

The breakage birth term is thus reduced and written on a more appropriate form:

$$\begin{aligned} B_B(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) \\ = \int_{V_{x,SV}} \nu(\mathbf{x}', \mathbf{r}, \mathbf{Y}, t) b_B(\mathbf{x}', \mathbf{r}, \mathbf{Y}, t) P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}, \mathbf{Y}, t) f^{(1)}(\mathbf{x}', \mathbf{r}, t) dV_{x'} \end{aligned} \quad (9.74)$$

in which  $P_B(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}, \mathbf{Y}, t)$  is the differential volume integrated daughter size distribution function with units  $(\frac{1}{[\mathbf{x}]})$ .

### Coalescence Birth Term

The population balance birth term due to coalescence is normally defined as [104]:

$$\begin{aligned} B_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) \\ = \frac{1}{\delta} \int_{V_{r,SV}} \int_{V_{x,SV}} a_C(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) f^{(2)}(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', t) \left. \frac{\partial(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})}{\partial(\mathbf{x}, \mathbf{r})} \right|_{\mathbf{x}', \mathbf{r}'} dV_{x'} dV_{r'} \end{aligned} \quad (9.75)$$

where  $\delta$  represents the number of times identical pairs have been considered in the interval of integration, thus  $1/\delta$  corrects for the redundancy. The state  $(\mathbf{x}', \mathbf{r}')$  is held constant in the definition of the Jacobian determinant. The  $a_C(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  denotes the coalescence frequency or the fraction of the parent particle pairs of states  $(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})$  and  $(\mathbf{x}', \mathbf{r}')$  that coalesce per unit time.

The coalescence frequency is defined for an ordered pair of particles, although from a physical viewpoint the ordering of particle pairs should not alter the value of the frequency. In other words,  $a_C(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  satisfies a symmetry property:  $a_C(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', \mathbf{Y}, t) = a_C(\mathbf{x}', \mathbf{r}', \tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{Y}, t)$ . It is thus essential to consider only one

<sup>11</sup> A local space dependency of the  $P_B$ -function is retained as the integration is over a differential microscopic volume  $dV_{r'}$ , thus the integrated  $P_B$ -function varies locally in space  $\mathbf{r}$  but the  $P_B$ -function does not differ over the microscopic differential volume  $dV_{r'}$  of the different particles.

of the above order for a given pair of particles. It is further noticed that the sizes of the three particles involved in a binary coalescence event are not independent. Thus, given the state  $(\mathbf{x}, \mathbf{r})$  of the child particle produced, the two coalescing parent particles are located in state space about  $(\mathbf{x}', \mathbf{r}')$  and  $(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})$ , respectively. Moreover, we might presuppose that it is possible to solve for the complement parent particle state given those of the primary parent particle and the new child particle. Thus, given the state of the child particle  $(\mathbf{x}, \mathbf{r})$ , and the state  $(\mathbf{x}', \mathbf{r}')$  of the primary parent particle, the state of the coalescing complement parent particle is known and denoted by  $(\tilde{\mathbf{x}}(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}'), \tilde{\mathbf{r}}(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}'))$ . Besides, the average number of distinct pairs of parent particles at time  $t$  per unit volumes in state space located about  $(\mathbf{x}', \mathbf{r}')$  and  $(\tilde{\mathbf{x}}(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}'), \tilde{\mathbf{r}}(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}'))$  is defined as  $f^{(2)}(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', t)$ . The birth term for the rate of production of particles of state  $(\mathbf{x}, \mathbf{r})$ , denoted by  $B_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t)$ , must thus account for the fact that the density with respect to the complement parent particle  $[\tilde{\mathbf{x}}(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}'), \tilde{\mathbf{r}}(\mathbf{x}, \mathbf{r}; \mathbf{x}', \mathbf{r}')] can be transformed into one in  $(\mathbf{x}, \mathbf{r})$  by using the appropriate Jacobian determinant of the transformation. The Jacobian determinant is denoted by  $J$  and defined as [104]:$

$$J = \frac{\partial(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})}{\partial(\mathbf{x}, \mathbf{r})} \bigg|_{\mathbf{x}', \mathbf{r}'} = \begin{vmatrix} \frac{\partial \tilde{x}_1}{\partial x_1} & \dots & \frac{\partial \tilde{x}_1}{\partial x_n} & \frac{\partial \tilde{x}_1}{\partial r_1} & \frac{\partial \tilde{x}_1}{\partial r_2} & \frac{\partial \tilde{x}_1}{\partial r_3} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \frac{\partial \tilde{x}_n}{\partial x_1} & \dots & \frac{\partial \tilde{x}_n}{\partial x_n} & \frac{\partial \tilde{x}_n}{\partial r_1} & \frac{\partial \tilde{x}_n}{\partial r_2} & \frac{\partial \tilde{x}_n}{\partial r_3} \\ \frac{\partial \tilde{r}_1}{\partial x_1} & \dots & \frac{\partial \tilde{r}_1}{\partial x_n} & \frac{\partial \tilde{r}_1}{\partial r_1} & \frac{\partial \tilde{r}_1}{\partial r_2} & \frac{\partial \tilde{r}_1}{\partial r_3} \\ \frac{\partial \tilde{r}_2}{\partial x_1} & \dots & \frac{\partial \tilde{r}_2}{\partial x_n} & \frac{\partial \tilde{r}_2}{\partial r_1} & \frac{\partial \tilde{r}_2}{\partial r_2} & \frac{\partial \tilde{r}_2}{\partial r_3} \\ \frac{\partial \tilde{r}_3}{\partial x_1} & \dots & \frac{\partial \tilde{r}_3}{\partial x_n} & \frac{\partial \tilde{r}_3}{\partial r_1} & \frac{\partial \tilde{r}_3}{\partial r_2} & \frac{\partial \tilde{r}_3}{\partial r_3} \end{vmatrix} \quad (9.76)$$

In order to elucidate the derivation of the coalescence birth term in further details, we follow the analysis performed by Sporleder et al. [125]. The analysis can be simplified by considering a problem with only one internal coordinate representing the particle size property. It follows that, if the internal size coordinate is mass or volume, the three particles are related as the size of the child particle equals the sum of the parent particle sizes:

$$M_x = M_{\tilde{x}} + M_{x'} \quad (9.77)$$

$$V_x = V_{\tilde{x}} + V_{x'} \quad (9.78)$$

On the other hand, if the size coordinate is equivalent diameter, the three particles are still related on the volume basis as:

$$x^3 = \tilde{x}^3 + (x')^3 \quad (9.79)$$

A differential birth term  $\mathcal{B}_C(x', \mathbf{r}', x, \mathbf{r}, \mathbf{Y}, t) dV_{x'} dV_x dV_{r'}$  may be defined as the number of parent particles with properties in the range  $[V_{x'}, V_{x'} + dV_{x'}]$  that disappear

due to coalescence in a volume  $dV_{r'}$  about  $\mathbf{r}'$  per unit volume and unit time, yielding children particles in the range  $[V_x, V_x + dV_x]$ . The local coalescence birth term  $B_C(x, \mathbf{r}, \mathbf{Y}, t)$  can thus be related to the number of children particles born. As there are more parent particles disappearing than children particles produced, the expression for the number of children particles produced must be divided by the number of parents that disappear per coalescence event because the children production rate is expressed in terms of the parent particle disappearance rate. The local coalescence birth term  $B_C(x, \mathbf{r}, \mathbf{Y}, t)$  can thus be defined in terms of the differential birth term  $\mathcal{B}_C(x', \mathbf{r}', x, \mathbf{r}, \mathbf{Y}, t)dV_{x'}dV_{r'}$  on the form:

$$B_C(x, \mathbf{r}, \mathbf{Y}, t) = \frac{1}{\delta} \int_{V_r} \int_{V_x} \mathcal{B}_C(x', \mathbf{r}', x, \mathbf{r}, \mathbf{Y}, t)dV_{x'}dV_{r'} \quad (9.80)$$

A major modeling assumption imposed is that the differential birth term  $\mathcal{B}_C(x', \mathbf{r}', x, \mathbf{r}, \mathbf{Y}, t)dV_{x'}dV_x$  is proportional to the product of the distribution density functions of the parent particles (each of them are defined as the number of parent particles per unit mixture volume and parent property), as follows:

$$\mathcal{B}_C(x', \mathbf{r}', x, \mathbf{r}, \mathbf{Y}, t)dV_{x'}dV_x = a_C(\tilde{x}, \tilde{\mathbf{r}}, x', \mathbf{r}', \mathbf{Y}, t)f^{(2)}(\tilde{x}, \tilde{\mathbf{r}}, x', \mathbf{r}', t)dV_{\tilde{x}}dV_{\tilde{\mathbf{r}}} \quad (9.81)$$

where the coalescence frequency,  $a_C$ , appears as a proportionality coefficient.

Since the above relation indicates that the integration on the RHS is over the complement parent particle domain, and not over the children  $(x, \mathbf{r})$  domain as foreseen on the LHS, it has been found convenient to express the particle state  $(\tilde{x}, \tilde{\mathbf{r}})$  in terms of the state  $(x, \mathbf{r})$ . A Jacobian determinant of transformation must thus be introduced to change the integration variable. Hence, it is foreseen that the argument of integration is manipulated as:

$$\begin{aligned} \mathcal{B}_C(x', \mathbf{r}', x, \mathbf{r}, \mathbf{Y}, t)dV_{x'}dV_x \\ = a_C(\tilde{x}, \tilde{\mathbf{r}}, x', \mathbf{r}', \mathbf{Y}, t)f^{(2)}(\tilde{x}, \tilde{\mathbf{r}}, x', \mathbf{r}', t) \frac{\partial(\tilde{x}, \tilde{\mathbf{r}})}{\partial(x, \mathbf{r})} dV_{x'}dV_x \end{aligned} \quad (9.82)$$

The coalescence birth term,  $B_C(x, \mathbf{r}, \mathbf{Y}, t)$ , can then be obtained by substituting (9.82) into (9.80), after multiplication with the differential volume ratio  $dV_{r'}/dV_x$ , and with  $\delta = 2$  yields:

$$B_C(x, \mathbf{r}, \mathbf{Y}, t) = \frac{1}{2} \int_{V_r} \int_{V_x} a_C(\tilde{x}, \tilde{\mathbf{r}}, x', \mathbf{r}', \mathbf{Y}, t)f^{(2)}(\tilde{x}, \tilde{\mathbf{r}}, x', \mathbf{r}', t) \frac{\partial(\tilde{x}, \tilde{\mathbf{r}})}{\partial(x, \mathbf{r})} dV_{x'}dV_{r'} \quad (9.83)$$

The Jacobian determinant appears in the relation as a consequence of the variable transformation from  $(\tilde{x}, \tilde{\mathbf{r}})$  to  $(x, \mathbf{r})$  [104, 82]. The coalescence birth term (9.75)

which is valid for multivariate problems follows as a generalization of the relation (9.83) which is valid for one internal coordinate or property only.

Still the coalescence birth term (9.75) contains the volume integral in physical space, which may not be consistent with the local property of the coalescence phenomena. The natural and consistent modeling approach to use in order to adapt the coalescence birth and death terms into the microscopic and local instantaneous population balance frameworks should be based on the same concepts as already outlined for the breakage birth term. Following these ideas, the integral in physical space is not considered appropriate for the local coalescence processes as the birth of the new child particle must occur at the same location as the binary set of parent particles did coalesce. The coalescence birth term model might thus be modified employing the same modeling ideas as employed for the breakage birth term. Using the variable notation as employed in the general coalescence birth term (9.75),  $a_C(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  represents the probability that two parent entities of state  $(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})$  and  $(\mathbf{x}', \mathbf{r}')$  coalesce at time  $t$  per unit time, and  $f^{(2)}$  is the entity-pair distribution function. A number of simplifying assumptions are then imposed to reduce the coalescence frequency  $a_C(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', \mathbf{Y}, t)$  to the integrated kernel function,<sup>12</sup>  $\kappa_C(\tilde{\mathbf{x}}, \mathbf{r}, \mathbf{x}', \mathbf{r}, \mathbf{Y})$ , denoting the volume integral of the frequency function  $a_C$ . The integrated kernel function represents the differential volume flux of particles crossing the cross-sectional area of one single particle. The first major assumption required is thus that the entity-pair function is approximated by the product of two single number density functions evaluated at  $(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})$  and  $(\mathbf{x}', \mathbf{r}')$  at any instant  $t$ . Thus, a common approximation used in kinetic theory of a dilute gas is adopted:  $f^{(2)}(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, \mathbf{x}', \mathbf{r}', t) \approx \tilde{f}^{(1)}(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, t) f'^{(1)}(\mathbf{x}', \mathbf{r}', t)$ . This assumption implies that there is no statistical correlation between colliding parent particles of states  $(\mathbf{x}', \mathbf{r}')$  and  $(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})$  at any instant  $t$ . The second major assumption imposed is that the single number density functions at point  $\tilde{\mathbf{r}}$  and point  $\mathbf{r}'$  are very similar considering that the distance between these two points is of the order of magnitude of the particle size, hence  $f^{(1)}(\mathbf{x}', \mathbf{r}', t) \approx f^{(1)}(\mathbf{x}', \tilde{\mathbf{r}}, t)$ .

The coalescence source term is then reduced to:

$$B_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) = \frac{1}{\delta} \int_{V_{x,SV}} \kappa_C(\tilde{\mathbf{x}}, \mathbf{r}, \mathbf{x}', \mathbf{r}, \mathbf{Y}, t) \tilde{f}^{(1)}(\tilde{\mathbf{x}}, \tilde{\mathbf{r}}, t) f'^{(1)}(\mathbf{x}', \mathbf{r}', t) \frac{\partial(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})}{\partial(\mathbf{x}, \mathbf{r})} \Big|_{\mathbf{x}', \mathbf{r}'} dV'_x \quad (9.84)$$

in which  $\kappa_C(\tilde{\mathbf{x}}, \mathbf{r}, \mathbf{x}', \mathbf{r}, \mathbf{Y}, t)$  denotes the coalescence density or the fraction of particle pairs of states  $(\tilde{\mathbf{x}}, \tilde{\mathbf{r}})$  and  $(\mathbf{x}', \mathbf{r}')$  that coalesce per unit time multiplied by a differential volume ( $\text{m}^3/\text{s}$ ). This quantity coincides with the quantity referred to as the *swept volume rate* of the particle in the discrete macroscopic PBE formulation.

<sup>12</sup> A local space dependency of the  $\kappa$ -function is retained as the integration is over a differential microscopic volume  $dV_{\rho'}$ , thus the  $\kappa$ -function varies locally in space  $\mathbf{r}$  but the  $\kappa$ -function does not differ over the microscopic differential volume  $dV_{\rho'}$  of the different particles.

Hence, an approximate coalescence closure can be obtained by adapting the macroscopic model.

### *Coalescence Death Term*

The death term due to coalescence  $D_C$  is generally defined as:

$$D_C(\mathbf{x}, \mathbf{r}, t) = \int_{V_{r'}} \int_{V_x} a_C(\mathbf{x}', \mathbf{r}', \mathbf{x}, \mathbf{r}, \mathbf{Y}, t) f^{(2)}(\mathbf{x}', \mathbf{r}', \mathbf{x}, \mathbf{r}, t) dV_{x'} dV_{r'} \quad (9.85)$$

where the states of the two parent particles are defined by  $(\mathbf{x}', \mathbf{r}')$  and  $(\mathbf{x}, \mathbf{r})$ , respectively.

With a consistent set of approximations as applied manipulating the coalescence birth term, the coalescence death term reduces to:

$$D_C(\mathbf{x}, \mathbf{r}, \mathbf{Y}, t) = \int_{V_{x,SV}} a_C(\mathbf{x}', \mathbf{r}, \mathbf{x}, \mathbf{r}, \mathbf{Y}, t) f^{(2)}(\mathbf{x}', \mathbf{r}, \mathbf{x}, \mathbf{r}, t) dV_{x'} \quad (9.86)$$

### *Diameter based Population Balance Source Terms*

To examine the derivation of the population balance source term closures, the bubble diameter is henceforth chosen as the only internal coordinate (i.e.,  $x = d$ ) as it is the most frequent choice. Adopting the generalized source term definitions as defined in this subsection, the diameter based source terms occurs directly by substituting the diameter into the different source term equations noting from (9.79) that the third diameter is computed in terms of the other two  $\tilde{d} = (d^3 - d'^3)^{1/3}$ , and the Jacobian determinant is  $d\tilde{d}/dd = (d/\tilde{d})^2$ . An alternative procedure for changing the internal coordinate in the PBE formulation from volume to diameter has been provided by Marchisio et al. [82].

The resulting local source term definitions are listed below:

$$B_B(d, \mathbf{r}, t) = \int_d^\infty \nu(d', \mathbf{r}) b_B(d', \mathbf{r}) P_B(d, \mathbf{r}; d') f^{(1)}(d', \mathbf{r}, t) dd' \quad (9.87)$$

$$D_B(d, \mathbf{r}, t) = b_B(d, \mathbf{r}) f^{(1)}(d, \mathbf{r}, t) \quad (9.88)$$

$$B_C(d, \mathbf{r}, t) = \frac{d^2}{2} \int_0^d \frac{\kappa_C((d^3 - d'^3)^{1/3}, \mathbf{r}, d', \mathbf{r})}{(d^3 - d'^3)^{2/3}} f^{(1)}((d^3 - d'^3)^{1/3}, \mathbf{r}, d', \mathbf{r}, t) dd', \quad (9.89)$$

$$D_C(d, \mathbf{r}, t) = f^{(1)}(d, \mathbf{r}, t) \int_0^\infty \kappa_C(d, \mathbf{r}; d', \mathbf{r}) f^{(1)}(d', \mathbf{r}, t) dd' \quad (9.90)$$

All the source terms have units,  $(1/\text{s m}^3[\text{m}])$ .

Comparing the source term expressions (9.87)–(9.90) with (9.3)–(9.6) it is clearly seen that only under particular conditions will the two formulations give rise to identical expressions for the source terms. The macroscopic formulation is explicitly expressed in terms of a discrete discretization scheme and is very difficult to convert to other schemes.

In the following sections examining the source term parameterizations, emphasis will be put on a selected number of the novel closures suitable for bubbly flow modeling.

### 9.1.2.2 Coalescence Density Closures, $\kappa_C(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y})$

Intuitively, bubble coalescence is related to bubble collisions. The collisions are caused by the existence of spatial velocity difference among the particles themselves. However, not all collisions necessarily lead to coalescence. Thus modeling bubble coalescence on these scales means modeling of bubble collision and coalescence probability (efficiency) mechanisms. The pioneering work on coalescence of particles to form successively larger particles was carried out by Smoluchowski [119, 120]. The more recent coalescence closures that were formulated directly within the macroscopic framework [79, 83, 102, 127] are frequently transformed and expressed in terms of probability densities and used within the average microscopic and local instantaneous balance frameworks without further considerations employing a discrete numerical discretization scheme. As for the collision density in the macroscopic model formulation, the collision density of fluid particles is usually described assuming that the mechanisms of collision is analogous to collisions between molecules as in the kinetic theory of gases.

The coalescence density,  $\kappa_C(d; d', \mathbf{Y})$ , can thus be defined as the product of an effective swept volume rate (or volume flux of particles crossing the cross-sectional area of one single particle)  $h_C(d; d', \mathbf{Y})$  and the coalescence probability,  $p_C(d; d', \mathbf{Y})$  (e.g., [17, 42, 48, 102, 128, 132]):

$$\kappa_C(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}) = h_C(d, \mathbf{r}; d', \mathbf{Y}) p_C(d, \mathbf{r}; d', \mathbf{Y}) \left( \frac{\text{m}^3}{\text{s}} \right) \quad (9.91)$$

This relation expresses that not all collisions lead to coalescence. The modeling of the coalescence processes thus means to find adequate physical expressions for  $h_C(d; d', \mathbf{Y})$  and  $p_C(d; d', \mathbf{Y})$ . Kamp et al. [42], among others, suggested that the microscopic and local closures can be formulated in line with the macroscopic population balance approach, thus we may define:

$$h_C(d, \mathbf{r}; d', \mathbf{Y}) = \frac{\pi}{4} (d + d')^2 (\bar{v}_{t,d}^2 + \bar{v}_{t,d'}^2)^{1/2} \left( \frac{\text{m}^3}{\text{s}} \right) \quad (9.92)$$

and

$$p_C(d, \mathbf{r}; d', \mathbf{Y}) = \exp\left(-\frac{\Delta t_{\text{coal}}}{\Delta t_{\text{col}}}\right)(-) \quad (9.93)$$

where suitable continuous closures are needed for the model variables like the mean turbulent bubble approach velocities and the time scales. Multi-fluid models may provide improved estimates for the mean turbulent bubble approach velocities as individual velocity fields for each of the bubble phases are calculated. However, the multi-fluid models are formulated in the Eulerian framework and can not provide information of the Lagrangian single bubble velocities. Besides, the existing closures for the time scales are very crude and need further considerations.

The coalescence terms in the average microscopic population balance can then be expressed in terms of the local effective swept volume rate (or volume flux of particles crossing the cross-sectional area of one single particle) and the coalescence probability variables:

$$B_C(d, \mathbf{r}, \mathbf{Y}, t) = \frac{d^2}{2} \int_0^d \frac{h_C((d^3 - d'^3)^{\frac{1}{3}}, \mathbf{r}; d', \mathbf{r}, \mathbf{Y})}{(d^3 - d'^3)^{\frac{2}{3}}} p_C((d^3 - d'^3)^{\frac{1}{3}}, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}) \\ \times \tilde{f}^{(1)}((d^3 - d'^3)^{\frac{1}{3}}, \mathbf{r}, t) f'^{(1)}(d', \mathbf{r}, t) dd' \quad (9.94)$$

$$D_C(d, \mathbf{r}, \mathbf{Y}, t) = f^{(1)}(d, \mathbf{r}, t) \int_0^\infty h_C(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}) p_C(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}) \tilde{f}^{(1)}(\tilde{d}, \mathbf{r}, t) d\tilde{d}' \quad (9.95)$$

It is noted that all the terms in the continuum population balance equation have common units,  $(1/\text{m}^3 \text{ s} [\text{m}])$ . By discretizing the continuous bubble number density in groups or classes, a PBE formulation equivalent to the discrete macroscopic framework is obtained.

### 9.1.2.3 Models for the Breakage Frequency, $b_B(d, \mathbf{r})$

Formulating average microscopic source term closure laws for the breakage processes usually means to derive relations for the time after volume average breakage frequency,  $b_B(d)$ , the average number of daughter bubbles produced,  $\nu$ , and the average daughter particle size distribution,  $P_B(d|d')$ .

During the last decades numerous models have been developed for the bubble breakage frequency,  $b_B(d)$ , under turbulent conditions ([60, 133]). Several different categories of breakage frequency models are distinguished in the literature; models based on reaction kinetic concepts (e.g., [111]), phenomenological models based on the turbulent nature of the system (e.g., [128]), and models based based on purely kinematic ideas (e.g., [84, 85]).

In an interesting attempt to overcome the limitations found in the turbulent breakage models described above, Martínez-Baán et al. [84] (see also Lasheras et al. [60]) proposed an alternative model in the kinetic theory (microscopic) framework based

on purely kinematic ideas to avoid the use of the incomplete turbulent eddy concept and the macroscopic model formulation. The basic premise of the model of Martínez-Bazán et al. [84] is that for a bubble to break, its surface has to be deformed, and further, that this deformation energy must be provided by the turbulent stresses produced by the surrounding fluid. The minimum energy needed to deform a bubble of size  $d$  is its surface energy,

$$E_s(d) = \pi \sigma_I d^2 \text{ (J)} \quad (9.96)$$

The surface restoring pressure is ( $E_s/\text{volume}$ )

$$\sigma_s(d) = \frac{6E_s}{\pi d^3} = 6 \frac{\sigma_I}{d} \text{ (Pa)}. \quad (9.97)$$

The size of these bubbles is assumed to be within the inertial subrange of turbulence, thus the average deformation stress, which results from velocity fluctuations existing in the liquid between two points separated by a distance  $d$ , was estimated as:

$$\sigma_t(d) = \frac{1}{2} \rho_c \overline{\Delta v^2(d)} \text{ (Pa)} \quad (9.98)$$

where  $\overline{\Delta v^2(d)}$  is the mean value of the velocity fluctuations between two points separated by a characteristic distance  $d$ , and  $\rho_c$  is the density of the continuous phase.

At the critical condition where the turbulent stresses are equal to the confining stresses,  $\sigma_t(d) = \sigma_s(d)$ , a critical diameter,  $d_c$ , is defined such that bubbles with  $d < d_c$  are stable and will not break. A bubble  $d > d_c$  has a surface energy smaller than the deformation energy  $\sigma_s(d) < \sigma_t(d)$ , and thus, the bubble deforms and may eventually breaks up in a time  $t_b$ . Martínez-Bazán et al. [84] applied Kolmogorov's universal theory valid for homogeneous and isotropic turbulent flow to estimate the mean value of the velocity fluctuations,  $\overline{\Delta v^2(d)} = C(\varepsilon d)^{2/3}$ . The critical diameter,  $d_c = (\frac{12\sigma_I}{C\rho_c})^{3/5} \varepsilon^{-2/5}$ , is defined by the crossing point of the two curves determined by  $\sigma_s(d)$  and  $\sigma_t(d)$ . Martínez-Bazán et al. [84] postulated in accordance with Newton's law that the acceleration of the bubble interface during deformation is proportional to the difference between the deformation and confinement forces acting on it. In other words, the probability of breaking a bubble of size  $d$  in time  $t_b$  increases as the difference between the pressure produced by the turbulent fluctuations on the surface of the bubble,  $\frac{1}{2} \rho_c \overline{\Delta v^2(d)}$ , and the restoring pressure caused by surface tension,  $6\sigma_I/d$ , increases. On the other hand, the breakage frequency should decrease to a zero limit value as this difference of pressures vanishes. Thus, the bubble breakage time can be estimated as:

$$t_b \propto \frac{d}{v_{\text{breakage}}} = \frac{d}{\sqrt{\overline{\Delta v^2(d)} - 12 \frac{\sigma_I}{\rho_c d}}} \text{ (s)} \quad (9.99)$$

where  $v_{\text{breakage}}$  is the characteristic velocity of the bubble breakage process.

The breakage frequency  $b_B(d, \varepsilon)$  is given by:

$$b_B(d, \varepsilon) = \frac{1}{t_b} = K_g \frac{\sqrt{\Delta v^2(d) - 12 \frac{\sigma_l}{\rho_c d}}}{d} = K_g \frac{\sqrt{\beta(\varepsilon d)^{2/3} - 12 \frac{\sigma_l}{\rho_c d}}}{d} \quad (9.100)$$

the constant value  $C = 8.2$  is determined from theoretical analysis and the empirical parameter  $K_g = 0.25$  was fitted to experimental data for bubbly flows in turbulent water jets.

The breakage frequency is zero for bubbles of size  $d \leq d_c$ , and it increases rapidly for bubbles larger than the critical diameter,  $d > d_c$ . After reaching a maximum at  $d_{b_B, \max} = (9/4)^{3/5} d_c \approx 1.63 d_c$ , the breakage frequency decreases monotonically with the bubble size. The maximum breakage frequency, achieved at  $d_{b_B, \max}$ , is given by  $b_{B, \max}(\varepsilon) = 0.538 K_g C^{1/2} \varepsilon^{3/5} (12 \frac{\sigma_l}{\rho_c \beta})^{-2/5}$ .

Although this approach avoids the eddy concept, it is still restricted to homogeneous and isotropic turbulent flows, it contains several hypotheses that are not verified yet for bubble column flows, and contains a few additional adjustable parameters that need to be fitted to many sets of experimental data. Furthermore, this model concept was originally applied to systems (i.e., turbulent water jets, see e.g., Martínez-Bazán et al. [84, 85]; Rodríguez-Rodríguez et al. [110]; Eastwood et al. [23]) where the turbulent dissipation rates are 2–3 orders of magnitude larger than what are observed in bubble columns. The bubble sizes considered were also very small, up to about 1 (mm) only. On the other hand, after careful investigations of the turbulent breakage processes in bubble columns it may be possible to extend the application of this approach to bubble column systems. The experimental techniques developed investigating breakage of bubbles on the center-line within the fully developed region of turbulent water jets [23, 110] may initiate ideas on how to study these phenomena in bubble columns. The digital image-processing techniques used in these studies [23, 110] gives satisfactory results in very dilute two-phase flows, but the method is still questionable when the bubble concentration increases considerably as for bubble columns operated in the heterogeneous flow regime.

A severe drawback for the integrated two-fluid/population balance models is that all the kernels suggested in the literature are very sensitive to the turbulent energy dissipation rate ( $\varepsilon$ ). As mentioned earlier, the local  $\varepsilon$  variable is difficult to calculate from the  $k$ - $\varepsilon$  turbulence model since the equation for the dissipation rate merely represents a fit of a turbulent length scale to single phase pipe flow data. Therefore, further work is needed elucidating the mechanisms of bubble breakage in turbulent flows. However, an alternative to the eddy concept has been reported which may make the work on model validation easier. Perhaps the greatest advantages lies in the fact that this closure is formulated in the average microscopic modeling framework avoiding the limitations of the macro scale formulation. It is finally remarked that working with the macroscopic and average microscopic model formulations, care should be taken as the discrete breakage density ( $\Omega_B(d_i)$ ) is sometimes erroneously assumed equal to the breakage frequency  $b_B(b)$ .

#### 9.1.2.4 Number of Daughter Bubbles Produced, $\nu$

In the average microscopic formulations this parameter determines the average number of daughter bubbles produced by breakage of a parent bubble of size  $d$ . The breakage of parent bubbles into two daughter bubbles is assumed in most investigations reported ( $\nu = 2$ ).

In a recent paper Risso and Fabre [109] observed that the number of fragments depended on the specific shape of the parent bubble during the deformation process and varies in a wide range. In their experiments a video processing technique was used making studies of two groups of bubbles, one group being of sizes in the range between 2–6 mm and the other of sizes in the range 12.4–21.4 mm. Two fragments were obtained in 48 % of the cases, between 3 and 10 in 37 % of the cases, and more than 10 fragments in 15 % of the cases. The breakage process is certainly not purely binary. Implementing this effect instead of binary breakage is expected to significantly alter the number of smaller bubbles and the interfacial area concentration predicted by the population balance equation. The experimental data of Risso and Fabre [109] also indicate that an equal size daughter distribution is more common for bubble breakage than an unequal one. Contrary, Hesketh et al. [35, 36] investigated bubble breakage in turbulent flows in horizontal pipes and concluded that an unequal size daughter distribution is more probable than an equal size one. The daughter bubble size distribution model of Luo and Svendsen [80] rely on the assumption that unequal sized is more probable than equal size breakage in accordance with the observations by Hesketh et al., as will be discussed in the next section. The deviating experimental observations indicate that further experimental investigations are needed determining reliable correlations for what physical systems and under which flow conditions the equal- and unequal breakage outcomes occur.

#### 9.1.2.5 Daughter Particle Distribution, $P_B(d, \mathbf{r}; d', \mathbf{r}')$

Among the papers adopting the average microscopic formulation, two of the earliest models for the daughter particle size distribution were proposed by Valentas et al. [129, 130]. The daughter particle probability distribution functions suggested by Valentas et al. [129, 130] were purely statistical relations. The first was a discrete model, in which a parent particle of diameter  $d$  is assumed to split into equally sized daughter particles of diameter  $d/\nu$ , where  $\nu$  is the number of daughter particles formed. The second model proposed by Valentas et al. is a logical, continuous analogue of the discrete daughter particle pdf. In this case it is assumed that the daughter particle sizes are normally distributed about a mean value.

Ross and Curl [111], Coualaloglou and Travlarides [17] and Prince and Blanch [102] argued that the particle breakage frequency should be a function of the difference in surface energy between a parent particle and the daughter particles produced, and the kinetic energy of a colliding eddy. Although Ross and Curl [111], Coualaloglou and Travlarides [17] and Prince and Blanch [102] developed

more physical models for the particle breakage frequency, the daughter particle size distributions still relied upon statistical relations.

Among the most widely used phenomenological models based on surface energy considerations is the one proposed by Tsouris and Tavlarides [128]. Their expression for the daughter particle pdf yields:

$$P_B(d; d') = \frac{e_{\min} + [e_{\max} - e(d')]}{\int_{d_{\min}}^d e_{\min} + [e_{\max} - e(d')] dd'} \left( \frac{1}{[m]} \right) \quad (9.101)$$

Considering binary breakage only, Tsouris and Tavlarides [128] postulated that the probability of formation of a daughter particle of size  $d'$  is inversely proportional to the energy required to split a parent particle of size  $d$  into a particle of size  $d'$  and its complementary particle of size  $\tilde{d} = (d^3 - d'^3)^{1/3}$ . This energy requirement is proportional to the excess surface area generated by splitting the parent particle:

$$e(d') = \pi\sigma_I d'^2 + \pi\sigma_I \tilde{d}^2 - \pi\sigma_I d^2 = \pi\sigma_I d^2 \left[ \left( \frac{d'}{d} \right)^2 + \left[ 1 - \left( \frac{d'}{d} \right)^3 \right]^{2/3} - 1 \right] \quad (9.102)$$

To avoid the singularity present in their daughter size distribution model for  $d' = 0$  (i.e., the parent particle does not break), a minimum particle size was defined,  $d_{\min}$ . The excess surface area relation reaches a minimum value when a particle of minimum diameter,  $d_{\min}$ , and a complementary one of maximum size,  $d_{\max} = (d^3 - d_{\min}^3)^{1/3}$ , are formed. The minimum energy,  $e_{\min}$ , is given by:

$$e(d_{\min}) = \pi\sigma_I d^2 \left[ \left( \frac{d_{\min}}{d} \right)^2 + \left[ 1 - \left( \frac{d_{\min}}{d} \right)^3 \right]^{2/3} - 1 \right] \quad (9.103)$$

This gives a minimum probability for the formation of two particles of the same size, and a maximum probability for the formation of a pair made up of a very large particle and a complementary very small one. The maximum energy corresponding to the formation of two particles of equal volumes or of diameters  $d' = (d^3 - d'^3)^{1/3} = d/2^{1/3}$  is  $e_{\max} = \pi\sigma_I d^2 [2^{1/3} - 1]$ .

By substitution of the energy definitions, the daughter pdf is given by an expression that does not depend on the flow conditions:

$$P_B(d^*) = \frac{(d_{\min}^{*2} + (1 - d_{\min}^{*3})^{2/3} - 1) + 2^{1/3} - d^{*2} - (1 - d^{*3})^{2/3}}{\int_0^1 [(d_{\min}^{*2} + (1 - d_{\min}^{*3})^{2/3} - 1) + 2^{1/3} - d^{*2} - (1 - d^{*3})^{2/3}] dd^*} \quad (9.104)$$

However, this pdf does not preserve volume and does not satisfy the symmetry property as required from (9.71). On the other hand, the daughter–bubble pdf would

preserve volume and satisfy the symmetry property provided that it was expressed in terms of volume. Thus, a better form of the daughter–bubble pdf can be expressed in terms of volume [86]:

$$P_B(V^*) = \frac{(V_{\min}^{*\frac{2}{3}} + (1 - V_{\min}^*)^{\frac{2}{3}} - 1) + 2^{\frac{1}{3}} - V^{*\frac{2}{3}} - (1 - V^*)^{\frac{2}{3}}}{\int_0^1 [(V_{\min}^{*\frac{2}{3}} + (1 - V_{\min}^*)^{\frac{2}{3}} - 1) + 2^{\frac{1}{3}} - V^{*\frac{2}{3}} - (1 - V^*)^{\frac{2}{3}}] dV^*} \quad (9.105)$$

This daughter size distribution on volume form can be expressed in terms of diameter as:

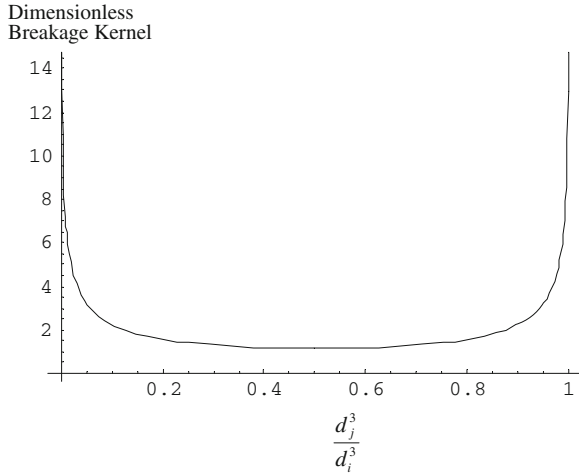

$$P_B(d^*) = \frac{(d_{\min}^{*2} + (1 - d_{\min}^{*3})^{\frac{2}{3}} - 1) + 2^{\frac{1}{3}} - d^{*2} - (1 - d^{*3})^{\frac{2}{3}}}{\int_0^1 [(d_{\min}^{*2} + (1 - d_{\min}^{*3})^{\frac{2}{3}} - 1) + 2^{\frac{1}{3}} - d^{*2} - (1 - d^{*3})^{\frac{2}{3}}] d^* dd^*} \quad (9.106)$$

Luo and Svendsen [80] derived a discrete expression for the breakage density of a particle of diameter  $d_i$  into two daughter particles of size  $d_j$  and  $(d_i^3 - d_j^3)^{1/3}$  respectively, using energy arguments similar to those employed by Tsouris and Tavlarides [128]. The significant difference between the Luo and Svendsen [80] model and its predecessors is that it gives both a partial breakage rate, that is, the breakage rate for a particle of size  $d_i$  splitting into a particle of size  $d_j$  and its complementary bubble, and an overall breakage rate. The previous surface energy models provided only an overall breakage rate. An expression for the daughter particle size distribution function can thus be calculated by normalizing the partial breakage rate by the overall breakage rate. As mentioned earlier, this variable was not required for the population balance closure but is rather a spin-off from the primary closures. The Luo and Svendsen daughter particle size distribution is thus determined from the expression:

$$P_B(d_i; d_j) = \frac{\Omega_B(d_i : d_j)}{\Omega_B(d_i)}(-) \quad (9.107)$$

In a similar way as the model of Tsouris and Tavlarides [128], the model of Luo and Svendsen [80] predicts that the probability of breaking a parent particle into a very small particle and a complementary large particle is larger than the probability of equal size breakage, Fig. 9.7. The distribution has a *U*-shape, with a minimum probability for the formation of two equally sized daughter particles and a maximum probability for the formation of a very large daughter particle and its complement  $d_{\min}$ . Moreover, it is noticed that the units of the discrete daughter bubble size distribution function probability are different from the units obtained deriving the continuous daughter size distribution function from the microscopic formulations ( $1/[m]$ ). Thus, it might not be trivial to adopt the macroscopic model of Luo [79]

**Fig. 9.7** A sketch of the breakage kernel of Luo and Svendsen [80]. An unequal daughter size distribution is predicted by this model. In this case the parent diameter size is,  $d_i = 0.006$  (m), and the turbulent energy dissipation rate is set at,  $\varepsilon = 1$  ( $\text{m}^2/\text{s}^3$ ). Reprinted with permission from [41]. Copyright 2005 American Chemical Society

within a more fundamental local modeling approach. On the other hand, the local specific rate of production of daughters of diameter  $d'$  by the breakage of particles with diameter  $d$  is related to the local breakage functions  $\nu(d)$ ,  $P_B(d, d')$  and  $b_B(d)$  as follows [90, 122]:

$$\Omega(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}, t) = \nu(d, \mathbf{r}, \mathbf{Y}, t) b_B(d, \mathbf{r}, \mathbf{Y}, t) P_B(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}, t) \quad (9.108)$$

From the  $P_B(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}, t)$  normalization properties, the breakage frequency can be determined as:

$$b_B(d, \mathbf{r}, \mathbf{Y}, t) = \frac{1}{\nu(d, \mathbf{r}, \mathbf{Y}, t)} \int_0^d \Omega(d, \mathbf{r}; d', \mathbf{r}, \mathbf{Y}, t) dd' \quad (9.109)$$

Although Hinze [38] and Risso and Fabre [109], among others, showed and discussed the diversity of shapes of the bubbles that can be found in turbulent flows, at present sufficient experimental data does not exist in the literature to assist in developing adequate daughter bubble probability density functions valid for bubble columns.

In an attempt to overcome the limitations found in the models for the daughter particle size distribution function described above based on the eddy collision concept, Martínez-Bazán et al. [85] proposed an alternative statistical model based on energy balance principles. The model was originally intended for the prediction of

air bubble breakage at the center-line of a high Reynolds number, turbulent water jet. It was assumed that when an air bubble is injected into the turbulent water jet, the velocity fluctuations of the underlying turbulence result in pressure deformation forces acting on the bubble's surface that, when greater than the confinement forces due to surface tension, will cause breakage. The model assumes that when a parent particle breaks, two daughter particles are formed ( $\nu = 2$ ) with diameters  $d'$  and  $(d^3 - d'^3)^{1/3}$ . The validity of this assumption is supported by high-speed video images, given by Martínez-Bazán et al. [85]. The diameters are related through the conservation of mass,  $(d^3 - d'^3)^{1/3} = d[1 - (d'/d)^3]^{1/3}$ . The particle-splitting process was not considered purely random, as the pressure fluctuations and thus the deformation stress ( $\sigma_t$ ) in homogeneous and isotropic turbulence are not uniformly distributed over all scales. It was further assumed that there is a minimum distance,  $d_{\min}$ , over which the turbulent stresses acting between two points separated by this distance,  $\frac{1}{2}\rho_c C(\varepsilon d_{\min})^{2/3}$ , are just equal to the confinement pressure due to surface tension:  $\sigma_t(d_{\min}) = \sigma_s(d)$ . In other words, at this distance, the turbulent pressure fluctuations are exactly equal to the confinement forces for a parent particle of size  $d$ . The probability of breaking off a daughter particle with  $d' < d'_{\min} = (\frac{12\sigma_t}{C\rho_c d})^{3/2}\varepsilon^{-1}$  should therefore be zero. The fundamental postulate of the Martínez-Bazán et al. [85] model is that the probability of splitting off a daughter particle of any size such that  $d'_{\min} < d' < d$  is proportional to the difference between the turbulent stresses over a length  $d'$  and the confinement forces holding the parent particle of size  $d$  together. For the formation of a daughter particle of size  $d'$ , the difference in stresses is given by  $\Delta\sigma_{t,d'} = \frac{1}{2}\rho_c C(\varepsilon d')^{2/3} - 6\sigma_t/d$ . For each daughter particle of size  $d'$ , a complementary daughter particle of size  $(d^3 - d'^3)^{1/3}$  is formed with a difference of stresses given by  $\Delta\sigma_{t,(d^3-d'^3)^{1/3}} = \frac{1}{2}\rho_c C(\varepsilon(d^3 - d'^3)^{1/3})^{2/3} - 6\sigma_t/d$ . The model states that the probability of forming a pair of complementary daughter particles of size  $d'$  and  $(d^3 - d'^3)^{1/3}$  from splitting a parent particle of size  $d$  is related to the product of the excess stresses associated with the length scales corresponding to each daughter particle size. That is,

$$P_B(d'/d) \propto [\frac{1}{2}\rho_c C(\varepsilon d')^{2/3} - 6\sigma_t/d][\frac{1}{2}\rho_c C(\varepsilon(d^3 - d'^3)^{1/3})^{2/3} - 6\sigma_t/d]. \quad (9.110)$$

Relating  $d'$  and  $(d^3 - d'^3)^{1/3}$  through the mass balance given above yields:

$$P_B(d'/d) \propto (\frac{1}{2}\rho_c C(\varepsilon d)^{2/3})^2 [(d'/d)^{2/3} - (d_c/d)^{5/3}][(1 - (d'/d)^3)^{2/9} - (d_c/d)^{5/3}] \quad (9.111)$$

or

$$P_B(d^*) \propto (\frac{1}{2}\rho_c C(\varepsilon d)^{2/3})^2 [d^{*2/3} - \Lambda^{5/3}][(1 - d^{*3})^{2/9} - \Lambda^{5/3}] \quad (9.112)$$

where  $\Lambda = d_c/d$ ,  $d_c$  is the critical diameter defined as  $d_c = (\frac{12\sigma_t}{C\rho_c})^{3/5}\varepsilon^{-2/5}$ .

The critical parent particle diameter defines the minimum particle size for a given dissipation rate of turbulent kinetic energy for which breakage can occur. The minimum daughter diameter defines the distance over which the turbulent normal stresses just balance the confinement forces of a parent particle of size  $d$ . The minimum diameter, therefore, gives the minimum length over which the underlying turbulence can pinch off a piece of the parent particle. This length is not arbitrarily selected, rather, its determination is based on kinematics. This model further assumes that the size of the parent particles is in the inertial subrange of turbulence. Therefore, it implies that  $d_{\min} \leq d' \leq d_{\max}$  provided that  $d_{\min} > \lambda_d$ , where  $\lambda_d$  is the Kolmogorov length scale of the underlying turbulence. Otherwise,  $d_{\min}$  is taken to be equal to  $\lambda_d$ . However, no assumption needs to be made about the minimum and maximum turbulent length scales that can cause particle breakage. All turbulent length scales between the Kolmogorov scale and the integral scale are taken into account.

The daughter particle probability density function can be obtained from the probability expression given above by utilizing the normalization condition:  $\int_{d_{\min}^*}^{d_{\max}^*} P(d^*) d(d^*) = 1$ . The pdf of the ratio of diameters  $d^* = d'/d$ ,  $P_B^*(d^*)$ , can then be written as:

$$P_B^*(d^*) = \frac{[d^{*2/3} - \Lambda^{5/3}][(1 - d^{*3})^{2/9} - \Lambda^{5/3}]}{\int_{d_{\min}^*}^{d_{\max}^*} [d^{*2/3} - \Lambda^{5/3}][(1 - d^{*3})^{2/9} - \Lambda^{5/3}] d(d^*)} (-) \quad (9.113)$$

Note that  $P_B(d'|d) = P_B^*(d^*)/d$ ,  $\Lambda = d_c/d = (d_{\min}/d)^{2/5}$ .

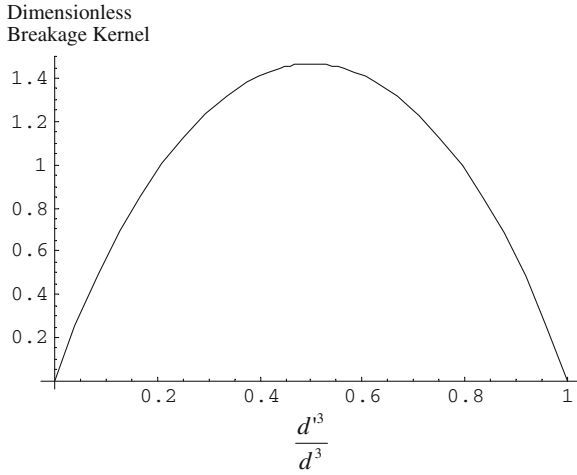

About a decade later Martínez-Bazán et al. [86] criticized their predecessor daughter distribution model for not being volume conservative. A detailed analysis of the model shows that the final normalization step implies that the probability density function (9.113) does not conserve volume. They revealed that the model derivation, the probability function was erroneously expressed as a function of  $d^*$  rather than in terms of volume  $V(d^*)$ , thus the correct way to express this relation is:

$$P_{B,V}(V^*) \propto \left(\frac{1}{2}\rho_c C(\varepsilon d)^{2/3}\right)^2 [V^{*2/9} - \Lambda^{5/3}][(1 - V^*)^{2/9} - \Lambda^{5/3}] \quad (9.114)$$

where  $V^* = V(d')/V(d)$  is the dimensionless volume of the product bubble.

Applying the normalization condition  $\int_0^1 P_V(V^*) dV^* = 1$ , which conserves volume the pdf can be written as:

$$P_{B,V}^*(V^*) = \frac{[V^{*2/9} - \Lambda^{5/3}][(1 - V^*)^{2/9} - \Lambda^{5/3}]}{\int_{V_{\min}^*}^{V_{\max}^*} [V^{*2/9} - \Lambda^{5/3}][(1 - V^*)^{2/9} - \Lambda^{5/3}] dV^*} (-) \quad (9.115)$$

**Fig. 9.8** A sketch of the breakage kernel of Konno et al. [46]. An equal daughter size distribution is predicted by this model. The kernel by Martínez-Bazán et al. [85] is quite similar to this one, but the shape of the profile is a little different close to the minimum and maximum  $d^*/d^3$  values. Reprinted with permission from [41]. Copyright 2005 American Chemical Society

This pdf in terms of volume can be transformed into a pdf in terms of diameter using the condition  $P_{B,V}^*(V^*)dV^* = P_B^*(d^*)d(d^*)$ , with  $V^* = d^{*3}$  and thus  $dV^* = 3d^{*2}d(d^*)$ , hence  $P_{B,V}^*(V^*)3d^{*2} = P_B^*(d^*)$ . The volume conserving expression for  $P_B^*(d^*)$  can be expressed as:

$$P_B^*(d^*) = \frac{d^{*2}[d^{*2/3} - \Lambda^{5/3}][(1 - d^{*3})^{2/9} - \Lambda^{5/3}]}{\int_{d_{\min}^*}^{d_{\max}^*} d^{*2}[d^{*2/3} - \Lambda^{5/3}][(1 - d^{*3})^{2/9} - \Lambda^{5/3}]d(d^*)} (-) \quad (9.116)$$

which differs from the original equation (9.113) in the  $d^{*2}$  factor.

Contrary to the collision based phenomenological models for the daughter particle size distribution, this model predicts a symmetric distribution with the highest probability for equal size particle breakage in accordance with the pure statistical model of Konno et al. [46], Fig. 9.8.

In general, purely statistical models for the daughter particle size distribution lack physical support. As for the breakage frequency models, the existing daughter particle size models based on the eddy collision arguments rely on the assumption that turbulence consists of a collection of eddies that can be treated using relationships from the kinetic theory of gases. Martínez-Bazán et al. [85], on the other hand, made a first approach developing an average microscopic kinematic/statistical model, where the physics were included through a daughter size distribution function expressed based on kinematic arguments. Alternatively, one may develop kinematic/statistical

models where an effective daughter size distribution function represents an average of a large number of simulations of the physical breakage phenomena for a series of operating conditions. The deviating experimental observations reported in the literature indicate that further experimental investigations are needed determining reliable correlations for which physical systems and under which flow conditions the equal- and unequal breakage outcomes occur.

### 9.1.3 Statistical Microscopic Population Balance Formulation

A statistical description of multiphase flow might be developed based on an analogy to the Boltzmann theory of gases [11, 39, 60, 63, 66, 91, 125, 135]. The fundamental variable is the particle distribution function with an appropriate choice of internal coordinates relevant for the particular problem in question. Most of the multiphase flow modeling work performed so far has focused on isothermal, non-reactive mono-disperse mixtures. However, in chemical reactor engineering the industrial interest lies in multiphase reactive flow systems that include poly-dispersed mixtures of multiple particle types, with their associated effects of mixing, segregation and heat and mass transfer.

The statistical multiphase modeling framework may be outlined as follows. Defining a single distribution function,  $p(\mathbf{x}, \mathbf{r}, \mathbf{c}, t)d\mathbf{x}d\mathbf{r}d\mathbf{c}$ , as the probable number of particles with internal coordinates in the range  $d\mathbf{x}$  about  $\mathbf{x}$ , located in the spatial range  $d\mathbf{r}$  about the position  $\mathbf{r}$ , with a velocity range  $d\mathbf{c}$  about  $\mathbf{c}$ , at time  $t$ . A Boltzmann-type equation can be written to describe the temporal and spatial rate of change of the single distribution function,  $p$ :

$$\frac{\partial p}{\partial t} + \nabla_{\mathbf{r}} \cdot (\mathbf{c}p) + \nabla_{\mathbf{c}} \cdot (\mathbf{F}p) = -\nabla_{\mathbf{x}} \cdot \left( \frac{d\mathbf{x}(t)}{dt} p \right) + B'_B - D'_B + B'_C - D'_C + S' \quad (9.117)$$

where the rates of change of  $p$  with time due to breakage and coalescence are denoted by  $B'_B - D'_B + B'_C - D'_C$  with units  $(1/[\mathbf{x}][\mathbf{r}]\text{m s}^{-1})$ . The force per unit mass acting on a particle is denoted by  $\mathbf{F}$ , and the rate of change with time of its internal coordinates is given by:  $\mathbf{v}_x$ .  $S'$  represents the rate of change of the distribution function caused by collisions which do not result in coalescence (i.e., rebound).

Integrating over the whole particle velocity space to eliminate the particle velocity dependence, one obtains the following equation:

$$\frac{\partial f}{\partial t} + \nabla_{\mathbf{r}} \cdot (\mathbf{v}_r f) = -\nabla_{\mathbf{x}} \cdot (\mathbf{v}_x f) + B_B - D_B + B_C - D_C \left( \frac{1}{[\mathbf{x}][\mathbf{r}]s} \right) \quad (9.118)$$

where

$$f(\mathbf{x}, \mathbf{r}, t) = \int_{-\infty}^{\infty} p d\mathbf{c}. \quad (9.119)$$

The single distribution function  $f(\mathbf{x}, \mathbf{r}, t)d\mathbf{x}d\mathbf{r}$  thus denotes the probable number of particles within the internal coordinate space in the range  $d\mathbf{x}$  about  $\mathbf{x}$ , in the external (spatial) range  $d\mathbf{r}$  about  $\mathbf{r}$  at time  $t$ .  $\mathbf{v}_r$  is the mean velocity of all particles of properties  $\mathbf{x}$  at a location  $\mathbf{r}$  at time  $t$ . The velocity independent birth and death terms are defined by:

$$B_B - D_B + B_C - D_C = \int_{-\infty}^{\infty} (B'_B - D'_B + B'_C - D'_C) d\mathbf{c}. \quad (9.120)$$

Integrating the force term over the whole velocity space no net contribution appears explicitly in the population balance equation since the distribution function vanishes as the velocity approaches  $\pm\infty$ . Furthermore, the  $S'$ -term vanishes in the average equation as the number of particles is conserved during the rebound processes. Note, however, that the two last mentioned terms have direct effects on the size distribution as an consistent multi-fluid model developed from the Boltzmann equation (i.e., a granular model based on the population balance distribution function) would contain additional momentum transfer terms due to particle bouncing (e.g., a particle pressure contribution) and particle interactions with the wake of proceeding bubbles. These phenomena may also affect the coalescence and breakage processes, and may be accounted for by the corresponding closure laws. To close the population balance problem, models are required for the growth, birth and death kernels. In the kinetic theory context, as distinct from the continuum mechanical approach, the continuum closure may be considered macroscopic in a similar manner as in the granular theory treating macroscopic particle properties.

### 9.1.3.1 Using Particle Diameter as Inner Coordinate

For non-reactive, isothermal, particle mixtures it is customary to assume that all the relevant internal variables can be calculated in some way from the particle volume or diameter. It is natural to use the particle diameter as inner coordinate for the population balance analysis because this choice of inner coordinate coincides with the classical kinetic theory of gases. This inner coordinate is especially useful describing solid particle and fluid particle dispersions. A statistical description of dispersed multiphase flow can then be obtained by means of a distribution function  $f_{d_p}(d_p, \mathbf{r}, t)$ , defined so that the number of particles with diameters in the range  $d_p$  and  $d_p + d(d_p)$ , located in a volume  $d\mathbf{r}$  around a spatial location  $\mathbf{r}$  at time  $t$  is  $f(d_p, \mathbf{r}, t)d(d_p)d\mathbf{r}$ . In this case the population balance (9.118) is usually expressed as:

$$\frac{\partial f}{\partial t} + \nabla_{\mathbf{r}} \cdot (\mathbf{v}f) = -\frac{\partial(v_d f)}{\partial d_p} + B_B - D_B + B_C - D_C \left( \frac{1}{[\mathbf{m}][\mathbf{r}]s} \right) \quad (9.121)$$

where  $v_d$  is a particle growth rate (m/s).

To close the population balance problem, models are required for the growth, birth and death kernels. It is required that these kernels are consistent with the inner coordinate used. The coalescence and breakage kernels presented in this chapter are expressed in terms of the particle diameter.

### 9.1.3.2 Using Particle Mass as Inner Coordinate

For flows where compressibility effects in a gas are important the use of the particle mass as internal coordinate may be advantageous because this quantity is conserved under pressure changes [11]. In this approach it is assumed that all the relevant internal variables can be derived from the particle mass, so the particle number distribution is described by the particle mass, position and time. Under these conditions, the dispersed phase flow fields are characterized by a single distribution function  $f(m, \mathbf{r}, t)$  such that  $f(m, \mathbf{r}, t)d\mathbf{r}dm$  is the number of particles with mass between  $m$  and  $m + dm$ , at time  $t$  and within  $d\mathbf{r}$  of position  $\mathbf{r}$ . Notice that the use of particle diameter and particle mass as inner coordinates give rise to equivalent population balance formulations in the case of describing incompressible fluids. By taking the mass moments of the distribution function we define the following important multiphase flow parameters.

The particle number density:

$$N(\mathbf{r}, t) = \int_0^\infty f(m, \mathbf{r}, t)dm; \quad (9.122)$$

The interfacial area density is defined as:

$$a(\mathbf{r}, t) = \int_0^\infty a(m, \mathbf{r})f(m, \mathbf{r}, t)dm; \quad (9.123)$$

where  $a(m, \mathbf{r})$  is the interfacial area of a particle having mass  $m$  located at position  $\mathbf{r}$ .

The particle mass density is defined as:

$$\rho_p^m(\mathbf{r}, t) = \rho_p(\mathbf{r}, t)\alpha_p(\mathbf{r}, t) = \int_0^\infty mf(m, \mathbf{r}, t)dm. \quad (9.124)$$

The dispersed phase volume fraction is related to the mass density by:

$$\alpha_p(\mathbf{r}, t) = \frac{\rho_p^m(\mathbf{r}, t)}{\rho_p(\mathbf{r}, t)} = \frac{\rho_p(\mathbf{r}, t)\alpha_p(\mathbf{r}, t)}{\rho_p(\mathbf{r}, t)} \quad (9.125)$$

where  $\rho_p(\mathbf{r}, t)$  is the local particle density which includes the effects of local pressure.

Assuming that the particle velocity for a given size is known,  $\mathbf{v} = \mathbf{v}(m, \mathbf{r}, t)$ , one may express a Boltzmann type of transport equation for the single distribution function:

$$\begin{aligned} \frac{\partial f(m, \mathbf{r}, t)}{\partial t} + \nabla_{\mathbf{r}} \cdot [\mathbf{v}_r(m, \mathbf{r}, t)f(m, \mathbf{r}, t)] + \frac{\partial}{\partial m} \left[ \frac{dm(t)}{dt} f(m, \mathbf{r}, t) \right] \\ = B_B(m, \mathbf{r}, t) - D_B(m, \mathbf{r}, t) + B_C(m, \mathbf{r}, t) - D_C(m, \mathbf{r}, t) \left( \frac{1}{[\text{kg}] \text{m}^3 \text{s}} \right) \end{aligned} \quad (9.126)$$

where  $B_B(m, \mathbf{r}, t)$ ,  $D_B(m, \mathbf{r}, t)$ ,  $B_C(m, \mathbf{r}, t)$  and  $D_C(m, \mathbf{r}, t)$  are the corresponding birth and death terms due to particle breakage and coalescence. The third term on the left hand side is related to the mass change of the particle that is caused by condensation, evaporation or dissolution.

Considering binary interactions only, as were assumed in the previous section, the particle breakage terms can be written as:

$$B_B(m, \mathbf{r}, t) = \int_m^\infty b(m, m''; m') f(m', \mathbf{r}, t) dm' = \int_m^\infty b(m, m' - m; m') f(m', \mathbf{r}, t) dm' \quad (9.127)$$

$$D_B(m, \mathbf{r}, t) = \int_0^m b(m, m''; m') f(m, \mathbf{r}, t) dm' = \int_0^m b(m, m' - m; m') f(m, \mathbf{r}, t) dm' \quad (9.128)$$

where  $b(m, m''; m')$  is the breakage frequency and represents the probability per unit time and mass that a particle of mass  $m'$  splits creating a particle of mass  $m''$  and a particle of mass  $m$ . As no mass is lost or gained in the breakage (and coalescence) processes, we have used the mass conservation principle  $m' = m'' + m$  to rewrite the particle breakage terms.

The corresponding coalescence terms yield:

$$B_C(m, \mathbf{r}, t) = \frac{1}{2} \int_0^m \omega_C(m - m'; m') p_C(m - m', m', \mathbf{r}, t) dm' \quad (9.129)$$

$$D_B(m, \mathbf{r}, t) = \int_0^\infty \omega_C(m', m) p_C(m, m', \mathbf{r}, t) dm' \quad (9.130)$$

where  $\omega_C$  denotes the collision density (i.e., probability per unit time) between bubbles of mass  $m'$  and  $m$ , and  $p_C$  is the coalescence probability denoting the probability of coalescence if a collision occurs. As for the breakage terms, the mass conservation principle  $m' = m'' + m$  has been implemented to rewrite the fluid particle coalescence terms.

The particles can change their mass if sublimation, condensation or evaporation occurs, or if mass is lost or gained due to interfacial mass transfer (mass diffusion and convection). The interfacial mass transfer rate can be represented by use of the simple film model and expressed in terms of a mass transfer coefficient:

$$N \frac{dm_i(t)}{dt} = k_i a (\rho_i - \rho_i^*) \left( \frac{\text{kg}}{\text{m}^3 \text{ s}} \right) \quad (9.131)$$

where  $k_i$  denotes the mass transfer coefficient (m/s),  $a$  denotes the interfacial area ( $\text{m}^2/\text{m}^3$ ),  $\rho_i$  denotes the mass density of component  $i$  in the bulk of the phase, and  $\rho_i^*$  denotes the mass density of component  $i$  at the interface (i.e., for fluid particles it denotes the equilibrium mass density), and  $N$  denotes the local bubble number density.

The growth term can thus be approximated as:

$$\frac{\partial}{\partial m} \left[ \frac{dm}{dt} f(m, \mathbf{r}, t) \right] = \frac{1}{N} \frac{\partial}{\partial m} \left[ \sum_i k_i a (\rho_i - \rho_i^*) f(m, \mathbf{r}, t) \right]. \quad (9.132)$$

### 9.1.3.3 Using Multiple Inner Coordinates

For non-isothermal, reactive multi-component mixtures more advanced definitions of the distribution function is required. Adopting a kinetic theory modeling framework the dispersed particle phases might be separated on the basis of their physical properties (diameter, density, viscosity) or through their thermo-chemical properties (reactive versus inert particles). From Chap. 4 we reiterate that to enable the description of segregation effects a multi-fluid approach is required where the macroscopic balance equations are derived from the kinetic theory of granular flow using inelastic rigid-sphere models, thereby accounting for collisional transfer in high-density regions. Separate transport equations are constructed for each of the particle phases, as well as for the equilibration processes whereby momentum and energy are exchanged between the respective particle phases and the carrier fluid. Aimed at high-density suspensions, such as fluidized bed reactors, the relations obtained for the stress tensor are augmented by a model for frictional transfer, suitably extended to poly-dispersed systems. For reactive chemical processes the model are further extended to include heat and mass transfer, as well as chemical reactions.

To describe a chemical process in a fluid bed reactor Lathouwers and Bellan [63] introduced an extended form of the single-particle distribution function of particle phase  $i$  such that  $p_i^{(1)}(m, \mathbf{r}, \mathbf{c}, \omega_c, T, t)$  is the probable number of particles having their center of mass in the region  $\mathbf{r}, \mathbf{r} + d\mathbf{r}$ , a velocity in the region  $\mathbf{c}, \mathbf{c} + d\mathbf{c}$ , mass in the region  $m, m + dm$ , mass fractions in  $\omega_c, \omega_c + d\omega_c$ , temperature in  $T, T + dT$ , at time  $t$ . A combined multifluid-population balance model for reactive flows might be derived following the kinetic theory concepts. Maxwellian average of the resulting model equations over the whole velocity space gives a model that resolves the internal coordinates and thus the particle size, species mass concentrations and temperature. Ongoing research continues to elucidate this modeling approach.

### 9.1.4 Moment Transformation of the Population Balance Equation

Considering a reduced form of the population balance equation with particle size  $\xi$  as the only internal coordinate or property. The  $j$ -th moment of the population density function can be defined as [106]:

$$\mu_j(\mathbf{r}, t) = \int_0^{\infty} \xi^j f(\mathbf{r}, \xi, t) d\xi \quad (9.133)$$

The PBE can thus be reduced to a set of PDEs by multiplying with  $\xi^j d\xi$  and integrating over the whole particle size distribution [106]:

$$\int_0^{\infty} \left[ \frac{\partial f}{\partial t} + \nabla_r \cdot (\mathbf{v}_r f) + \frac{\partial}{\partial \xi} (v_{\xi} f) + D_C - B_C + D_B - B_B \right] \xi^j d\xi = 0 \quad (9.134)$$

for  $j = 1, 2, \dots$

Introducing the moment definition, the PBE can be expressed in terms of moments:

$$\frac{\partial \mu_j}{\partial t} + \int_0^{\infty} \nabla_r \cdot (\mathbf{v}_r f) \xi^j d\xi + \int_0^{\infty} \frac{\partial}{\partial \xi} (v_{\xi} f) \xi^j d\xi = \int_0^{\infty} [-D_C + B_C - D_B + B_B] \xi^j d\xi \quad (9.135)$$

for  $j = 1, 2, \dots$

Reversing the order of integration and differentiation gives the first two terms in the PBE as:

$$\int_0^{\infty} \left[ \frac{\partial f}{\partial t} + \nabla_r \cdot (\mathbf{v}_r f) \right] \xi^j d\xi = \frac{\partial}{\partial t} \int_0^{\infty} \xi^j f d\xi + \nabla_r \cdot \int_0^{\infty} \mathbf{v}_r f \xi^j d\xi \quad (9.136)$$

Assuming that the external convective velocity in physical space is independent of the property coordinate (e.g., particle size), the convective term takes a simpler form:

$$\begin{aligned} \int_0^{\infty} \left[ \frac{\partial f}{\partial t} + \nabla_r \cdot (\mathbf{v}_r f) \right] \xi^j d\xi &= \frac{\partial}{\partial t} \int_0^{\infty} \xi^j f d\xi + \nabla_r \cdot \mathbf{v}_r \int_0^{\infty} f \xi^j d\xi \\ &= \frac{\partial \mu_j}{\partial t} + \nabla_r \cdot (\mathbf{v}_r \mu_j) \end{aligned} \quad (9.137)$$

It is recommended to adopt the fundamental form of the convection term for most dispersed flows as the velocity  $\mathbf{v}_r(\mathbf{r}, \xi, t)$  is generally a complex function of the inner coordinate.

The third term on the RHS of the PBE represents the growth term which can be integrated by parts to give:

$$\begin{aligned} \int_0^\infty \frac{\partial}{\partial \xi} (v_\xi f) \xi^j d\xi &= v_\xi f \xi^j \Big|_0^\infty - \int_0^\infty v_\xi(\xi) j \xi^{j-1} f d\xi \\ &= -v_\xi(0) f(\mathbf{r}, \xi=0, t) 0^j - \int_0^\infty v_\xi(\xi) j \xi^{j-1} f d\xi \end{aligned} \quad (9.138)$$

for  $j = 1, 2, \dots$ . The first term on the RHS corresponds to the nucleation rate in crystallization engineering. The term at the maximum boundary vanishes because the number distribution function  $f$  is assumed to approach zero at the maximum and minimum boundaries. The second term on the RHS of the growth relation is more difficult to integrate.

However, in the particular cases in which the size dependency can be neglected the term can easily be integrated as:

$$\int_0^\infty v_\xi(\xi) j \xi^{j-1} f d\xi \approx v_\xi j \int_0^\infty \xi^{j-1} f d\xi = v_\xi j \mu_{j-1} \quad (9.139)$$

Similarly, in crystallization the growth velocity is sometimes assumed to be a linear function of size [39]. In these cases the growth term can be approximated as:

$$\begin{aligned} \int_0^\infty v_\xi(\xi) j \xi^{j-1} f d\xi &= aj \int_0^\infty \xi^{j-1} f d\xi + bj \int_0^\infty \xi^j f d\xi \\ &= j(a\mu_{j-1} + b\mu_j) \end{aligned} \quad (9.140)$$

It is recommended to keep the fundamental form of this term as the growth velocity can generally be a complex function of the inner coordinates.

In general, the birth and death terms are given in terms of the distribution function,  $f$ , as well as the independent coordinates  $\mathbf{r}$  and  $\xi$  as shown in (9.87)–(9.90). The moment form of the birth and death terms can be expressed as [14, 25, 75, 81, 82]:

$$\begin{aligned}
\langle B_{B,j}(\mathbf{r}, t) \rangle &= \int_0^\infty B_B(\xi, \mathbf{r}, t) \xi^j d\xi \\
&= \int_0^\infty \int_0^\infty \nu(\xi', \mathbf{r}) b_B(\xi', \mathbf{r}) P_B(\xi, \mathbf{r}; \xi') f'^{(1)}(\xi', \mathbf{r}, t) d\xi' d\xi
\end{aligned} \tag{9.141}$$

$$\langle D_{B,j}(\mathbf{r}, t) \rangle_j = \int_0^\infty D_B(\xi, \mathbf{r}, t) \xi^j d\xi = \int_0^\infty \xi^j b_B(\xi, \mathbf{r}) f^{(1)}(\xi, \mathbf{r}, t) d\xi, \tag{9.142}$$

$$\begin{aligned}
\langle B_{C,j}(\mathbf{r}, t) \rangle_j &= \int_0^\infty B_C(\xi, \mathbf{r}, t) \xi^j d\xi \\
&= \int_0^\infty \frac{\xi^2 \xi^j}{2} \int_0^\infty \frac{\kappa_C((\xi^3 - \xi'^3)^{\frac{2}{3}}; \xi') \tilde{f}^{(1)}((\xi^3 - \xi'^3)^{\frac{1}{3}}, \mathbf{r}, t) f'^{(1)}(\xi', \mathbf{r}, t) d\xi' d\xi}{(\xi^3 - \xi'^3)^{\frac{2}{3}}} \\
&= \frac{1}{2} \int_0^\infty f'^{(1)}(\xi', \mathbf{r}, t) \int_0^\infty \kappa_C(\tilde{\xi}, \mathbf{r}; \xi') (\tilde{\xi}^3 + \xi'^3)^{j/3} \tilde{f}^{(1)}(\tilde{\xi}, \mathbf{r}, t) d\tilde{\xi} d\xi',
\end{aligned} \tag{9.143}$$

$$\begin{aligned}
\langle D_{C,j}(\mathbf{r}, t) \rangle_j &= \int_0^\infty D_C(\xi, \mathbf{r}, t) \xi^j d\xi \\
&= \int_0^\infty \xi^j f^{(1)}(\xi, \mathbf{r}, t) \int_0^\infty \kappa_C(\xi, \mathbf{r}; \xi') f'^{(1)}(\xi', \mathbf{r}, t) d\xi' d\xi
\end{aligned} \tag{9.144}$$

in which the Jacobian determinant used in (9.143) to change the integration variable is defined as  $d\tilde{\xi} = \xi^2/\xi' d\xi$ .

For convenience, the  $\langle B_C(\mathbf{r}, t) \rangle$  term can be manipulated by reversing the order of integration and introducing the size of the third particle in a coalescence event, thus  $\xi^3 = \tilde{\xi}^3 + \xi'^3$ . It follows that:  $\xi^j = (\tilde{\xi}^3 + \xi'^3)^{j/3}$ .

The moment transformation of the PBE for one inner coordinate, can thus be expressed as:

$$\begin{aligned}
\frac{\partial \mu_j(\mathbf{r}, t)}{\partial t} + \nabla_r \cdot \int_0^\infty (\mathbf{v}_r(\mathbf{r}, \xi, t) f(\mathbf{r}, \xi, t)) \xi^j d\xi \\
= v_\xi(\mathbf{r}, \xi = 0, t) f(\mathbf{r}, \xi = 0, t) j + \int_0^\infty v_\xi(\mathbf{r}, \xi, t) j \xi^{j-1} f(\mathbf{r}, \xi, t) d\xi \\
+ \langle B_C(\mathbf{r}, t) \rangle - \langle D_C(\mathbf{r}, t) \rangle + \langle B_B(\mathbf{r}, t) \rangle - \langle D_B(\mathbf{r}, t) \rangle
\end{aligned} \tag{9.145}$$

for  $j = 1, 2, \dots$ . The fundamental moment forms of the birth and death terms are given by (9.141)–(9.144). The level of simplification that can be applied in the model formulations is of course problem dependent. A few typical simplifying approximations sometimes used have been outlined in this subsection.

Suitable initial and boundary conditions must be specified. A typical initial condition may be specified on the general form:

$$\mu_j(\mathbf{r}, t = 0) = \hat{\mu}_j(\mathbf{r}), \quad \text{for } j = 1, 2, \dots \quad (9.146)$$

The boundary conditions are generally problem dependent, normally on the Dirichlet, Neumann or mixed forms.

The moments form of the PBE is of the same dimensionality as the local fluid mechanical transport equations and can be solved side by side with the equations of continuity, momentum and energy transport to yield a complete mathematical description of the dispersion process [106]. However, the moment form of the PBE corresponds to an average macroscopic form of the PBE thus the microscopic phenomena are not resolved. Thus, for systems where the microscopic phenomena are important, it might be useful to choose a more fundamental modeling framework.

## Chapter 10

# Fluidized Bed Reactors

In this chapter the characteristics of fluidized gas–solid suspensions are described, and the basic designs of fluidized bed reactors are sketched. Several modeling approaches that have been applied to describe these units are outlined. The term *fluidization* has been used in the literature to refer to dense-phase and lean-phase systems, as well as circulation systems involving fast fluidization, pneumatic transport or moving beds [35, 48]. The broad field of fluidization engineering thus deals with all these modes of contacting, but the two major groups of fluidized bed reactors are the dense phase and lean-phase reactors. Among the dense phase reactors, the bubbling bed reactor design is most common. The lean-phase flow regimes are employed in circulating bed reactors. The first industrial applications of the fluidized bed technology considered gasification of coal and the chemical fluid catalytic cracking (FCC) process. Today, the FCC process and circulating fluidized bed combustion (CFBC) are the major technologies for circulating fluidized beds. Moving packed beds normally consist of a stack of catalyst particles inside a tube thus resembling a fixed bed. In a moving packed bed reactor, as distinct from fixed bed, the gravity force is generally utilized to shift the catalyst from top to bottom. However, other arrangements like upwards, horizontal and inclined beds exist as well. Therefore, the moving bed reactors have many of the same properties as fixed beds, but allow continuous regeneration of deactivated catalyst and lower pressure drop. Large scale operations of moving beds can thus be employed for rapidly deactivated catalysts [48]. Temperature gradients caused by extreme exothermic/endothermic reactions can also be minimized with appropriate solid circulation. Nevertheless, very little is known about the hydrodynamics, mixing, and transport characteristics of moving bed reactors. Moving beds are thus not considered further in this book.

## 10.1 Solids Classification

When gas is passed through a bed of solid particles, various types of flow regime are observed. Operating conditions, solid flux, gas flux and system configuration and the solid particle properties (e.g., mean size, size distribution, shape, density, and restitution coefficient) are factors that affect the prevailing flow regime. Geldart [30] investigated the behavior of solid particles of various sizes and densities fluidized by gases. From this study a four group classification of solids was proposed to categorize the bed behavior based on particle density and particle size:

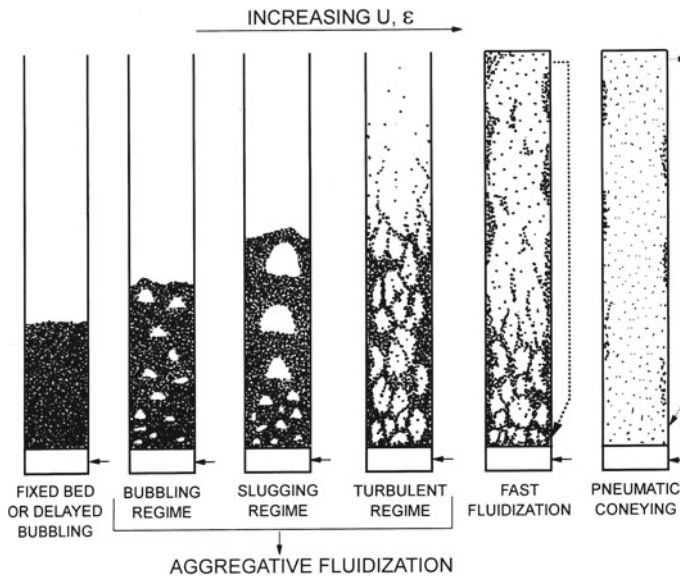

- *Group A*: Solid particles having a small mean size  $30 < d_p < 100 \mu\text{m}$  [31, 84] and/or low particle density  $\leq 1.4 \text{ g/cm}^3$ . These solids fluidize easily, with smooth fluidization at low gas velocities and bubbling/turbulent fluidization at higher gas velocities. Typical examples of this class of solid particles are catalysts used for fluid catalytic cracking (FCC) processes.
- *Group B*: Most solid particles of mean size  $100 \mu\text{m} < d_p < 800 \mu\text{m}$  [31] and density in the range  $1.4 \text{ g/cm}^3 < \rho_s < 4 \text{ g/cm}^3$ . These solids fluidize vigorously with formation of bubbles that may grow in size. Sand particles are representative for this group of solids.
- *Group C*: This class of solids includes very fine and cohesive powders. For most cases  $d_p < \sim 20 \mu\text{m}$  [31]. With these particles normal fluidation is extremely difficult because inter-particle forces are greater than those resulting from the action of gas. Cement, face powder, flour, and starch are representative for this group of solids.
- *Group D*: These solid particles are large  $d_p > \sim 1 \text{ mm}$  [31] and/or dense, and spoutable. Large exploding bubbles or severe channeling may occur in fluidization of this type of solids. Drying grains and peas, roasting coffee beans, gasifying coals, and some roasting metal ores are representative for these solids.

Apart from density and particle size, several other solid properties, including angularity, surface roughness and composition may also significantly affect the quality of fluidization. However, in many cases Geldart's classification chart is still a useful starting point to examine fluidization quality of a specific gas–solid system.

## 10.2 Fluidization Regimes for Gas–Solid Suspension Flow

Most gas–solid systems experience a range of flow regimes as the gas velocity is increased. Several important gas–solid fluidization regimes for the chemical process industry are sketched in Fig. 10.1. In dense fluidized beds regions of low solid density may be created. These gas pockets or voids are frequently referred to as bubbles.

Each of the fluidization regimes has characteristic solids concentration profiles. A plot of the profile showing the solids concentration versus the height above the distributor for the bubbling bed regime of fluidization takes a pronounced s-shape.

**Fig. 10.1** The primary gas–solid flow-regimes [31, 37]. Reprinted with permission from the author 2007

With increasing gas velocity the s-shape profile becomes less pronounced and is almost upright or uniform for the pneumatic conveying regime.

The main characteristics of the pertinent gas–solid flow regimes are [23, 27, 35, 48, 85]:

- *Fixed bed*: When a fluid is passing upward through a bed of fine particles at a low flow rate, and the fluid merely seeps through the void spaces between stationary particles.
- *Expanded bed*: With an increase in flow rate, a few particles vibrate and move apart in restricted ranges.
- *Minimum fluidization*: At a still higher velocity, a point is reached where all the particles are just suspended by the upward-flowing gas. At this point the frictional force between particle and fluid just counterbalances the weight of the particles, and the vertical component of the compressive force between adjacent particles disappears. The pressure drop through any section of the bed thus balance (approximately) the weight of fluid and particles in that section. Further increase in the gas velocity flow rate will not change the pressure drop noteworthy.
- *Smooth fluidization*: In fine particle A beds, a limited increase in gas flow rate above minimum fluidization can result in smooth, progressive expansion of the bed. Bubbles do not appear as soon as the minimum fluidization state is reached. There is a narrow range of velocities in which uniform expansion occurs and no bubbles are observed. Such beds are called a particulate fluidized bed, a homogeneously fluidized bed, or a smoothly fluidized bed. However, this regime does not exist in

beds of larger particles of type B and D, in these cases bubbles do appear as soon as minimum fluidization is reached.

- *Bubbling fluidization*: An increase in flow rate beyond the point of minimum fluidization results in large instabilities with bubbling and channeling of gas. At higher flow rates, agitation becomes more violent and the movement of solids becomes more vigorous. Bubble coalescence and breakage take place, and with increasing gas velocity the tendency of bubble coalescence is normally enhanced. However, the bed does not expand much beyond its volume at minimum fluidization.
- *Slugging fluidization*: The gas bubbles coalesce and grow as they rise, and in a deep enough bed of small diameter they may eventually become large enough to spread across the vessel. Fine particles flow smoothly down by the wall around the rising void of gas. These voids are called axial slugs. For coarser particle beds, the portion of the bed above the bubble is pushed upward. Particles fall down from the slug, which finally disintegrates. Then another slug forms, and this unstable oscillatory motion is repeated. This is called a flat slug. Slugging normally occurs in long, narrow fluidized beds.
- *Turbulent fluidization*: This is often regarded as a transition regime from bubbling to lean phase fluidization. At relatively low gas velocities in this regime, bubbles are present. Moreover, when fine Geldart A particles are fluidized at a sufficiently high gas flow rate, the terminal velocity of the solids is exceeded, thus the upper surface of the bed becomes more diffuse with a large particle concentration in the freeboard, the solids entrainment becomes appreciable, and a turbulent motion of solid clusters and voids of gas of various sizes and shapes occurs. In contrast to the bubbling regime, in this regime the tendency for bubble breakage is enhanced as the gas velocity increases. For this reason the mean bubble size is significantly smaller than in the bubbling regime, hence the suspension becomes more uniform as the gas velocity further increases toward the lean phase fluidization regimes. However, for very high gas velocities within this regime pronounced radial gradients may occur, with a marked tendency for solids to be present in much greater concentration in the wall region, while the core of the column has a significantly smaller volume fractions of particles [35].
- *Dense phase fluidization*: Gas fluidized beds are considered dense phase fluidized beds as long as there is a clearly defined upper limit or surface to the dense bed. The dense-phase fluidization regimes include the smooth fluidization, bubbling fluidization, slugging fluidization, and turbulent fluidization regimes. In a dense-phase fluidized bed the particle entrainment rate is low but increases with increasing gas velocity.
- *Spouting bed fluidization*: Spouting can occur when the fluidizing gas is injected vertically at a high velocity through a small opening into a bed of Geldart D particles. The gas jet penetrates the whole bed and form a dilute flow in the core region. A solids circulation pattern is created, as the particles carried upwards to the top of the core region by the fluidizing gas move downward in a moving bed mode in the annular region. The gross scale particle circulation induced by the axial spout gives rise to more regular and cyclic mixing behavior than in bubbling and turbulent fluidization.

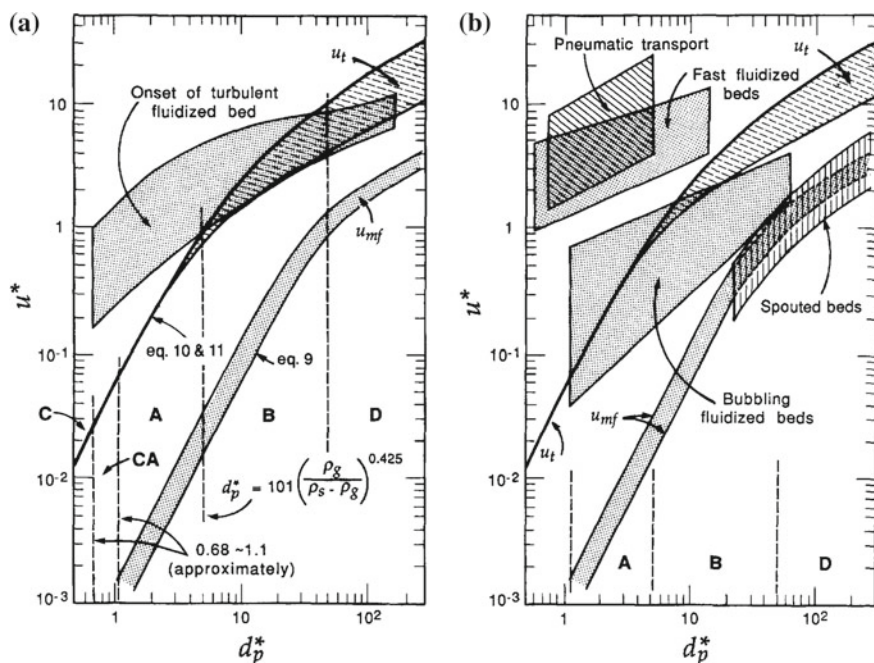

- *Channeling*: In a fluidized bed channeling frequently occur if the gas distribution is nonuniform across the distributor. Channeling can also be caused by aggregation effects of cohesive Geldart C particles due to inter-particle contact forces.
- *Lean phase fluidization*: As the gas flow rate increases beyond the point corresponding to the disappearance of bubbles, a drastic increase in the entrainment rate of the particles occurs such that a continuous feeding of particles into the fluidized bed is required to maintain a steady solid flow. Fluidization at this state, in contrast to dense-phase fluidization, is generally denoted lean phase fluidization. Lean phase fluidization encompasses two flow regimes, these are the fast fluidization and dilute transport regimes.
- *Fast fluidization*: The fast fluidization regime is considered to be initiated when there is no longer a clear interface between a dense bed and a more dilute freeboard region. Instead, there is a continuous, gradual decrease in solids content over the whole height of the column. Particles are transported out of the top of the vessel and must be replaced by adding solids near the bottom. Clusters of particles move downwards near the wall, while gas and entrained dispersed particles move upward in the core of the vessel. The term clustering refers to the phenomenon that solids coalesce to form a larger pseudo-particle.
- *Dilute transport fluidization*: The gas velocity is so large that all the particles are carried out of the bed with the gas. This solid transport by gas blowing through a pipe is named pneumatic conveying. In vertical pneumatic transport, particles are always suspended in the gas stream mainly because the direction of gravity is in line with that of the gas flow. The radial particle concentration distribution is almost uniform. No axial variation of solids concentration except in the bottom acceleration section [37].

The model predictions of the transition borders between the different gas–solid flow regimes shown in Fig. 10.1 are still not reliable. The borders are generally sharp and fairly well correlated for the minimum fluidization (mf) and minimum bubbling (mb) transitions, whereas the transitions at higher gas superficial velocities are diffuse and poorly understood. The general flow regime diagram shown in Fig. 10.2 illustrates the progression of changes in behavior of a bed of solids as the gas velocity is progressively increased. The letters A, B, C and D refer to the Geldart classification of solids.

### 10.3 Reactor Design and Flow Characterization

The fluidized bed reactors can roughly be divided into two main groups in accordance with the operating flow regimes employed. These two categories are named the dense phase and lean phase fluidized beds.

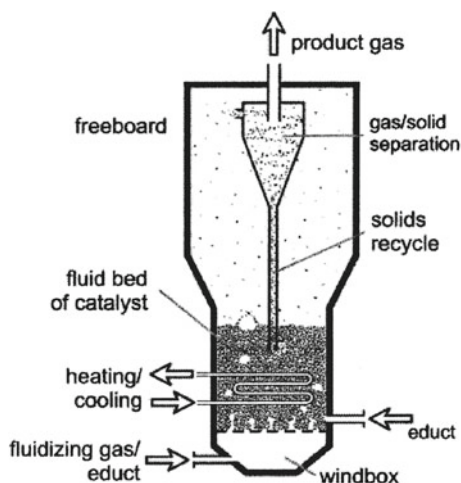

**Fig. 10.2** Flow regime map of gas–solid contacting. **a** Characteristics of turbulent flow regime. **b** Characteristics of spouted beds, bubbling fluidized beds, fast fluidized beds and pneumatic transport regimes. In the figure notation the ordinate  $u^* = U_{in}^s [\rho_g^2 / \{\mu(\rho_p - \rho_g)g\}]^{1/3}$  is a dimensionless gas velocity, the abscissa  $d_p^* = d_p [\rho_g(\rho_p - \rho_g)g / \mu^2]^{1/3}$  a dimensionless particle size,  $u_t = [\frac{4d_p(\rho_s - \rho_g)g}{3\rho_g C_D}]^{1/2}$  the terminal velocity of a particle falling through the gas (m/s), and  $u_{mf}$  the gas velocity at minimum fluidization (m/s). Letters A, B, C and D refer to the Geldart classification of solid particles. Reprinted from [49] with permission from Elsevier

### 10.3.1 Dense-Phase Fluidized Beds

A dense phase fluidized bed generally consist of a gas distributor, a cyclone, a dipleg, a heat exchanger, an expanded section, and baffles [23]. A schematic representation of a dense phase fluidized bed reactor is shown in Fig. 10.3. At the bottom of the vessel is the gas distributor which yields the desired distribution of fluidizing gas and supports particles in the bed. A distributor with sufficient flow resistance to obtain a uniform distribution of gas across the bed is required, and sometimes caps are used to avoid gas jetting effects and plate clogging by fine particles. There are two basic designs of distributors, some for use when the inlet gas contains solids and others for use when the inlet gas is clean. For clean gases the distributor is designed to prevent back flow of solids during normal operation, and in many cases it is designed to prevent back flow during shutdown. Perforated plate distributors are widely used in industry because they are cheap and easy to fabricate [48]. However, the perforated plate distributors cannot be used under severe operating conditions, such as high

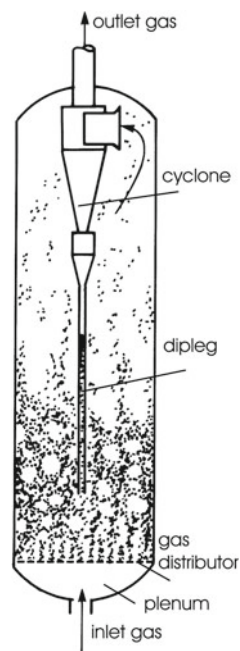

**Fig. 10.3** A typical dense phase bubbling bed reactor design. The reactor consists of a gas distributor, an internal cyclone with solids recycle through a dipleg, and a heat exchanger. The freeboard section of the vessel is expanded and the heat exchanger may also function as a baffle. Reprinted with permission from [79]. Copyright 2004 American Chemistry Society

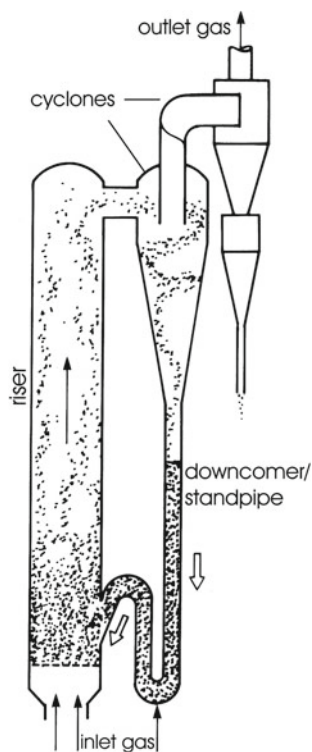

temperature or highly reactive environment. The tuyere type of distributors are normally used in these situations, but these are more expensive than perforated plates. The tuyere distributor design prevents solids from falling through the distributor. The high pressure drop porous plate distributors are commonly used in laboratory scale units to ensure even distribution of gas across the bed entrance. A dense phase fluidized bed vessel has two zones, a dense region having a distinct upper surface separating it from an upper dilute region. The section of the vessel between the surface of the dense phase and the exit of the gas stream is called the *freeboard zone*. In vessels containing fluidized beds, the gas leaving the dense bed zone carries some suspended particles. Particle *entrainment* refers to the ejection of particles from the dense bed into the freeboard by the fluidizing gas. Particle *elutriation* refers to the separation of fine particles from a mixture of particles and their ultimate removal from the freeboard. The flux of solids leaving the freeboard with the gas is called *carry-over*. The entrained solids are normally separated from the outlet gas by internal or external cyclones and returned to the bed. In many cases several cyclones are combined to form a multistage cyclone system. A dipleg returns the particles separated by the internal cyclones into the vessel. The outlet of a dipleg may be located in the freeboard or immersed in the dense bed. A standpipe can be used to return the particles separated by the external cyclones into the dense bed. Sometimes a heat exchanger device is placed in the dense bed or the freeboard to control the temperature. The heat exchanger removes generated heat from or adds required heat to the fluidized bed by a cooling or heating fluid. An expanded freeboard section on the top of the vessel may be used to reduce the local gas velocity in the freeboard so that settling of the particles carried by the fluidizing gas can be efficiently achieved. Any internals other than diplegs can be employed as baffles to restrict flow, enhance the breakage of bubbles, promote gas–solid contact, and reduce particle entrainment. The primary *bubbling fluidized bed* consists of gas bubbles flowing through a dense emulsion region with gas percolating through the bed of solids. A fluidized

**Fig. 10.4** A schematic representation of a turbulent fluidized bed. The illustration shows that in a turbulent fluidized bed entrainment is significant and an internal cyclone with solids recycle through a dipleg is required. Reprinted from [48] with permission from Elsevier

bed reactor of this type designed for catalytic reactions operated in the bubbling bed regime has been shown in Fig. 10.3. In many cases the particle entrainment rate is so low that the cyclone is considered superfluous. In the *turbulent fluidized bed* larger amounts of particles are entrained precluding steady state operations. To maintain steady state operation the entrained particles have to be collected by cyclones and returned to the bed. For vessels operating in the turbulent fluidization regime internal cyclones may deal with the moderate rate of entrainment. This fluidization system, as sketched in Fig. 10.4, is sometimes called a *fluid bed*. Since smooth and steady recirculation of solids through a solid trapping device is crucial for optimal operations of these units, Kunii and Levenspiel [48] included the turbulent fluidized beds in the reactor classification named circulating fluidized beds (i.e., the main lean-phase reactor design). However, this is not a conventional classification of the turbulent bed operation mode. Bubbling and turbulent fluidized beds are operated with small granular or powdery non-friable catalysts. Rapid deactivation of the solids can then be handled, and the efficient temperature control allows large scale operations. The main advantages of a turbulent fluidized bed over a standard bubbling fluidized bed are a more homogeneous fluidization that provides better contacting between gas and catalyst (i.e., low gas bypassing), and higher heat transfer coefficients between the suspension and heat transfer surfaces. In design of fluidized bed systems the cross sectional area is determined by the volumetric flow of gas and the allowable or required fluidizing velocity of the gas at operating conditions. Generally, bed heights are not less than 0.3 m or more than 15 m [62]. For fluidized bed units operated at elevated temperatures refractory-lined steel is the most economical material.

**Fig. 10.5** A schematic representation of a circulating fluidized bed. The CFB loop consists of a riser, gas–solid cyclone separators, standpipe type of downcomer, and a non-mechanical solids flow control device. Reprinted from [48] with permission from Elsevier

### 10.3.2 Lean-Phase Fluidized Beds

The primary exploitation of the lean-phase fluidized beds is associated with the circulating fluidized bed (CFB) reactors. The operation of circulating fluidized bed systems requires that both the gas flow rate and the solids circulation rate are controlled, in contrast to the gas flow rate only in a dense phase fluidized bed system. The solids circulation is established by a high gas flow. The integral parts of a CFB loop are the riser, gas–solid separator, downcomer, and solids flow control device [23]. The CFB is thus a fluidized bed system in which solid particles circulate between the riser and the downcomer, as illustrated in Fig. 10.5. The riser is the main component of the system. The name *riser* is generally used to characterize a tall vessel or column that provides the principal reaction zone. On average, the particles travel upwards (or rise) in the riser, though the motion at the wall may be downwards. The fluidized gas is introduced at the bottom of the riser, where solid particles from the downcomer are fed via a control device and carried upwards in the riser. The fast fluidization regime is the principal regime under which the CFB riser is operated. The particles exit at the top of the riser into the gas–solid separators which are normally cyclones. In lean-phase fluidized beds, the rate of entrainment is far larger than in turbulent fluidized beds, and bigger cyclone collectors outside the bed are usually necessary. The sepa-

rated particles then flow to the downcomer and return to the riser. The entrance and exit geometries of the riser often significantly affect the gas and solid flow behavior in the reactor. The efficiency of the cyclones determine the particle size distribution and solids circulation rate in the system. The downcomer provides hold volume and a static pressure head for particle recycling to the riser. The downcomer can be a large reservoir which aids in regulating the solids circulation rate, a heat exchanger, a spent solid regenerator, hopper or a standpipe. The main task in achieving smooth operation of a CFB system is to control the solids recirculation rate to the riser. Several designs of valves for solids flow control are used. The solids flow control device serves two main functions, namely to seal the riser gas flow to the downcomer and to control the solids circulation rate. Rotary valves are effective sealing devices for solids discharge. The L-valve can act as a seal and as a solids-flow control valve. There are many other valve designs available to suit specific conditions. The riser cannot be considered as an isolated entity in the CFB loop because the pressure drop over the riser must be balanced by that imposed by the flow through its accompanying components such as the downcomer and the recirculation device. In general, the high operating gas velocities for lean phase fluidization yield a short contact time between the gas and solid phases. Fast fluidized beds and co-current pneumatic transport are thus suitable for rapid reactions, but attrition of catalyst may be serious. However, it is not always easy to distinguish between the flow behavior encountered in the fast fluidization and the transport bed reactors [35]. The transport reactors are sometimes called dilute riser (transport) reactors because they are operated at very low solids mass fluxes. The dense riser transport reactors are operated in the fast fluidization regime with higher solids mass fluxes. The transition between these two flow regimes appears to be gradual rather than abrupt. However, fast fluidization generally applies to a higher overall suspension density (typically 2–15 % by volume solids) and to a situation wherein the flow continues to develop over virtually the entire height of the reactor, whereas the flow usually associated with transport bed reactors tends to be more dilute (typically 1–5 % by volume solids) and uniform. However, in practice the differences in operation are generally small, hence the names are often used in an indistinguishable manner.<sup>1</sup> This regime overlap is also indicated in the regime map shown in Fig. 10.2. The pertinent characteristics that distinguish the CFB from the dense phase fluidized beds and from the riser (transport) reactors are summarized in Table 10.1.

Advantages of the fast fluidization regime, relative to the dense phase fluidization regimes, include higher gas throughput per unit area, adjustable retention time of solids, limited axial dispersion of gas coupled with near uniformity of temperature and solids composition, reduced tendency for particles to undergo agglomeration, and possibility of staged addition of gaseous reactants at different levels. Gas–solid contacting also tends to be very favorable. However, by increased overall reactor

---

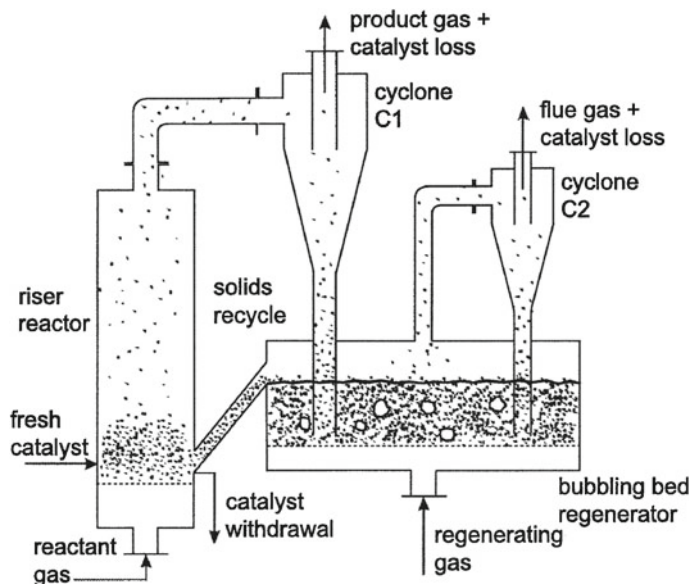

<sup>1</sup> Berruti et al. [7], for example, used the term CFB to generically describe systems like fast fluidized bed, riser reactor, entrained bed, transport bed, pneumatic transport reactor, recirculating solid riser, highly expanded fluid bed, dilute phase transported bed, transport line reactor and suspended catalyst bed in co-current gas flow.

**Table 10.1** The key features that distinguish circulating fluidized bed reactors from low-velocity fluidized beds and from lean-phase transport reactors [37]

|                                     | Low-velocity FB reactor                                   | CFB reactor                 | Transport reactors            |

| Gas mixing                          | Intense                                                   | Intermediate                | Little                        |

height and added complexity in designing and operating the recirculating loop the CFB systems tend to have higher capital costs than low-velocity systems, so that one or more of the above advantages must be very significant for this option to be viable. One of the most important factors inhibiting the commercialization of novel processes operated in risers is scale-up uncertainties arising from the complex hydrodynamic behavior of the CFB reactors.

A combination of a circulating fluidized bed riser reactor operating in the fast fluidization regime and a bubbling fluidized bed regenerator is frequently used in industry for heterogeneous catalyzed gas phase reactions in cases where the catalyst rapidly deactivates and has to be regenerated continuously. Such a catalytic circulating fluidized bed reactor design is sketched in Fig. 10.6. The most prominent chemical reactions operated within such a reactor design is the FCC process, which is widely used in the modern petroleum refinery industry. In this catalytic chemical process vaporized heavy hydrocarbons crack into lower-molecular-weight compounds. To explain the principal operating principles of this particular CFB unit, a FCC riser reactor can be divided into four parts from bottom to top according to their functions [24]: The prelift zone, the feedstock injection zone, the reaction zone, and the quenching zone. In the prelift zone, catalysts enter the riser reactor from the regenerator and are then conveyed by the prelift gas. In the feedstock injection zone, feed oil is introduced into the riser through the feed nozzles, and the heavy oil comes in contact with the high-temperature catalyst. Rapid reactions are then taking place in the reaction zone. Apart from the mentioned application of CFB to the fluid catalytic cracking (FCC) process, circulating fluidized beds utilizing the fast fluidization regime have been used for a number of gas–solid reactions including calcination, combustion of a wide variety of fuels, gasification, and dry scrubbing of gas streams [35]. Applications for catalytic reactions can be taken to include the

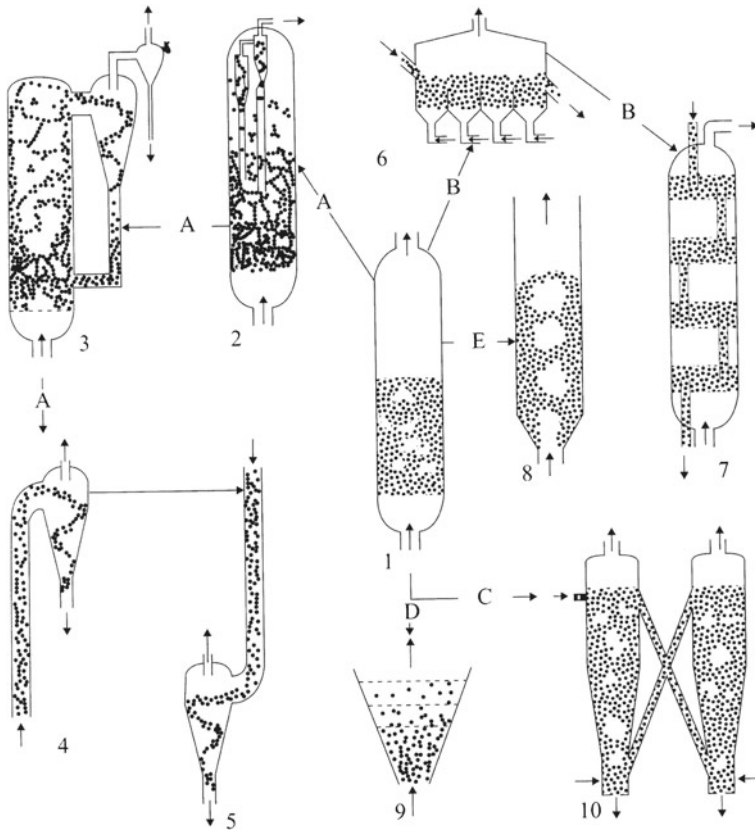

**Fig. 10.6** A typical catalytic circulating bed reactor design. This CFB loop consists of a riser, gas–solid cyclone separators, and a downcomer. In this particular case the downcomer consists of a spend solid regenerator. Reprinted from [78] with permission from Elsevier

transport reactors employed in modern catalytic cracking operations in the petroleum industry and certain Fischer-Tropsch synthesis reactors.

Generally, to maximize profitability, the gas and solids residence times in CFBs are chosen to achieve the highest product yield per unit volume [8]. In FCC units, for example, a short and uniform catalyst residence time in the riser reactor, with reduced back-mixing, leads to better reactor performance by reducing the inventory of the deactivated catalyst in the riser. In other words, a uniform radial profile of solids velocity and little solids back-mixing in the riser is preferred, leading to shorter and more uniform solids residence times. In a FCC unit axial mixing is disadvantageous. For other catalytic reactions, lower gas velocities may be preferred because this gives higher solids holdup, thus maximizing the specific activity per unit volume [7].

Scale-up of CFBs is generally less of a problem than with bubbling beds [62]. Moreover, the higher velocity in CFB means higher gas throughput, which can minimize the reactor costs. Several CFB loop designs have been proposed for getting smooth steady state circulation of solids. Basically, there are two basic types of solids circulation loops distinct in that some include a reservoir of solids while others do not. The solids circulation loops which do not include a reservoir of solids (hopper) are less flexible in operation compared to the circulation systems with reservoirs.

**Fig. 10.7** Types of fluidized bed reactors [43]. Reprinted with permission from the authors. The primary fluidized bed reactor types: 1 bubbling fluidized bed, 2 turbulent fluidized bed, 3 circulating fluidized bed, 4 riser, 5 downer, 6 cross-current fluid bed, 7 counter-current fluid, 8 spouted fluidized bed, 9 floating fluidized bed, 10 twin fluidized bed. The key issues leading to re-design of the conventional bubbling fluid bed: A higher gas velocity, B counter-current contacting is beneficial, C incompatible differences in desired environment, D dusty environment, E large particles/low gas load

### 10.3.3 Various Types of Fluidized Beds

Numerous types of fluidized bed reactor designs exist within each of the two categories mentioned in the previous subsection, some of them are illustrated in Fig. 10.7. The key issues leading to re-design of the primary bubbling fluid bed are also indicated.

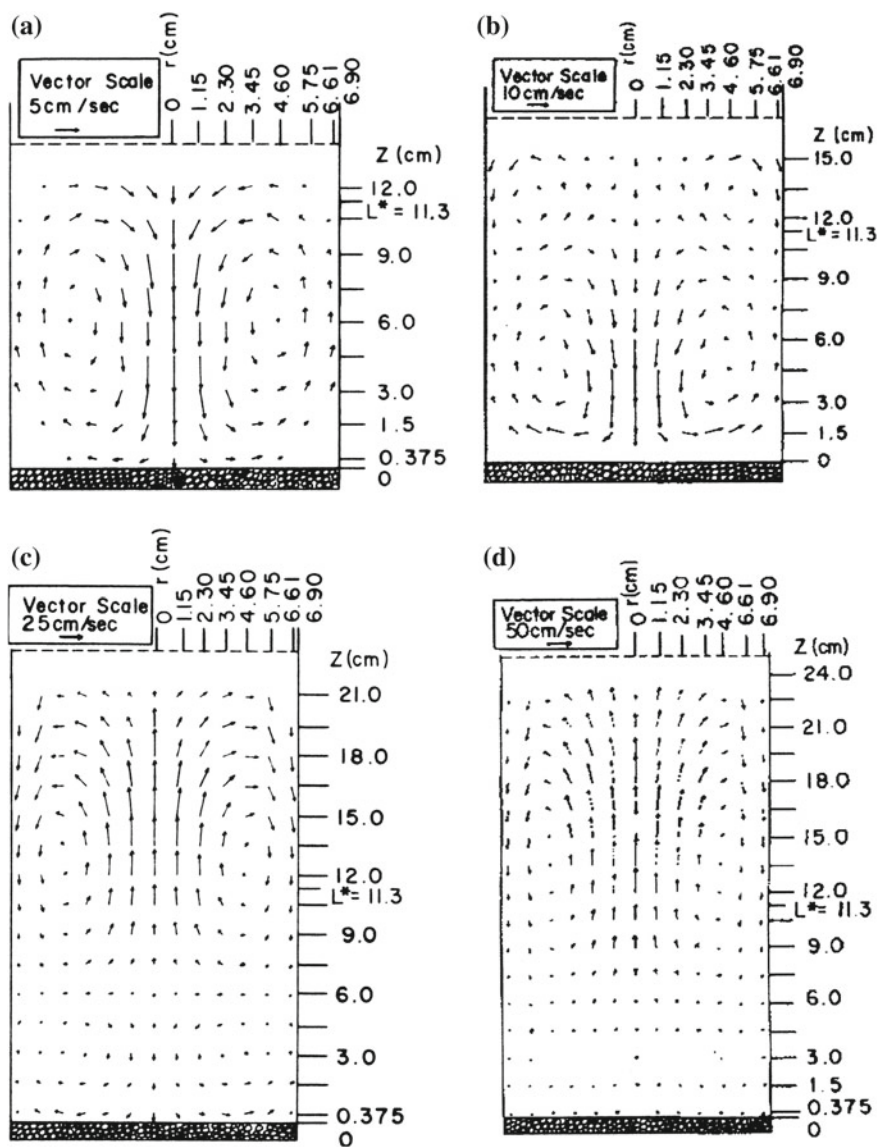

### 10.3.4 Experimental Investigations

The first experimental investigations of bubbling bed fluidization led to the flow interpretation that the bubbles are flowing evenly through an essentially stagnant emulsion without affecting the flow of the emulsion. This picture of the bubbling bed hydrodynamics is named the two-phase theory [17, 74]. This name is somewhat improper as in the two regions called bubbles and emulsion, the two real phases are the gas and solids. A better term might be the two-zone theory.

The subsequent experimental investigations on solids mixing and circulation in bubbling beds revealed that the bubbling phenomenon creates particle circulation patterns [5, 32, 48, 68]. Moreover, the axial and radial transport of solids within the fluidized bed influence many parameters governing the chemical process performance in these units. Most important, the heat transport within the bed is efficient due to the chaotic motion of solid particles having the property of high heat capacity compared to the fluidizing gas, making the bed close to isothermal. Lin et al. [55] were among the first to use the modern non-invasive Computer Automated Radioactive Particle Tracer (CARPT) technique to measure the Lagrangian solid particle motion in gas–solid bubbling fluidized beds. This advanced measuring technique determines the time-average solids velocity components in all three space dimensions simultaneously so that the derived Eulerian flow field map and various turbulence fields can be visualized. A number of experiments were conducted measuring mean velocity distributions for Geldart B glass beads of density 2.5 (g/cm<sup>3</sup>) and diameters ranging from 0.42–0.60 (mm) in an air fluidized bed of 13.8 (cm) diameter, at various superficial air velocities ranging from 32–89 (cm/s). The mean circulating flow patterns observed are summarily presented in Fig. 10.8a–d. For bubbling fluidized beds consisting of Geldart A and B particles operating well above the minimum fluidization conditions the bubble flow will cause the solid particles to develop certain characteristic flow patterns. For a shallow bed there is normally an upflow of particles near the wall and a downflow in the center of the bed at low gas velocities, as shown in Fig. 10.8a and b. Increasing the gas velocity may reverse this flow pattern. In this case the bed apparently consists of one circulating cell just above the distributor similar to the one observed in shallow beds with upflow near the wall and down flow in the center. In the upper part of the bed the solids have an upward motion in the center and downwards near the wall. This flow pattern is shown in Fig. 10.8c, d. An additional advantage associated with the CARPT technique is that it can be used to characterize dense high flux suspensions as emphasized in industrial practice such as fluid catalytic cracking (FCC) units and CFB combustors. The CARPT measuring technique has thus been applied by Bhusarapu et al. [8] investigating the solids velocity field in gas solid risers. Measurements were performed in two different risers at low and high solid fluxes at varying superficial gas velocity spanning both the fast-fluidized and dilute phase transport regimes.

Based on the experimental investigations reported in the literature, using both invasive and non-invasive techniques [73], it is recognized that most CFBs operating in the *fast fluidization flow regime* are subject to predominantly downflow of relatively

**Fig. 10.8** Particle circulation patterns at various fluidizing velocities for a gas fluidized bed ID 13.8 (cm) consisting of 0.42–0.6 (mm) diameter glass beads [55].  $L^*$  denotes the static bed height. Case **a**  $U_{in}^s = 32$  (cm/s) and  $U_{in}^s/U_{mf}^s = 1.65$ , Case **b**  $U_{in}^s = 45.8$  (cm/s) and  $U_{in}^s/U_{mf}^s = 2.36$ , Case **c**  $U_{in}^s = 64.1$  (cm/s) and  $U_{in}^s/U_{mf}^s = 3.41$ , and Case **d**  $U_{in}^s = 89.2$  (cm/s) and  $U_{in}^s/U_{mf}^s = 4.6$ . Reprinted with permission of John Wiley & Sons Inc, Copyright 1985

dense suspensions along the outer wall while there is a net dilute upflow in the core [38, 42, 59, 76]. The fast fluidization regime is also characterized by a dense region at the bottom of the riser and a dilute region at the top. Due to the large reflux and density of the suspension, the temperature gradients are normally very small. In *vertical pneumatic transport regime* the radial particle concentration distribution is almost uniform, but some particle strands may still be identified near the wall. Little or no axial variation of solids concentration except in the bottom acceleration section is observed [37]. The flow associated with transport bed reactors tends to be dilute (typically 1–5 % by volume solids) and uniform. By virtue of the smaller reflux and density of the suspension within the dilute pneumatic conveying regime, there might be larger temperature gradients than within the fast fluidization regime [35]. Optical techniques like laser doppler anemometry (LDA) can be used to obtain knowledge about the local solids hydrodynamics in CFB units close to walls at low solids fluxes [8]. Such LDA measurements of FCC particles in a riser in circulating fluidized bed have been reported by [70, 71]. An overview of sources of experimental data in the open literature characterizing the hydrodynamics of CFB risers can be found in [7]. These investigations might be useful for CFB riser model validation. However, despite the development of novel experimental techniques and many experimental investigations, there is still considerable uncertainty and disagreement with regard to the dependence of fine scale structures on the operating conditions. This dependency is important in scale-up, design, and optimization of these units.

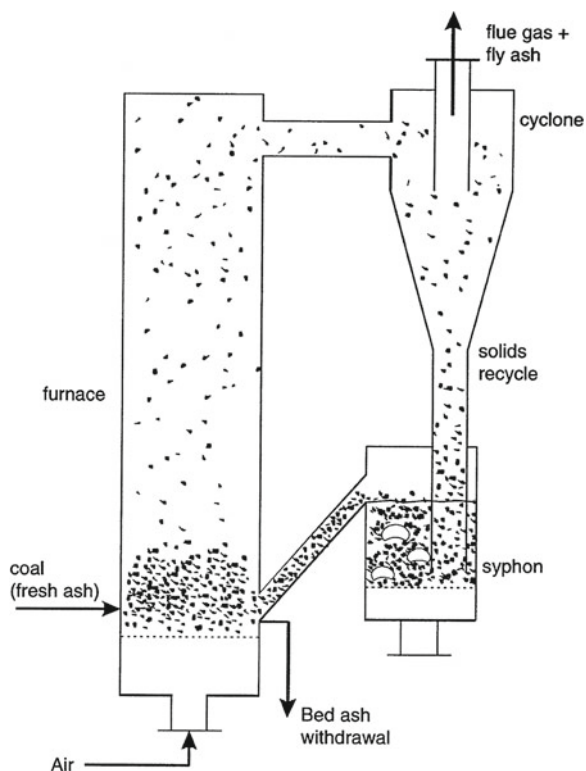

## 10.4 Fluidized Bed Combustors

Although the scope of this book is the design of fluidized bed vessels used as chemical reactors, a brief outline of the combustor units representing the most widespread use of this technology is considered very useful for the general understanding of the chemical reactor operation but also to orientate oneself in the vast literature on fluidization technology. Recent reviews of fluidized bed combustion systems are given by Anthony [2], Leckner [51], Longwell et al. [56] and Issangya et al. [40]. The popularity of fluidized bed combustion is due largely to the technology's fuel flexibility and the capability of meeting sulfur dioxide and nitrogen oxide emission requirements without the need for expensive flue-gas treatment.

In the early 1960s engineers in Britain and China considered fluidized bed combustion (FBC) to be an alternative future combustion technology to enable utilization of low-grade coal and oil shale fines, fuels that cannot be burned efficiently in conventional boiler furnaces [48]. Several power generation cycles utilizing the fluidization technology were commercialized [10, 51, 52]. The working principles of the conventional cycles can be outlined as follows. The fluidized bed boilers supply steam to a Rankine cycle. The efficiency of the electric power production has been further increased in a combined cycle with a pressurized FBC serving as the heat source for both the steam and the gas turbine cycle. More advanced cycles, such as the air blown gasification cycle and the integrated gasification combined cycle (IGCC), are

currently being developed. In a fluidized bed combustor the bed is made up primarily of inert material which may be ash, absorbent, or some other inert material such as sand. The technology's fuel flexibility arises from the fact that the fuel is present in the combustor at a low level and are burnt surrounded by these inerts [2]. The solid fuel normally represent between 0.5 and 5 % of the total bed material. In general, almost any solid, liquid, slurry or gas containing carbon, hydrogen and sulfur can be used as fuels for energy production. The first fluidized bed gasifiers were designed for burning coal. The second generation units were utilizing petroleum fuels. However, in order to compensate for the shortage of petroleum, the utilization of coal for combustion and gasification has again become dominating. Currently almost half of the total worldwide FBC capacity is primarily fueled by coals [52]. Other fossil fuels like oil and natural gas can also be burned effectively and efficiently in a CFB unit. Nevertheless, other combustible materials like petroleum coke, biomass and municipal waste are gaining in popularity. In particular, waste and biomass are used to replace a part of the coal as  $CO_2$ -neutral fuels. In addition, co-firing coal and petroleum coke can also be beneficial. The first fluidized bed applications employed bubbling bed boilers, but problems with erosion of in-bed cooling tubes diverted the mainstream of development towards the circulating fluidized bed boiler [51]. The first circulating fluidized bed combustion (CFBC) systems were developed in the late 1970s by Ahlstrom Pyropower in Finland, Lurgi in Germany, and Studsvik Energiteknik in Sweden [10]. However, bubbling beds remain important for particular applications for which they have cost advantages. Today the circulating fluidized bed (CFB) has become the dominating design for combustors operated at atmospheric pressure. Pressurized circulating fluidized bed combustors are under development for combined power cycle applications, but so far no clear advantages have been revealed yet. For this reason the existing commercial pressurized fluid bed systems are bubbling beds. During the last decades several FBC technologies have become available for the combustion of coal and alternative fuels, with the trend that circulating fluidized bed combustion (CFBC) is prevailing over bubbling fluidized bed combustion (BFBC) [2, 4].

One of the most attractive features of FBC, employing bubbling and circulating beds, is the potential to use a low cost sorbent to capture sulfur (in situ) within the fluidized bed in cases where high sulfur-fuels are burnt. The sorbent is typically limestone or dolomite (minerals composed of calcium and magnesium carbonates) and is fed to the bed either together with the fuel or as a separate solid stream [3, 53]. More than 90 % of the sulfur pollutants in coal can be captured by the sorbent. Low  $NO_x$  emissions is enforced since the fuel is burnt at temperatures of about 750–950°C, well below the threshold where nitrogen oxides form (i.e., nitrogen oxide pollutants are produced at about 1400°C). The environmental pollution by combustion ash containing residual sorbents must also be treated properly [46]. It should be mentioned that the combustion technology is not limited to these major designs. In catalytic fluidized bed combustion of low-sulfur natural gas, for example, powder catalysts are operated in the turbulent flow regime where the gas–solid contact is optimal so as to maintain a high combustion efficiency [26].

**Fig. 10.9** A typical circulating fluidized bed combustor design [39]. The furnace (riser) is normally operated in the fast fluidization regime. The ash which is entrained from the furnace is separated from the flue gas in the cyclone. Most of the ash particles are sent into the siphon. The siphon is a small bubbling fluidized bed acting as a pressure lock. From the siphon the ash flows back into the riser. Reprinted with permission from Elsevier, copyright Elsevier 2007

The fast fluidization regime is most often encountered in circulating fluidized beds where provision for continuous return of a significant flow of entrained solids is an integral part of the equipment. In combustion systems, the return is accomplished by capturing the entrained solids in one or more external cyclones or in impingement separators. These key features of a circulating fluidized bed combustion system are shown schematically in Fig. 10.9. The captured particles are sent back to the base of the reactor (riser) through a vertical standpipe (downcomer), and then through a non-mechanical seal or a non-mechanical valve (mechanical valves are more common in FCC installations). The bottom section of the riser might also be tapered to prevent solids from sitting and agglomerating in the bottom section. In some cases, the solids pass through a separate low-velocity fluidized bed heat exchanger or a siphon only (equivalent to a catalyst regenerator in a FCC reactor installation) during their journey from cyclones capture to re-injection. The design of CFB employed in chemical reactor engineering and circulating fluidized bed combustion may be distinguished

**Table 10.2** Comparison of typical operating conditions for the two principal applications of fast fluidization: fluid catalytic cracking and circulating fluidized bed combustion [35, 40]

|                                                                    | FCC riser reactor | CFB combustor      |
|--------------------------------------------------------------------|-------------------|--------------------|

| Height-to-diameter-ratio                                           | >20               | <5–10              |
| Average solids residence time per pass (s)                         | 2–4               | 20–40              |

by the aspect ratio ( $H/D$ ) of the riser [40, 61]. For chemical process analysis tall and narrow riser units with an aspect ratio of the order of 20 or higher is normally used. A chemical reactor utilizing the fast fluidization regime typically operates at high net solids fluxes for the purpose of producing product chemicals. A typical industrial scale CFB combustor is designed as larger units, with a lower aspect ratio typically less than 10, for the purpose of producing heat, electricity, fuel-gas or combinations of these.

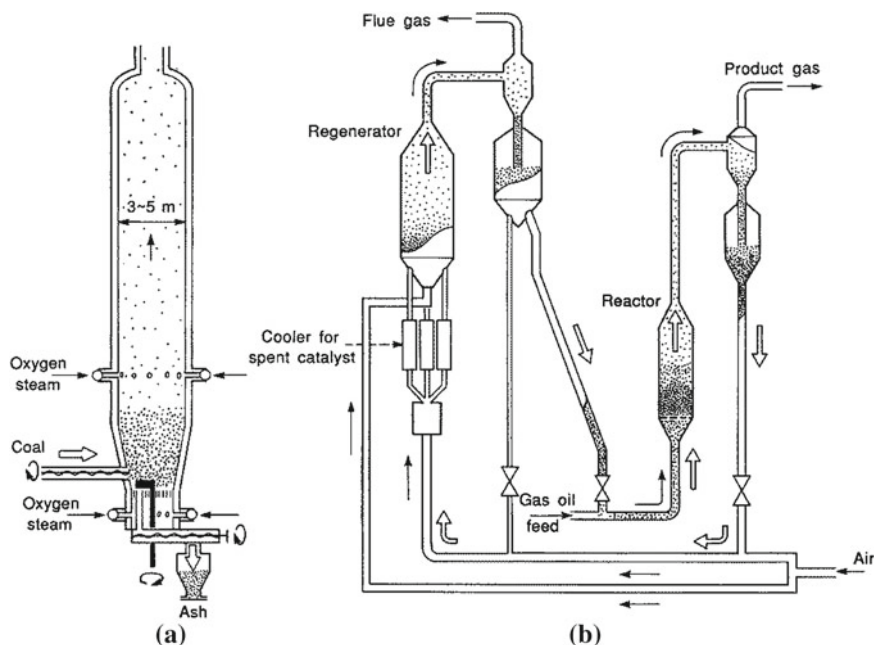

The group B solids normally used in large scale CFBC and circulating fluidized bed gasification (CFBG) units consists of silica sand and/or primary ashes, and sorbent in the case of coal-fired units. We reiterate that the common FCC particles belongs to the Geldart group A. The particle sizes applied to fluid bed combustion are normally in the range 150–250 ( $\mu\text{m}$ ), whereas for catalytic cracking and other chemical processes finer particles with sizes in the range 60–70 ( $\mu\text{m}$ ) are used [40]. The flow pattern in CFB gasifiers and combustors is similar since the overall riser geometry, fluidization conditions and properties of the solids used are similar [61]. However, minor differences in the flow behavior can occur because of corner effects since combustors generally have a square or rectangular cross section and may partly have bare membrane tube walls, whereas the riser of a gasifier normally has a circular cross section with plane walls. Nevertheless, the flow pattern of the large CFB combustors and the gasifier units differs significantly from those of tall and narrow CFB reactor units (which normally have a circular cross section) due to the dissimilar operating conditions employed, so the abundant literature on CFBC and CFBG is seldom applicable for CFB reaction technology and vice versa. The important features of the two principal applications of the fast fluidization regime, the fluid catalytic cracking riser reactor and the solid fuel combustion vessel, are compared in Table 10.2.

Although considerable work has been done to understand the flow dynamics of CFBs, much of the CFB data reported are for low density CFB systems representative of CFB combustors. Further work is thus required on high density systems to better understand the riser reactor behavior leading to more reliable scale-up and design of these units. Many of the modern combustion processes can be characterized by relatively low reaction rates compared to the modern catalytic processes operated in chemical reactors [40]. Therefore, these combustion processes do require lower gas velocities and higher solids circulation rates. On the other hand, many catalytic gas-phase reactions, including FCC, Fischer-Tropsch synthesis and oxidation of butane, utilize a relatively high gas velocity in the riser to promote plug flow operating conditions and short contact times between the gas and solids. The solids residence time distribution (RTD) in the riser may thus be important in non-catalytic gas–solid reactions, as in a combustor, since this distribution characterizes the degree of solids mixing and provides information about the physical properties of the solid particles in the riser [8]. Moreover, lateral mixing and internal recirculation of solids in a CFB combustor are necessary to maintain uniform temperatures over the entire length of the riser. Hence, lateral and longitudinal mixing is advantageous in a CFB combustor.

Prediction of the flow and transport processes is crucial in modeling the heat transfer and combustion/gasification gas produced. The conventional modeling of bubbling and circulating fluidized bed coal combustors were outlined by Arena et al. [4]. Saraiva et al. [72] presented an extended model for a circulating atmospheric fluidized bed combustor (CAFBC) which included hydrodynamics for the fast section at the top of the bed as well a bubbling bed section at the bottom of the CAFBC. For the fast section of the bed, one dimensional momentum and energy balances were used to predict the temperature and velocity profiles for gas and particles throughout the reactor. The model contain species mass balances for five gas species including SO<sub>2</sub>, as well as a model of SO<sub>2</sub> retention by limestone particles. A bubbling bed model was considered to simulate the chemical process at the bottom of the combustor. Recently, Pallarés and Johnsson [61] presented an overview of the macroscopic semi-empirical models used for the description of the fluid dynamics of circulating fluidized bed combustion units. They summarized the basic modeling concepts and assumptions made for each model together with the major advantages and drawbacks. In order to make a structured analysis of the processes involved, the CFBC unit is often divided into 6 fluid dynamical zones like the bottom bed, freeboard, exit zone, exit duct, cyclone and downcomer and particle seal, which have been shown to exhibit different fluid dynamical behavior.

## 10.5 Milestones in Fluidized Bed Reactor Technology

Fuel conversion in a fluidized bed was first introduced by Winkler who patented a gasifier in 1922 [80]. The first large-scale use of fluidized beds, the Winkler gas generator, was thus established for the process of gasification of coal in 1926 [27, 48]. These units were 13 (m) high, 12 (m<sup>2</sup>) in cross section and fed by powered

**Fig. 10.10** Two pioneering fluidized bed reactors: **a** the Winkler gas generator; **b** the first large-scale pilot plant for fluid catalytic cracking. Reprinted from [48] with permission from Elsevier

coal to produce synthesis gas for the chemical industries.<sup>2</sup> A sketch of the pioneering Winkler gas generator is shown in Fig. 10.10a. A number of more efficient bubbling bed and lean-phase CFB fluidization technologies for gasifying coal have been developed over the years [21]. An informative overview of the gasification chemistry, gasifier types and coal gasification reactor models is given by Denn and Shinnar [20].

In chemical reactor engineering, on the other hand, the fluidization technique is considered initiated by the cooperative work of the Standard Oil Development Co, the MW Kellogg Co, and Standard Oil of Indiana developing the first FCC unit. With war threatening in Europe and the Far East around 1940, the chemical engineering community in USA was urged to find new ways of transforming kerosene and gas oil into high-octane gasoline fuels. The real breakthrough of the fluidized bed technology was thus associated with the catalytic cracking of gas-oil into gasoline, first practiced in 1942 at the Baton Rouge refinery of Standard Oil of New Jersey (now Exxon)

<sup>2</sup> The gasification process involves conversion of coal and air (or oxygen) into a gaseous mixture of mainly CO, CO<sub>2</sub>, H<sub>2</sub>, H<sub>2</sub>O, CH<sub>4</sub> and N<sub>2</sub>.

[48, 86]. Before that, the catalytic cracking was carried out in fixed bed reactors<sup>3</sup> as commercialized in 1937. Catalytic cracking deposits carbonaceous products on the catalyst, causing rapid deactivation of the latter. To maintain the production capacity, the coke had to be burned off. This regeneration required switching the fixed bed reactor out of production. In order to eliminate the cycling, attempts were made to circulate the catalyst and burn off the coke in a separate vessel, the re-generator. Both the reactor and the regenerator were operated under transport conditions. A sketch of the pioneering FCC reactor is shown in Fig. 10.10b. Today this reactor is classified as a CFB, but it was then called an upflow unit [58]. The term *circulating fluidized bed* was first applied to alumina calciners by Reh [64] in 1971.

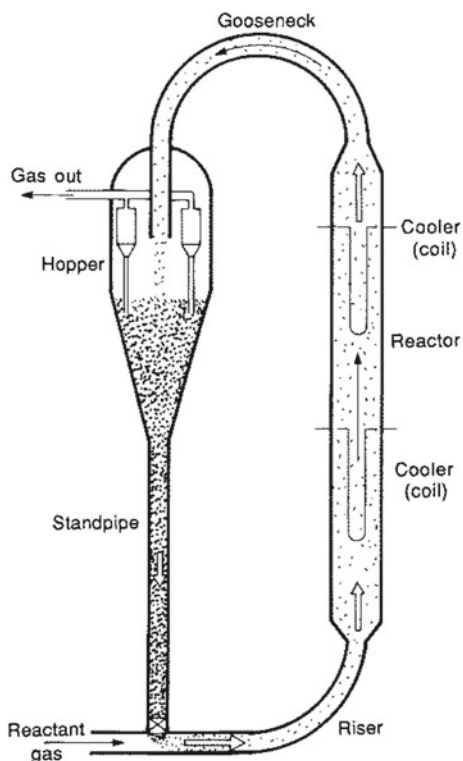

The high turbulence created in the fluid-solid mixture leads to much higher heat transfer coefficients than those which can be obtained in fixed beds. The resulting uniformity of the fluidized bed makes it applicable for effecting catalytic reactions, especially highly exothermic and temperature sensitive reactions. However, the fluidization technology is much more complicated than that associated with fixed bed reactors. For the low activity FCC catalysts then available, the bubbling bed design was a decided improvement over the first CFB reactor. Until the mid-1970s, virtually all FCC units maintained a dense phase bubbling or turbulent bed in the reactor vessel. A few of the second generation bubbling bed FCC reactors are still in operation [58]. The contemporary commercial reactors used for sulphide ore roasting, Fischer-Tropsch synthesis and acrylonitrile manufacture were routinely operated in the bubbling and turbulent fluidization regimes [35, 63]. With the introduction of zeolites in the early 1960s, the FCC catalyst activity began to increase steadily [58]. By 1980 many units were again operating in a CFB mode to reduce the residence time of the gas reactants in the reactor. Today, by far the greatest use of CFB reactors is for the FCC process in petroleum refining. There are processes in which the total amount of catalyst is entrained by the gas. The reactors then belong to the category of transport reactors. Examples are some of the present Fischer-Tropsch reactors for the production of hydrocarbons from synthesis gas and the modern catalytic cracking units. Figure 10.11 shows the Synthol circulating solids reactor. In the dilute side of the circuit, reactant gases carry suspended catalyst upward, and the fluidized bed and stand-pipe on the other side of the circuit provide the driving force for the smooth circulation of the solid catalyst. For the removal of heat, heat exchangers are positioned in the reactor. Figure 10.12a shows a Fluid Catalytic Cracking (FCC) unit (Exxon's model IV), in which the catalyst is circulating through a pair of U-tubes. Liquid oil is fed to the riser under the reactor, and on vaporization it reduces the bulk density of the up-going mixture and promotes the circulation of catalyst. The stacked unit in Fig. 10.12b is an alternative design by Universal Oil Products Company. It uses a higher pressure in the re-generator than in the reactor, a single riser and a micro-spherical catalyst. Some of the synthetic crystalline zeolite catalyst introduced were so active that the cracking mainly or entirely took place in the riser,

---

<sup>3</sup> This fixed bed process itself was already representing a major improvement over the earlier thermal-cracking methods yielding more gasoline of higher octane rating and less low-value, heavy fuel oil by-product [86].

**Fig. 10.11** Synthol circulating fluid bed Fischer-Tropsch reactor. Reprinted from [48] with permission from Elsevier

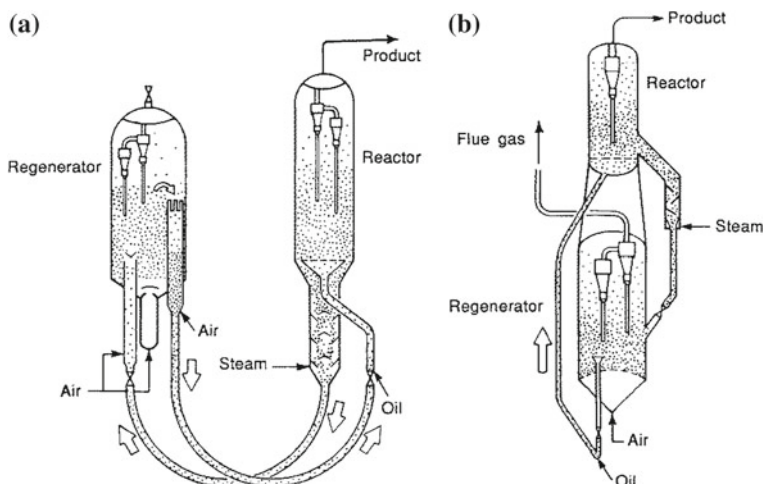

so that the reaction vessel caused over-cracking into undesired light gases and coke. In recent versions of the catalytic cracker, the catalyst is completely entrained in the riser-reactor to reduce the contact time.

Table 10.3 contains a few examples of industrial applications of fluidized beds for synthesis reactions. Other examples are given by [32, 37, 48, 86]. Other fluid bed applications have also used CFBs in preference to dense phase fluidized beds, but the use of CFBs is limited to situations where the higher capital and operational costs of higher gas velocity can be justified by significant process advantages. In many applications, a well designed dense phase fluidized bed may suffice and be less costly to construct and operate than a CFB.

## 10.6 Advantages and Disadvantages

In general, fluidized beds are of special interest when a high degree of gas to solid contact coupled with large throughput of gas at fairly low pressure drop is needed. In industry many different reactor designs are employed for the catalytic gas–solid processes, most important are the fixed bed, moving bed and fluidized bed designs. In

fixed bed reactors the catalyst particles are arranged in a vessel, generally a vertical cylinder, with the flux of reactants and products passing through the stagnant bed. In moving bed reactors the bed can be removed either continuously or periodically in portions. The fluid circulation is similar to that in a fixed bed. Among these vessels, the fixed bed reactors are the conventional workhorses for these processes. The fixed bed reactors are generally used for very slow or non-deactivating catalysts. For some of these processes serious temperature control problems limit the size of the reactor

units. In the fixed bed units the catalyst particles must be fairly large and uniform, and with poor temperature control the catalyst may sinter and clog the reactor. Bubbling and turbulent fluidized beds are more suitable for small granular or powdery nonfriable catalysts. Rapid deactivation of the solids can then be handled, and excellent temperature controlled allows large scale operations. In general, fluidized beds are of special interest when a high degree of gas to solid contact coupled with large throughput of gas at fairly low pressure drop is needed. Comparing the fluidized bed and fixed bed reactor investment costs, physical characteristics and operation performance the important advantages and disadvantages of fluidized beds relative to fixed beds can be summarized as follows.

*Advantages of fluidized beds:*

- The ability to withdraw and reintroduce solids continuously.
- Possibility of continuous regeneration of the catalyst particles. This is particularly useful for processes where the catalyst is rapidly deactivated.
- The rapid mixing of solids leads to close to isothermal conditions throughout the reactor. Low risk of hot spots, runaway and thermal instability. The fluidized bed is well suited for exothermic reactions.
- Low impact of internal and external diffusion phenomena because of the small particle size.
- Efficient gas–solid contacting. Heat and mass transfer rates between gas and particles are high when compared with fixed bed reactors.
- The convective heat transfer coefficients at the surfaces immersed in the bed are high. This property indicates that internal heat exchangers require relatively small surface areas.

*Disadvantages of fluidized beds:*

- For the same weight of catalyst, expansion of the bed requires an increase in reactor volume.
- The random movement of the particles causing back-mixing result in an overall reactor behavior that is closer to a CSTR than a plug flow reactor. This may lead to an increase in the reaction volume and a loss of selectivity.
- The entrainment of solid particles necessitates the installation of a device (like a cyclone) for separating and recycling fines.
- Friable solids are pulverized and entrained by the gas and must be replaced.
- Erosion of internals, pipes, and vessels from particle abrasion can be severe.
- Broad residence time distributions of solids due to intense mixing, erosion of the bed internals, and attrition of the catalyst particles.
- Broad residence time distributions of the gas due to dispersion and gas-bypass in the form of bubbles, especially when operated in the bubbling bed regime.
- Reactor hydrodynamics and modeling are complex. Scale-up and design thus presents serious challenges which limits the use of these reactors to applications that can justify the significant research and development efforts involved.

## 10.7 Chemical Reactor Modeling

Although many of the earliest fluidized beds were operated at high gas velocities, technical difficulties led to a decrease in superficial gas velocities in the early years [35]. At the same time, the academic research focused mainly on the bubbles and slugs in fluidized beds. Call to mind that the characteristic nature of basic science guides academic researchers to proceed analyzing any problem in a systematic manner trying to understand the low velocity phenomena before the more complex high velocity flow patterns were studied. This naturally led to significant advances in the understanding of processes carried out at relatively low gas velocities, high-velocity processes and hydrodynamics were all simply ignored. In recent years renewed interest in fluidized beds operated at high gas velocities (1.5 m/s or more) in hydrodynamic regimes beyond the bubbling and slugging regimes arise, firstly because some industrial fluid bed reactor processes were always operated at such high gas velocities. Secondly, the interest has been increased by the development of new circulating fluidized bed (5–10 m/s) and substantial external recycle of entrained solids. Larger units were constructed and operated to increase the profit and competitive ability.

### 10.7.1 Conventional Models for Bubbling Bed Reactors

In order to predict the performance of a chemical reactor information on the reaction kinetics, thermodynamics, heat and mass transfer, and flow patterns are generally required. For bubbling fluidized bed reactors in particular the flow and the phase interaction phenomena are the most challenging modeling tasks. In the early days, ideal flow models such as plug flow, continuous stirred tank or mixed flow, dispersion, and the tank in series approaches were assessed. Then, led by Toomey and Johnstone [74] a number of two-region models were proposed. The basic advantage of these models was that they enable the investigators to account for the observed non-homogeneity of dense fluidized beds, identifying the dilute *bubble* and the dense *emulsion* phases. The word phase in this context refers to a region which may include both gas and solid particles. These regions are distinguished from one another in terms of the volume fraction of solids, by physical appearance, and through their flow characteristics [33].

Two major discoveries in the understanding of the gas/solid interaction phenomena in bubbling fluidized beds were obtained in the 1960s [47]. Firstly, the Davidson and Harrison [17] analysis of the flow of gas within and in the vicinity of rising gas bubbles. Secondly, the Rowe and Partridge [67] and Rowe [68] finding that a rising bubble was accompanied by a wake of solids and that this was the main mechanism causing solids circulation in a dense fluidized bed.

These developments led to a novel type of reactor models, the hydrodynamic models, in which the bed behavior was based on the characteristics of the rising bubbles. Several models of this kind were derived for the industrial relevant fine

particle suspensions in which the rising bubbles are surrounded by very thin clouds of circulating gas. Various combinations of assumptions have been used to represent the phase interaction phenomena in this region [47]:

- Two- or three zone models. In the three zone case the bubble, cloud, and emulsion zones are treated as separate regions. The three-zone model can be reduced to a two-zone model either by treating the bubble and cloud zones as a single region, or by treating the cloud and emulsion zones as a single region.
- The bubbles are spherical or non-spherical.
- The bubble wake region is accounted for or ignored.
- The simplest model versions consider one mean bubble size in the whole bed. The simple model can be extended so that bubbles are allowed to grow as they rise in the bed but are of the same size over the cross section of the bed at any level in the bed. The most advanced models are similar to the previous group of extended models but consider also a bubble size distribution at any level in the bed.
- The solids in the bubbles are considered or ignored.

A few of the early bubbling bed modeling approaches are assessed in the subsequent sub-sections. Reliable engineering models, at this simple level of complexity, can only be derived based on appropriate empirical information characterizing the important bed properties. The theory and typical parameterizations used to determine the relevant behavior of the gas and solids in the bubble, cloud, emulsion and wake regions are outlined.

### 10.7.1.1 Pressure Drop and Minimum Fluidization Velocity

Increasing the gas flow just passing the point of minimum fluidization conditions the onset of particle fluidization will occur when the drag forces acting on the particles due to the upward moving gas are balanced by the weight of the solid particles [18].

The cross sectional average global pressure drop over a fluidized bed operated at minimum fluidization conditions is normally calculated by an extrapolation of the Ergun [22] Eq. (6.14) for fixed packed beds, the flow regime that is prevailing until the minimum fluidization flow rate has been reached, as described in Chap. 6:

$$-\frac{\Delta p_t}{L_{mf}} = f \frac{\rho_g (U_{mf}^s)^2}{d_p} \quad (10.1)$$

where  $f$  denotes an appropriate friction factor, as for example (6.15), and  $L_{mf}$  represents the height of the fixed bed at minimum fluidization conditions.

The weight of the cross sectional averaged bed at minimum fluidization is:

$$-\frac{\Delta p_t}{L_{mf}} = (1 - \varepsilon_{mf})(\rho_p - \rho_g)g \quad (10.2)$$

**Table 10.4** Voidage at minimum fluidizing conditions,  $\varepsilon_{mf}$  (from [48], p. 69)

| Particles                                 | Size, $d_p$ (mm) |      |      |      |      |      |      |

| Carborundum                               | –                | 0.61 | 0.59 | 0.56 | 0.48 | –    | –    |

where  $\varepsilon_{mf}$  denotes the gas holdup (overall bed void fraction) in the bed at minimum fluidization (generally a measured characteristic of the bed packing). In Table 10.4 typical experimental values of  $\varepsilon_{mf}$  is given.

The superficial gas velocity at minimum fluidization conditions  $U_{mf}^s$  is then found by combining the two relations for the pressure drop:

$$U_{mf}^s = \sqrt{\frac{d_p(1 - \varepsilon_{mf})(\rho_p - \rho_g)g}{\rho_g f}}. \quad (10.3)$$

### 10.7.1.2 Volumetric Gas Flow Rate and Bubble Rise Velocity

The volumetric gas flow rate to the bubble zone in a fluidized bed  $Q_b$  is defined as the average rate at which the bubble volume crosses any level in the bed [12]. However, the flow of gas in the bubble zone is generally greater than the volumetric gas flow rate in bubble because of the so-called bulk *throughflow* of gas into and out of each bubble (i.e., convective interfacial mass transfer). A first estimate for  $Q_b$  is given by the *two-phase theory of fluidization*, proposed by Toomey and Johnstone [74] and developed by Davidson and Harrison [17, 18]. In this theory a bubbling fluidized bed consists of two zones or phases, referred to as the bubble phase consisting of pure gas and the emulsion phase consisting of uniformly distributed particles in a supporting gas stream. The emulsion zone is assumed to be operating at minimum fluidization conditions  $U_e^s \approx U_{mf}^s$ , while the bubble zone carries the remaining gas flow  $U_b^s \approx U_{in}^s - U_{mf}^s$ . This simple model can then be used to estimate the volumetric gas flow rate in bubble zone as the excess gas flow above that required for minimum fluidization:

$$Q_b \approx (U_{in}^s - U_{mf}^s)A \quad (\text{m}^3/\text{s}) \quad (10.4)$$

where  $A$  is the cross sectional area of the bed ( $\text{m}^2$ ).

Experimental investigations indicate that the actual  $Q_b$  is 10–50% smaller than the value given by the simple two-zone model [12]. Nevertheless, the two-zone theory

has been the basis for much work in fluidization technology. For example, knowing the bubble zone volumetric gas flow rate the average fraction of the bed area occupied by bubbles can be approximated as:

$$\varepsilon_b \approx \frac{Q_b}{Au_b} \approx \frac{U_{in}^s - U_{mf}^s}{u_b} \quad (-) \quad (10.5)$$

where  $u_b$  is the average rise velocity of bubbles in the bubbling bed.

The simple two-zone theory results (10.4) and (10.5) can thus be adopted determining a first estimate of the *bed expansion*  $\Delta L = L - L_{mf}$  due to the bubble formation in dense beds. The expansion of the bed above its depth at minimum fluidization is obtained from the bubble zone volume balance:

$$A\Delta L = A \int_0^L (1 - \varepsilon_b) dz - A \int_0^{L_{mf}} (1 - \varepsilon_b) dz \approx \int_{L_{mf}}^L \frac{Q_b}{u_b} dz \quad (\text{m}^3) \quad (10.6)$$

provided that the average rise velocity of bubbles is known (since the  $L_{mf}$  and  $U_{in}^s$  parameters are normally specified and  $U_{mf}^s$  is calculated from suitable semi-empirical models).

The *rise velocity of a single bubble* rising in an emulsion unaffected by other bubbles and the walls is frequently calculated from an expression derived for gas liquid flow. Bubbles in a fluidized bed behave in many ways like bubbles in a low viscosity liquid [48, 68]. A small bubble is spherical, but a bubble becomes deformed with increasing size and the larger ones have a spherical capped shape. The smallest bubbles rise slowly. The larger bubbles generally rise faster. Bubbles flowing in series may coalesce to produce larger bubbles. Wall effects usually decreases the bubble rise velocity. However, in contrast to gas–liquid flow there is a high degree of gas interchange between the bubbles and the gas in the dense emulsion zone. Davies and Taylor [19] studied the rate of rise of large spherical cap bubbles of air through nitrobenzene or water. An approximate calculation showed that the velocity of rise of a single bubble is  $u_{bl,rise} = \frac{2}{3}(gR_n)^{1/2}$ . In this formula  $R_n$  is the radius of curvature at the nose of the gas bubble. Clift et al. [13] (p. 206) summarized the experimental rate of rise data for gas bubbles in liquids found in more recent publications. For particular bubble Reynolds and Eötvös numbers,  $Re_b = \rho_g d_e u_{bl,rise} / \mu_g > 150$  and  $Eo = g\Delta\rho d_e^2 / \sigma_I \geq 40$ , the data on spherical cap bubbles indicate that a semi-empirical relation for the terminal velocity expressed in terms of the volume equivalent bubble diameter is appropriate [33]:

$$u_{bl,rise} \approx \left[ \frac{2}{3} \sqrt{\frac{R_n}{d_e}} \right] (gd_e)^{1/2} \approx 0.711 (gd_e)^{1/2} \quad (\text{m/s}) \quad (10.7)$$

where  $u_{bl,rise}$  denotes the rise velocity of a spherical cap bubble in liquid (m/s), and  $d_e$  is the equivalent bubble diameter (m). The term in the bracket is generally a weak function of  $Re_b$ , but for  $Re_b > 100$  the pre-factor is about constant. For gas–liquid

flows the modified coefficient value is confirmed fairly well in several experimental investigations [16, 19, 68, 81].

Even though (10.7) is strictly only valid in liquids, the formula is widely used for calculations of the ideal rise velocity of single bubbles in fluidized beds, when the ratio of bubble to bed diameters is  $d_b/d_t < 0.125$  [17, 48]:

$$u_{br,0} \approx 0.711(gd_b)^{1/2} \quad (10.8)$$

However, experimental data on rise velocities in fluidized beds consisting of group A and B particles indicates that the pre-factor in (10.8) is about 2/3 as for a single spherical cap bubble in liquid. For group D particles the given pre-factor of 0.711 seems appropriate.

Wall effects are found to retard the single bubbles when  $d_b/d_t > 0.125$ . Kunii and Levenspiel [48] proposed that for  $0.125 < d_b/d_t < 0.6$  the rise velocity of a single bubble can be estimated from:

$$u_{br,0} \approx [0.711(gd_b)^{1/2}] \times 1.2 \times \exp\left(-1.49\frac{d_b}{d_t}\right) \quad (10.9)$$

For  $d_b/d_t > 0.6$ , the bed operates in the slugging regime which is not very interesting from a chemical reactor engineering point of view.

In reactor modeling we need to deal with the behavior of the bubbling bed as a whole rather than single rising bubbles. In extending the simple two-zone theory, Davidson and Harrison [17] proposed that the average velocity of bubbles in a freely bubbling bed can be approximated by:

$$u_b = U_b^s + u_{br,0} \approx U_{in}^s - U_{mf}^s + u_{br,0} \quad (10.10)$$

where  $u_{br,0}$  is the ideal rise velocity of an isolated bubble of the same size and computed from (10.8). This relation and the arguments for its use were first presented by Nicklin [60] for gas–liquid systems determining the rise velocity of a single bubble in a cloud of gas bubbles rising through a stagnant liquid, and later used by Davidson and Harrison [17] (p. 28) for bubbles in fluidized beds.

The relation (10.10) is not generally valid but considered to give a fair approximation of the average flow rate of bubbles when  $U_{in}^s$  is close to  $U_{mf}^s$  for all types of particles, and for all velocities of interest considering larger type B and type D particles. However, in large diameter beds consisting of fine particles and operated at higher gas velocities the real bubble rise velocity is several times the velocity predicted by (10.10). This deviation is primarily caused by the existence of preferred emulsion flow patterns [47, 48]. For small B and fine A particles the emulsion zone gas and solids are not really stagnant but develop distinct flow patterns, frequently referred to as *gulf streaming*, induced by the uneven rise or channeling of gas bubbles. In these gulf streaming patterns the bubbles rise in bubble rich regions with less friction thus a substantially higher mean bubble rise velocity occur in these zones. In small and narrow beds this flow pattern might be reduced or prevented by

the wall friction. Several modified relations for the average bubble rise velocity in dense fluidized beds have been reported over the years, each of them valid for particular Geldart solids, bed designs and operating conditions. Kunii and Levenspiel [47], for example, proposed a correlation for Geldart A solids with  $d_t \leq 1$  (m):

$$u_b = 1.55 \left\{ (U_{in}^s - U_{mf}^s) + 14.1(d_b + 0.005) \right\} d_t^{0.32} + u_{br,0} \quad (\text{m/s}) \quad (10.11)$$

A similar correlation was given for Geldart B solids with  $d_t \leq 1$  (m):

$$u_b = 1.6 \left\{ (U_{in}^s - U_{mf}^s) + 1.13d_b^{0.5} \right\} d_t^{1.35} + u_{br,0} \quad (\text{m/s}). \quad (10.12)$$

### 10.7.1.3 The Davidson-Harrison Model for Gas Flow Around Bubbles

The first model for the movement of both gas and solids and the pressure distribution around single rising bubbles was given by Davidson and Harrison [17] (Chap. 4). Two versions of the model were developed, considering two- and three-dimensional fluidized beds. The theory is based on the following assumptions:

- There is no solids in a gas bubble. A three-dimensional bubble is spherical, whereas a two-dimensional bubble is cylindrical.
- As a bubble rises, the particles move aside, as would an incompressible inviscid fluid having the same bulk density as the whole bed at incipient fluidization  $\rho_s(1 - \varepsilon_{mf}) + \rho_g \varepsilon_{mf}$ .
- The gas flows in the emulsion zone as an incompressible viscous fluid. The relative velocity between the gas and the solid particles must satisfy Darcy's law:

$$\mathbf{v}_g - \mathbf{v}_s = -K \nabla p \quad (10.13)$$

where  $K$  is a permeability constant characteristic of the particles and the fluidizing fluid.

From potential flow theory, invoking the given model assumptions, the pressure distribution in the bed can be found by solving a Laplace equation. The boundary conditions used express that far from a single bubble an undisturbed pressure gradient exist as given by (10.2), and that the pressure in the bubble is constant. Then, after the pressure distribution is known the flow pattern for the solids and the gas in the vicinity of a rising bubble can be calculated. The solution shows that the pressure in the lower part of the bubble is lower than that in the surrounding bed, whereas in the upper part it is higher. For this reason the gas flows into the bubble from below and leaves at the top. A distinct difference in the gas flow pattern has been identified, depending on whether the bubble rises faster or slower than the emulsion gas. The gas flow pattern is thus classified dependent on the relative velocity between a single bubble  $u_{br,0}$  and the emulsion gas  $u_e = U_{mf}^s / \varepsilon_{mf}$  far from the bubble.

For slow bubbles ( $u_{br,0} < u_e$ ) in beds consisting of large particles the emulsion gas rises faster than the bubble, hence the faster rising emulsion gas shortcuts through the rising bubble on its way through the bed. The emulsion zone gas enters the bottom of the bubble and leaves at the top. Within the bubble an annular ring of gas is forced to circulate as it moves upwards with the bubble. For a fast bubble ( $u_{br,0} > u_e$ ) in beds consisting of small particles the emulsion gas rises slower than the bubble, but still the emulsion zone gas enters the bottom of the bubble and leaves at the top. However, since the bubble is rising faster than the emulsion gas, the gas leaving the top of the bubble is swept around and returns to the base of the bubble. The region around the bubble penetrated by this circulating gas is called the *cloud*. The rest of the gas in the bed does not mix with the recirculating gas but moves aside as the fast bubble with its cloud passes by. The cloud zone might be considered infinite in thickness at  $u_{br,0} = u_e$ , but thins with increasing bubble velocity. For very fast bubbles,  $u_{br,0}/u_e > 5$ , the cloud is very thin and most of the gas stays within the bubble. In general slow cloudless bubbles occurs in beds of coarse particles (group D, or B) while fast bubbles with thin clouds are typically observed for group A and B particles at high gas velocities.

For a two-dimensional bed the cloud size is given by [17, 18]:

$$\frac{R_c^2}{R_b^2} = \frac{u_{br,0} + u_e}{u_{br,0} - u_e} \quad (10.14)$$

For a three-dimensional bed the cloud size is given by [17, 18]:

$$\frac{R_c^3}{R_b^3} = \frac{u_{br,0} + 2u_e}{u_{br,0} - u_e} \quad (10.15)$$

For a two-dimensional bed the ratio of cloud to bubble size is defined as [48]:

$$f_c = \frac{R_c^2}{R_b^2} \approx \frac{u_{br,0} + u_e}{u_{br,0} - u_e} \approx \frac{2u_e}{u_{br,0} - u_e} \approx \frac{2U_{mf}^s/\varepsilon_{mf}}{u_{br,0} - U_{mf}^s/\varepsilon_{mf}} \quad (10.16)$$

For a three-dimensional bed the ratio of cloud to bubble volume is defined as [48]:

$$f_c = \frac{R_c^3}{R_b^3} = \frac{u_{br,0} + 2u_e}{u_{br,0} - u_e} \approx \frac{3u_e}{u_{br,0} - u_e} \approx \frac{3U_{mf}^s/\varepsilon_{mf}}{u_{br,0} - U_{mf}^s/\varepsilon_{mf}} \quad (10.17)$$

These estimates for  $f_c$  are obtained considering the particular case when  $u_{br,0} \approx u_e$ .

This simple theory also provides estimates of the gas exchange between the bubble and the emulsion zone. For a two-dimensional bed of unit thickness the flow of gas through the bubble is  $v = 4u_e\varepsilon_{mf}r_b$ , and for a three-dimensional bed the flow of gas through the bubble is  $v = 3u_e\varepsilon_{mf}\pi r_b^2$ . Rowe [68] and Davidson et al. [18] summarized the experimental investigations of the properties of bubbles and clouds,

explained the elementary theories using nice illustrations and provided pictures of the physical phenomena observed.

#### 10.7.1.4 The Wake Region

In an early study Rowe and Partridge [67] (see also [68]) did show that gas fluidized beds are characterized by the formation of bubbles which rise through denser bed zones of the bed and determine a gross scale gas and solid flow pattern. It was observed that like a single bubble in liquid, a rising bubble in a fluidized bed drags a wake of material consisting of a gas–solid mixture up the bed behinds it. Close to the bottom of the bed, just above the gas distributor, solids are entrained by the rising bubbles to form the bubble wake. There is also a continuous interchange of solids between the wake and emulsion as the bubble rise. At the top of the bed the wake solids rejoin the emulsion to move down the bed. The bubble wake fraction is given by the volume ratio of the wake to the bubble:

$$f_w = \frac{V_w}{V_b} \quad (10.18)$$

The wake volume  $V_w$  is defined as the volume occupied by the wake within the sphere that circumscribes the bubble. The wake fraction is normally determined from experimental analysis [48].

#### 10.7.1.5 Bubble Size

In bubbling fluidized beds there are several mechanisms affecting the bubbles properties [18, 48, 67, 68]. The main mechanisms determining the mean bubble size are bubble growth, bubble coalescence and bubble breakage. The primary bubble growth mechanism for a single bubble unaffected by other bubbles is gas transfer from the emulsion zone into the bubble. In a freely bubbling bed the main mechanism for bubble growth is bubble-bubble coalescence. Binary breakage of bubbles frequently occur as a result of small disturbances, often proceeded by a slight flattening of the bubble, initiated near the top of the roof of the bubble and these rapidly grow in a cutting edge of particles that may divide the parent bubble into two equal or unequal daughter bubbles. Later these daughter bubbles commonly re-combine either by gas leakage from one bubble to the other or because a small bubble falling behind the larger one is caught in its wake and coalescence. Experiments have shown that in beds consisting of B type particles the bubbles increase steadily, whereas in beds consisting of type A particles the bubbles grow rapidly until they reach a stable size determined by a state of equilibrium between the coalescence and breakage processes [48]. When performing experimental investigations of bubble properties two dimensional beds have proved to be useful [34]. These two-dimensional columns are of rectangular cross section, the width being considerably greater than the thick-

ness. The fluidized particles are contained in the gap between two transparent faces, separated by 2–3 cm. The bubbles span the bed thickness and are thus viewed. However, while these two-dimensional columns are useful for qualitative purposes, there are important quantitative differences between the two- and three-dimensional fluid bed flow behavior. These differences arise from quantitative differences in rise velocities of isolated bubbles, bubble coalescence properties, bubble shape and wake characteristics, reduced solids mixing, etc. To characterize the bubble properties in three dimensional dense beds intrusive probes are normally used [73]. For modeling purposes it is important to distinguish between the relations obtained characterizing two- and three-dimensional beds.

The equivalent bubble diameter  $d_e$ , defined as the diameter of a spherical bubble with a volume equal to the average bubble volume, is often used as a measure of bubble size. A representative relation for the equivalent bubble diameter in a three-dimensional bed with B particles supported by a perforated plate distributor was given by [77]:

$$d_e = d_{e,0}[1 + 27.2(U_{in}^s - U_{mf}^s)]^{1/3}(1 + 6.84z)^{1.21} \quad (\text{m}) \quad (10.19)$$

where  $d_{e,0}$  denotes the initial bubble size at the distributor, and  $z$  is the position above the distributor.

A more general relation for the equivalent bubble diameter in three-dimensional beds was derived by Darton et al. [15]:

$$d_e = \frac{0.54}{g^{1/5}}(U_{in}^s - U_{mf}^s)^{2/5}(z + 4\sqrt{A_0})^{4/5} \quad (\text{m}) \quad (10.20)$$

where  $A_0$  is the *catchment area* for the bubble stream at the distributor plate, which characterize different distributors, and is usually the area of plate per orifice. For a porous plate distributor a typical value  $A_0 \approx 5.6 \times 10^{-5} \text{ (m}^2\text{)}$  was proposed.

To determine the growth of circular bubbles in two-dimensional fluidized beds Lim et al. [54] modified the relation of Darton et al. [15] and proposed:

$$d_e = \left[ \frac{8(U_{in}^s - U_{mf}^s)(2^{3/4} - 1)}{\pi \lambda g^{1/2}} z + d_{e,0}^{3/2} \right]^{2/3} \quad (\text{m}) \quad (10.21)$$

The initial equivalent bubble diameter just above the distributor is given by:

$$d_{e,0} = \left[ \frac{8(U_{in}^s - U_{mf}^s)A_0}{\pi \lambda g^{1/2}} \right]^{2/3} \quad (\text{m}) \quad (10.22)$$

The dimensionless proportionality constant  $\lambda \sim 2$  is related to the distance a bubble travels in a stream before coalescing with the adjacent stream to form a single stream of larger bubbles.

### 10.7.1.6 The Basic Two-Zone Model

A number of fluidized bed reactor model versions are based on the cross sectional averaged two-phase transport equations as presented in Sect. 3.4.7. Due to the vigorous particle flow the fluidized beds were often considered to operate under essentially uniform temperature conditions, so no differential energy balance was supposedly required. Under such operating conditions, a global CSTR heat balance was sufficient to determine the uniform operating temperature and the necessary heating/cooling capacity. In addition, the necessary species mole balance was deduced from (3.505). The solids were considered to be completely mixed in the dense phase and was essentially stagnant, so only an overall mass balance was generally needed for the solid phase. For the particular case of an irreversible gas solid catalyzed reaction with no accompanying volume change, the mole balance for a species A in the interstitial gas phase moving through the emulsion zone is frequently simplified assuming axially constant transport parameters (i.e.,  $f_e$ ,  $u_e$ ,  $D_e$ , and  $k_{be}$ ) [28, 37, 47, 48, 83, 84]:

$$f_e \frac{\partial C_{Ae}}{\partial t} + f_e u_e \frac{\partial C_{Ae}}{\partial z} = f_e D_e \frac{\partial^2 C_{Ae}}{\partial z^2} + k_{be}(C_{Ab} - C_{Ae}) + r_{Ae} \rho_e f_e \quad (10.23)$$

where  $C_{Ae}$  represents the cross sectional average mole concentration of A in the emulsion zone gas (kmol/m<sup>3</sup>),  $U_e^s = f_e u_e$  the superficial velocity of the emulsion zone gas (m<sup>3</sup>/m<sup>2</sup> s),  $u_e$  the interstitial emulsion gas velocity (m/s),  $D_e$  an effective diffusivity for the emulsion gas (m<sup>2</sup>/s),  $k_{be}$  an interchange mass transfer rate coefficient per unit volume of bubble gas (m<sup>3</sup>/m<sup>3</sup> s),  $r_{Ae}$  reaction rate in emulsion zone (kmol/kg s),  $f_e$  is the fraction of the bed gas volume taken by the emulsion gas (m<sup>3</sup>/m<sup>3</sup>), and  $\rho_e$  the mass concentration of the catalyst particles in the emulsion zone (kg/m<sup>3</sup>).

The corresponding mole balance for species A in the bubble zone is:

$$f_b \frac{\partial C_{Ab}}{\partial t} + f_b u_b \frac{\partial C_{Ab}}{\partial z} = f_b D_b \frac{\partial^2 C_{Ab}}{\partial z^2} - k_{be}(C_{Ab} - C_{Ae}) + r_{Ab} \rho_b f_b \quad (10.24)$$

where  $C_{Ab}$  represents the cross sectional average mole concentration of A in the bubble zone (kmol/m<sup>3</sup>),  $U_b^s = f_b u_b$  the superficial velocity of the bubble zone gas (m<sup>3</sup>/m<sup>2</sup> s),  $D_b$  an effective diffusivity for the bubble gas (m<sup>2</sup>/s),  $r_{Ab}$  reaction rate in bubble zone (kmol/kg s),  $f_b$  the volume fraction of the bed gas taken by the bubble gas (m<sup>3</sup>/m<sup>3</sup>), and  $\rho_b$  the mass concentration of the catalyst particles in the bubble zone (kg/m<sup>3</sup>). Moreover, it is noted that  $f_e$  and  $f_b$  are related  $1 = f_e + f_b$ .

The overall outlet concentration  $C_{A,out}$  is calculated as:

$$U_{in}^s C_{A,out} = f_b u_b C_{Ab} + f_e u_e C_{Ae} \quad (10.25)$$

in which  $U_{in}^s$  denotes the overall superficial gas velocity ( $\text{m}^3/\text{m}^2 \text{ s}$ ).

The model equations are normally solved applying the following initial and boundary conditions:

Bubble zone [14]:

$$-D_b \frac{dC_{Ab}}{dz} \Big|_{z=0} = u_b (C_{Ab}|_{z=0} - C_{Ab}) \quad (10.26)$$

$$\frac{dC_{Ab}}{dz} \Big|_{z=L} = 0 \quad (10.27)$$

Emulsion zone [14]:

$$-D_e \frac{dC_{Ae}}{dz} \Big|_{z=0} = u_e (C_{Ae}|_{z=0} - C_{Ae}) \quad (10.28)$$

$$\frac{dC_{Ae}}{dz} \Big|_{z=L} = 0 \quad (10.29)$$

The undetermined model parameters like  $U_b^s$ ,  $u_b$ ,  $k_{be}$ ,  $D_e$ ,  $f_e$ ,  $f_b$ ,  $u_e$  and  $U_e^s$  are approximated from empirical correlations determined by experimental measurements.  $U_{in}^s$  and  $\varepsilon_{mf}$  are generally measured or specified, thus  $U_{mf}^s$  can be determined from (10.3).

Recently, Fang et al. [25] and Rout and Jakobsen [66] extended the basic two-zone model for simulating non-isothermal  $\text{CO}_2$  capture processes by including the corresponding differential heat balances in terms of temperature. Moreover, Rout and Jakobsen [66] did also include transient terms in the model in order to enable simulations of the dynamic SE-SMR process.

### 10.7.1.7 The Davidson-Harrison Two-Zone Model

The Davidson and Harrison [17, 18] bubbling bed reactor model represents one of the first modeling attempts that was based on bubble dynamics. The model rest on the following assumptions:

- The reactor operates at steady state, thus the transient terms in (10.23) and (10.24) disappear.
- The gas bubble are evenly distributed throughout the bed and are of equal size.
- The bubble zone gas flow can be described by a plug flow model, hence the bubble zone dispersion term in (10.24) vanishes.
- No solids in the bubbles, thus no catalytic reaction takes place in the bubble zone gas.

- The emulsion zone gas flows with a superficial velocity  $U_{mf}^s$  and is either considered completely mixed or plug flow.
- Gas is exchanged between the non-reactive bubble and the reactive emulsion zones by a combined molecular and convective transport flux.

Species mass balances were developed for the two zones and solved analytically for first order reactions. Thus, for the case of a completely mixed emulsion zone the concentration of a reactant leaving this zone is given by:

$$C_e = \frac{C_{in}(1 - f_b e^{-X})}{1 - f_b e^{-X} + \frac{kL_{mf}}{U^s}} \quad (10.30)$$

where  $X = K_{be}L/U_b^s$  is the interface exchange parameter,  $L$  represents the bed height and  $U_b^s$  the bubble velocity, and  $f_b = 1 - U_{mf}^s/U^s$ .

For the bubble zone operated in plug flow:

$$C_b = C_e + (C_{in} - C_e)e^{-X} \quad (10.31)$$

The concentration of unconverted reactant  $C_{out}$  leaving the bed as a whole was then found from:

$$C_{out} = f_b C_b + (1 - f_b)C_e \quad (10.32)$$

The overall fraction of unconverted reactant becomes:

$$\frac{C_{out}}{C_{in}} = f_b e^{-X} + \frac{(1 - f_b e^{-X})^2}{1 - f_b e^{-X} + \frac{kL_{mf}}{U^s}} \quad (10.33)$$

For the case when the emulsion gas phase is in plug flow, the overall fraction unconverted reactant leaving the bed becomes:

$$\frac{C_{out}}{C_{in}} = \frac{1}{m_1 - m_2} \left[ m_1 e^{-m_2 L} \left( 1 - \frac{m_2 L U_{mf}^s}{X U^s} \right) - m_2 e^{-m_1 L} \left( 1 - \frac{m_1 L U_{mf}^s}{X U^s} \right) \right] \quad (10.34)$$

where  $m_1$  and  $m_2$  are obtained from:

$$2L(1 - f_b)m = \left( X - \frac{kL_{mf}}{U^s} \right) \pm \left[ \left( X - \frac{kL_{mf}}{U^s} \right)^2 - 4 \frac{kL_{mf}}{U^s} X(1 - f_b) \right]^{1/2} \quad (10.35)$$

In the latter expression  $m = m_1$  with the positive sign and  $m = m_2$  with the negative sign.

The details of the model derivation and the analytical solution can be found in [17, 69, 83, 84]. It is noted that this model was developed before the importance of bubble clouds and wakes were realized. Although this model is not derived from first principles and uses empirical information, the model predictions have been found to agree fairly well with experimental data in a number of cases and may thus be

adequate for design purposes. However, the empirical relationships are derived from experiments on laboratory scale equipment, thus these relations can not be applied to large industrial units without validation.

### 10.7.1.8 The van Deemter Two-Zone Model

This model represents one of the first modeling approaches used to describe large industrial beds that has been fully documented and discussed in the open literature. The model was adopted by the Shell company designing a fluidized bed reactor for their solid catalyzed hydrogen chloride oxygen process. However, the model has many of the same limitations as the Davidson-Harrison model because it was developed before the importance of bubble clouds and wakes were realized.

The fairly general transport equations constituting the basic two-zone model, given in (10.23) and (10.24), were simplified making the van Deemter model specific assumptions [27, 75, 84]:

- The reactor operates at steady state, thus the transient terms disappear.
- The bubble gas flow can be described by a plug flow model, hence the bubble zone dispersion term vanishes.
- No solids in the bubbles so no catalytic reaction takes place in the bubble zone, thus the reaction term disappears in the bubble gas mole balance.

For a single reaction, a generic cross sectional average species mole balance for component A in the bubble zone gas can thus be written as:

$$f_b u_b \frac{dC_{Ab}}{dz} = -k_{be}(C_{Ab} - C_{Ae}) \left( \frac{\text{kmol}}{\text{m}^3 \text{s}} \right) \quad (10.36)$$

The corresponding cross sectional average species mole balance for component A in the emulsion zone gas is written as:

$$f_e u_e \frac{dC_{Ae}}{dz} = f_e D_e \frac{d^2 C_{Ae}}{dz^2} + k_{be}(C_{Ab} - C_{Ae}) - r_{Ae} \rho_e f_e \left( \frac{\text{kmol}}{\text{m}^3 \text{s}} \right) \quad (10.37)$$

The overall outlet concentration  $C_{A,out}$  is calculated as:

$$U_{in}^s C_{A,out} = f_b u_b C_{Ab} + f_e u_e C_{Ae} \quad (10.38)$$

in which  $U_{in}^s$  denotes the overall superficial gas velocity ( $\text{m}^3/\text{m}^2 \text{s}$ ).

The model equations are normally solved applying the following initial and boundary conditions:

Bubble zone:

$$C_{Ab} = C_{Ab}|_{z=0} \quad (10.39)$$

Emulsion zone [14]:

$$-D_e \frac{dC_{Ae}}{dz} \Big|_{z=0} = u_e (C_{Ae}|_{z=0} - C_{Ae}) \quad (10.40)$$

$$\frac{dC_{Ae}}{dz} \Big|_{z=L} = 0 \quad (10.41)$$

The undetermined model parameters like  $U_b^s$ ,  $u_b$ ,  $k_{be}$ ,  $D_e$ ,  $f_e$ ,  $f_b$ ,  $u_e$  and  $U_e^s$  were approximated from empirical correlations determined by experimental measurements.  $U_{in}^s$  and  $\varepsilon_{mf}$  are generally measured or specified, thus  $U_{mf}^s$  can be determined from (10.3).

A typical correlation for  $k_{be}$  is given by [27, 69]:

$$\frac{U_{in}^s}{f_b k_{be}} \approx (1.8 - \frac{1.06}{d_t^{0.25}})(3.5 - \frac{2.5}{Z^{1.4}}) \quad (\text{m}) \quad (10.42)$$

where  $Z$  is the total reactor height (m).

The effective diffusivity in the emulsion zone may be approximated by [6]:

$$D_e \approx 0.35(gU_{in}^s)^{1/3} d_t^{4/3} \quad (\text{m}^2/\text{s}) \quad (10.43)$$

In the basic two-zone model a prescribed fraction of the total gas flow rate through the bed, which is coinciding with the minimum fluidization operating conditions, is assumed to move through the emulsion zone [17, 74]. The relative velocity between the interstitial gas and the solids in the emulsion zone is thus  $u_e = U_{mf}^s/\varepsilon_{mf}$ . The rest of the gas constitutes the bubble zone. The superficial bubble gas velocity is thus generally approximated as:

$$U_b^s = f_b u_b \approx U_{in}^s - U_{mf}^s \quad (\text{m}^3/\text{m}^2\text{s}) \quad (10.44)$$

Likewise, the superficial emulsion gas velocity is approximated as:

$$U_e^s = f_e u_e \approx U_{mf}^s = u_e \varepsilon_{mf} \quad (\text{m}^3/\text{m}^2\text{s}) \quad (10.45)$$

The average bubble rise velocity (10.10) is approximated by the bubble rise velocity among a swarm of bubbles [77]:

$$u_b = U_e^s - U_{mf}^s + u_{br,0} \approx u_{br,0} \approx K\sqrt{gd_b} \quad (10.46)$$

where  $K = 0.64$  when  $d_t < 0.1$  (m),  $K = 1.6d_t^{0.4}$  when  $0.1 < d_t < 1.0$  (m), and  $K = 1.6$  when  $d_t > 1.0$  (m).

The flow pattern for solids is generally downward near the wall and upward in the central core. This particle movement also affects the gas flow in the emulsion zone. In this model the net rise velocity of solids is neglected, hence  $u_s = 0$ .

For a perforated plate distributor the bubble size might be approximated by (10.19).

### 10.7.1.9 The Kunii-Levenspiel Three-Zone Model

The celebrated Kunii-Levenspiel [44, 45, 47, 48] (p. 289) reactor model presented in this section was designed for the particular case of fast bubbles in vigorously bubbling beds which is relevant for industrial applications with Geldart A and AB solids. In such beds there are definite gross mixing patterns for the solid, downward near the wall and upward in the central core. This has a marked effect on the gas flow in the emulsion zone, which is also forced downward near the wall. However, based on experimental data analysis, Kunii and Levenspiel found that at gas flow rates above  $U_{in}^s/U_{mf}^s \sim 6 - 11$  there are practically no net gas flow through the emulsion zone. To take these observations into account a three zone model was proposed in which many ideas from the Davidson bubble theory, the Davidson-Harrison and the van Deemter reactor models were adapted. The Rowe cloud and wake observations were also considered. The basic model assumptions were:

- The bed is assumed to consist of three zones, the bubble, cloud and emulsion, with the wake region considered to be a part of the cloud zone.
- For industrial relevant operating conditions well above minimum fluidization,  $U_{in}^s \gg U_{mf}^s$  and practically all the moving gas is transported in the bubble zone. In this fast bubbling regime, for which  $u_b > 5U_{mf}^s/\varepsilon_{mf}$ , the clouds are very thin.
- Interchange mass transfer coefficients are used to account for the mass transfer between the zones.
- The rising bubbles contain no solid.
- The bubble zone operates under plug flow conditions.
- The cloud and emulsion zones are stagnant ( $u_e \approx u_c \approx 0$ ).
- Spherical bubbles of uniform size accompanied by wakes throughout the bed.
- First-order reaction is assumed. The catalytic reaction rate is given in accordance with modern literature [27].

Bubble zone:

For a single catalytic reaction, a generic cross sectional average species mole balance for component A in the bubble zone gas can be written as:

$$u_b \frac{dC_{Ab}}{dz} = -k_{bc}(C_{Ab} - C_{Ac}) - r_{Ab}\rho_b \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.47)$$

where  $k_{bc}$  denotes the interchange coefficient determining the mass transfer between the bubble and cloud gas zones, referred to unit bubble gas volume ( $\text{m}^3/\text{m}^3\text{s}$ ), and  $C_{Ac}$  the molar concentration of species A in the cloud zone gas ( $\text{kmol}/\text{m}^3$ ).

Cloud zone:

For a single reaction a generic species mole balance for component A in the stagnant cloud zone gas is written as:

$$k_{bc}(C_{Ab} - C_{Ac}) = r_{Ac}\rho_c \frac{V_c}{V_b} + k_{ce}(C_{Ac} - C_{Ae}) \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.48)$$

where  $V_c$  denotes the volume of the cloud zone ( $\text{m}^3$ ),  $V_b$  the volume of the bubble zone ( $\text{m}^3$ ),  $\rho_c$  the mass concentration of the catalyst particles in the cloud zone ( $\text{kg}/\text{m}^3$ ), and  $k_{ce}$  denotes the interchange coefficient determining the mass transfer between the cloud and emulsion zones, referred to unit bubble volume ( $\text{m}^3/\text{m}^3\text{s}$ ).

For a single reaction a generic species mole balance for component A in the stagnant emulsion zone gas is written as:

$$k_{ce}(C_{Ac} - C_{Ae}) = r_{Ae}\rho_e \frac{f_e}{f_b} \approx r_{Ae}\rho_e \frac{1 - f_b}{f_b} \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.49)$$

In general, the plug flow model can be solved numerically with appropriate initial conditions for the ODE (10.47):

$$C_{Ab} = C_{Ab}|_{z=0} \quad (10.50)$$

Analytical solution:

The model can be solved analytically for first order reactions. Eliminating the unknown  $C_{Ac}$  and  $C_{Ae}$  concentrations from the model equations, we obtain:

$$f_b u_b \frac{dC_{Ab}}{dz} = K_r C_{Ab} \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.51)$$

where the overall rate coefficient  $K_r$  contains all the interfacial transfer resistances as well as the reaction resistance terms. The overall rate coefficient  $K_r$  can be defined as [27]:

$$K_r = k \left[ \rho_b + \frac{1}{\frac{k}{k_{bc}} + \frac{1}{\rho_c \frac{V_c}{V_b} + \frac{1}{\frac{k}{k_{ce}} + \frac{1}{\rho_e \frac{1-f_b}{f_b}}}}} \right] \quad (1/\text{s}) \quad (10.52)$$

Integration over the whole reactor bed from  $z = 0$  to  $z = L$  gives:

$$C_{Ab} = C_{A,in} \exp\left(-\frac{K_r L}{U_b^s}\right) \quad \left( \frac{\text{kmol}}{\text{m}^3} \right) \quad (10.53)$$

The celebrated K-L model did gain its popularity because it is very simple, yet developed for large scale industrially relevant flows and considers most of the pertinent bubbling bed phenomena.

Over the years the range of uses of the K-L model has been extended to chemical processes that can not be described by first order kinetics. For these problems no analytical solution can be obtained so the resulting set of DAEs are solved numerically.

Gascon et al. [29], for example, investigated the behavior of a two zone fluidized bed reactor for the propane dehydrogenation and n-butane partial oxidation processes employing the K-L model framework. In any case the undetermined model parameters are determined from appropriate empirical correlations [44, 45, 47, 48]. The mass transfer coefficients, all based on unit bubble volume, can be obtained from:

$$k_{bc} = 4.5 \frac{u_{mf}^s}{d_b} + 5.85 \left( \frac{D_{Am} g^{1/4}}{d_b^{5/4}} \right) \quad (\text{m}^3/\text{m}^2\text{s}) \quad (10.54)$$

$$k_{ce} = 6.78 \left( \frac{\varepsilon_{mf} D_{Am} u_b}{d_b^3} \right)^{1/2} \quad (\text{m}^3/\text{m}^2\text{s}) \quad (10.55)$$

where  $D_{Am}$  is the diffusivity for species A in the mixture ( $\text{m}^2/\text{s}$ ).

In the two-zone view the solids in the bubble zone is ignored ( $\varepsilon_b \approx 1$ ), thus the overall void fraction in the bubbling bed is:

$$\varepsilon_{ov} = f_b \varepsilon_b + (1 - f_b) \varepsilon_e \approx f_b + (1 - f_b) \varepsilon_e \quad (10.56)$$

If  $\varepsilon_{ov}$  and  $f_b$  are known from experiments,  $\varepsilon_e$  can be determined by this equation. However, in many cases  $\varepsilon_{ov}$  and  $f_b$  are unknown, so  $\varepsilon_e$  cannot be determined in this way. For modeling purposes Kunii and Levenspiel [47] proposed some rough approximations. For beds of Geldart A solids,  $\varepsilon_e \approx \varepsilon_{mb}$ , whereas for beds of Geldart B and D solids,  $\varepsilon_e \approx \varepsilon_{mf}$ . In the latter case, where  $\varepsilon_e \approx \varepsilon_{mf}$ , the volume balance over the bed can be written as:

$$1 - \varepsilon_{ov} \approx (1 - f_b)(1 - \varepsilon_{mf}) \quad (10.57)$$

The volume fraction of the bed consisting of bubbles  $f_b$  is determined by the prevailing flow regime. For fast bubbles in vigorously bubbling beds, where  $u_b > 5U_{mf}^s/\varepsilon_{mf}$  and  $U_{in}^s \gg U_{mf}^s$ , the clouds are thin and one may use the following approximation [47]:

$$f_b = \frac{V_b}{V_r} \approx \frac{U_{in}^s - U_{mf}^s}{u_b - U_{mf}^s} \approx \frac{U_{in}^s}{u_b} \quad (10.58)$$

The volume fraction of bed gas comprising the emulsion zone gas is:

$$f_e = 1 - f_b = \frac{u_b - U_{in}^s}{u_b - U_{mf}^s} \quad (10.59)$$

The distribution of solids in the three regions were defined by:

$$\gamma_b = \frac{V_{bs}}{V_b}, \quad \gamma_c = \frac{V_{cs}}{V_b}, \quad \gamma_e = \frac{V_{es}}{V_b} \quad (10.60)$$

A material balance for the solids and (10.57) then relates these  $\gamma$ -values:

$$f_b(\gamma_b + \gamma_c + \gamma_e) = 1 - \varepsilon_{ov} = (1 - \varepsilon_{mf})(1 - f_b) \quad (10.61)$$

hence

$$\gamma_e = \frac{(1 - \varepsilon_{mf})(1 - f_b)}{f_b} - \gamma_b - \gamma_c \quad (10.62)$$

Values of  $\gamma_c$  have been estimated considering a spherical bubble and accounting for the solids in both the cloud and wake regions:

$$\gamma_c = (1 - \varepsilon_{mf})\left(\frac{V_c}{V_b} + \frac{V_w}{V_b}\right) \approx (1 - \varepsilon_{mf})\left(\frac{3U_{mf}^s/\varepsilon_{mf}}{0.711(gd_b)^{1/2} - U_{mf}^s/\varepsilon_{mf}} + f_w\right) \quad (10.63)$$

The volume of the cloud surrounding each of the fast rising bubbles is given by:

$$\frac{V_c}{V_b} \approx \frac{3U_{mf}^s/\varepsilon_{mf}}{0.711(gd_b)^{1/2} - U_{mf}^s/\varepsilon_{mf}} \quad (10.64)$$

Like bubbles in liquids, it might be expected that every rising bubble in fluidized beds has an associated wake of material rising behind it. The ratio of wake to bubble volume  $f_w = V_w/V_b$  has to be determined by experiments, but the void fraction of the wake is frequently assumed to be that of the emulsion zone. Moreover, experiments in beds of uniformly sized bubbles indicates that  $\gamma_b \approx 0.001 \sim 0.01$ . One may imagine that just above the distributor solid is entrained by the rising bubbles to form the bubble wake. This solid is carried up the bed with the bubbles at velocity  $u_b$  and is continually exchanged with fresh emulsion solid. At the top of the bed the wake solids rejoin the emulsion to move down the bed at velocity  $u_s$ . The upward velocity of gas flowing through the emulsion is thus:

$$u_e = \frac{u_{mf}}{\varepsilon_{mf}} - u_s \quad (10.65)$$

Under particular operating conditions the circulation of solids may then get high enough so that the gas flow is directed downward in the emulsion. However, in vigorous bubbling beds the rise velocity of solids is about zero:

$$u_s \approx 0 \quad (10.66)$$

The distribution of solids  $\gamma$  used in the original Kunii and Levenspiel model [48] can be linked to the bulk solid density in the following manner [27]. The bulk density of solids in the bubble zone yields:

$$\rho_b = \gamma_b \rho_s, \quad (10.67)$$

where  $\rho_s$  is the mass density of the solid catalyst material.

The bulk density of solids in the cloud and wake zones is given by:

$$\rho_c = \gamma_c \rho_s \frac{V_b}{V_c} \quad (10.68)$$

in which  $V_c$  is the volume of the cloud zone, and  $V_b$  is the volume of the bubble consisting of pure gas.

The bulk density of solids in the emulsion zone is obtained from:

$$\rho_e = \gamma_e \rho_s \frac{V_b}{V_e} = \gamma_e \rho_s \frac{f_b}{f_e} \approx \gamma_e \rho_s \frac{f_b}{1 - f_b} \quad (10.69)$$

In the latter relation the volume of the thin cloud zone is ignored.

### 10.7.2 Turbulent Fluidized Beds

Models for turbulent fluidized bed reactors are normally based on one dimensional gas flow, despite the significant radial density gradients observed experimentally [35, 36].

For reactors operated in the turbulent regime the following reactor modeling approaches have been proposed:

- The first modeling attempts employed one dimensional pseudo-homogeneous plug flow models for the gas phase. For first order reactions the model can be written as:

$$U_g^s \frac{dC}{dz} = R_C = -k(1 - \varepsilon)C \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.70)$$

The customary initial condition is:

$$C = C_{in} \quad (10.71)$$

- For non-ideal flows the modeling approach has been extended adapting one dimensional pseudo-homogeneous axial dispersion models for the gas phase. The latter model can be written as:

$$U_g^s \frac{dC}{dz} = \frac{d}{dz} (D_{g,ax} \frac{dC}{dz}) - k(1 - \varepsilon)C \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.72)$$

The boundary conditions are [14]:

$$C_{in}U_{g,in}^s = CU_g^s - D_{g,ax}\frac{dC}{dz} \quad \text{at } z = 0 \quad (10.73)$$

$$\frac{dC}{dz} = 0 \quad \text{at } z = L \quad (10.74)$$

The dispersion coefficient for the turbulent regime has been determined from correlations on the form:

$$D_{g,ax} \approx 0.84\varepsilon_{ov}^{-4.445} \quad (\text{m/s}) \quad (10.75)$$

where  $\varepsilon_{ov}$  is the overall void fraction in the turbulent regime.

### 10.7.3 Circulating Fluidized Beds

For reactors operated in the fast fluidization and pneumatic conveying regimes the following modeling approaches have been used [7, 36, 57]:

- One dimensional pseudo-homogeneous plug flow models for the species in the gas phase.

For pneumatic conveying all the particles are evenly dispersed in the gas. This makes contacting ideal or close to ideal. The plug flow model is thus well suited for the dilute transport reactors, but has also been used for the denser fast fluidization regime neglecting gradients in the solids distribution. For first order reactions the model can be written as:

$$U_g^s \frac{dC}{dz} = -k(1 - \varepsilon)C \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.76)$$

The initial condition is:

$$C = C_{in} \quad (10.77)$$

- One dimensional pseudo-homogeneous axial dispersion model for the species in the gas phase.

This model has been used for denser transport reactors and reactors operated in a dilute fast fluidization regime intending to account for the non-ideal flow behavior. For first order reactions the model can be written as:

$$U_g^s \frac{dC}{dz} = \frac{d}{dz} (D_{g,ax} \frac{dC}{dz}) - k(1 - \varepsilon)C \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.78)$$

The boundary conditions are [14]:

$$C_{in}U_{g,in}^s = CU_g^s - D_{g,ax}\frac{dC}{dz} \quad \text{at } z = 0 \quad (10.79)$$

$$\frac{dC}{dz} = 0 \quad \text{at } z = L \quad (10.80)$$

The dispersion coefficient was determined by correlations on the form:

$$D_{g,ax} \approx 0.1953 \times \varepsilon_{ov}^{-4.1197} \quad (\text{m/s}) \quad (10.81)$$

where  $\varepsilon_{ov}$  is the overall void-age in the reactor. This correlation is valid for all the regimes ranging from turbulent fluidization to pneumatic transport.

- Core/annulus models for the gas phase.

Most CFB reactor models designed for the fast fluidization regime make use of the core/annulus approach, which dates back to the work of [9]. These models are based on the experimental data interpretation that two zones exist in the riser at every axial location, an upward moving dilute core zone and a dense annulus zone with high solids concentration. The gas was assumed to pass upward in plug flow through the central core. Some of this gas was exchanged with the outer annular region where the gas is stationary. Each of the two-regions was assumed to be radially uniform. An inter-region mass transfer coefficient and the radius of the core, both assumed to be independent of height, were obtained by fitting the models to experimental axial gas mixing data. The catalyst particles were assumed to be small enough so that both intra-particle diffusion resistances and external particle mass transfer do not need to be considered.

Applying this model to a first order reaction with steady state operation leads to molar balances of the generic form [42]:

Core region:

$$U_g^s \left( \frac{R^2}{r_c^2} \right) \frac{dC_c}{dz} = - \frac{2K}{r_c} (C_c - C_a) - k(1 - \varepsilon_{cs})C_c \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.82)$$

Annulus region:

$$\left( \frac{r_c^2}{R^2 - r_c^2} \right) \frac{2K}{r_c} (C_c - C_a) = -k(1 - \varepsilon_{as})C_a \quad \left( \frac{\text{kmol}}{\text{m}^3\text{s}} \right) \quad (10.83)$$

where  $K$  and  $k$  are the cross flow mass transfer coefficient and first order kinetic rate constant, respectively. Furthermore, Kagawa et al. [42] employed the following model parameters:  $k_c = k(1 - \varepsilon_c)$ ,  $k_a = k(1 - \varepsilon_a)$ ,  $r_c/R = 0.85$ ,  $\varepsilon_c = 0.6\langle\varepsilon_s\rangle_A$ ,  $\varepsilon_a = 2.0\langle\varepsilon_s\rangle_A$ , and  $U_c = U/0.85^2$ .

A common initial boundary condition is:

$$C_c = C_{in} \quad \text{at } z = 0 \quad (10.84)$$

It is recognized that this model is formally analogous to the two-zone bubbling bed model, with the annulus replacing the stagnant dense phase and the dilute core replacing the bubble zone.

As the interest in high velocity fluidized beds operating in the turbulent, fast fluidization and pneumatic conveying regimes has grown, several attempts have been made to provide appropriate reactor models, often by extending the models originally devised for the bubbling bed reactors.

Kunii and Levenspiel [47] presented models for bubbling beds for all types of particles considering the lean phase freeboard and for fast fluidized beds. A free-board entrainment reactor model was developed to account for the extra conversion taking place above dense bubbling beds. For fast fluidized bed reactors the vessel was divided into two zones, a lower dense zone and an upper free-board zone. Later, Kunii and Levenspiel [49, 50] deduced engineering models for determining the performance behavior of a CFB reactor extending the bubbling bed model by adjusting the parameters to the turbulent, fast fluidization and pneumatic conveying regimes.

### 10.7.3.1 The Overall Pressure Balance Around a CFB Loop

In the CFB loop the pressure drop over the riser must be balanced by the pressure imposed by the flow through its accompanying components such as the downcomer and the recirculation device. The pressure drops across the downcomer, the solids circulation and control device, and the riser are the major elements in the pressure balance around the CFB loop. The pressure drop balance is thus such that the sum of the control device, fluidized bed riser and cyclone (piping) pressure drops must equal the downcomer and hopper pressure drops. The hopper pressure drop is usually negligible so that:

$$\Delta p_R + \Delta p_C + \Delta p_{CD} \approx \Delta p_D \quad (10.85)$$

A balance of the pressure around the CFB loop requires quantitative information for the pressure drops in each component. Typical design formulas for the pressure drop associated with the major components in a CFB loop can be given as follows [1, 11, 23, 65].

- Pressure Drop Across the Riser,  $\Delta p_R$ :

For the gas flow in the riser, kinetic energy in the gas phase is partially transferred to the solids phase through gas-particle interactions and is partially dissipated as a result of friction. Under most operating conditions in fluidized beds, gravitational effects dominate the overall gas phase energy consumption. Thus, neglecting the particle acceleration effects, the pressure drop in the riser can be approximated by the weight of the particles:

$$\Delta p_R = \int_0^L \rho_p \epsilon_p g dz = \rho_p \epsilon_p g L \quad (10.86)$$

where  $L$  is the riser height.

- Pressure Drop Through the Cyclone,  $\Delta p_C$ :

Cyclone pressure drop is essentially a consequence of the vortex energy, the solid loading and the gas-wall friction. The main contribution is the suspension vortex energy. Generally, the pressure drop through a cyclone is proportional to the velocity head and approximated by [62]:

$$\Delta p_C = k \rho_g (U_{g,in}^s)^2 \quad (10.87)$$

The value for the coefficient  $k$  may vary from 1–20, depending on the cyclone design [23].

- Pressure Drop Across the Downcomer,  $\Delta p_D$ :

The solids flow in the downcomer is either in a dense fluidized state or in a moving packed state.

The maximum pressure drop through in the downcomer is established when particles are fluidized, a state that can be expressed in terms of the pressure drop under the minimum fluidization condition as [23]:

$$\Delta p_{D,max} = L_D (1 - \alpha_{g,mf}) \rho_p g \quad (10.88)$$

where  $L_D$  is the height of the solids in the downcomer.

- Pressure Drop Through the Solids Flow Control Devices,  $\Delta p_{CD}$ :

If the particles in the downcomer are fluidized, the pressure drop through the mechanical solids flow control device can be expressed as [41]:

$$\Delta p_{CD} = \frac{1}{2 \rho_p (1 - \alpha_{g,mf})} \left( \frac{W_s}{C_0 A_0} \right)^2 \quad (10.89)$$

where  $W_s$  is the solids feeding rate and  $A_0$  is the opening area for the mechanical valve. The coefficient  $C_0 \sim 0.7 - 0.8$  over a variety of systems and control device opening configurations.

The solids flow rate can be controlled by non-mechanical valves such as an  $L$ -valve with a long horizontal leg. The overall pressure drop across an  $L$ -valve is normally calculated as a linear sum of two terms accounting for the pressure drop through the elbow and the pressure drop caused by the gas–solid flow in the horizontal leg [82]:

$$\Delta p_{CD} = \Delta p_{CD,elbow} + \Delta p_{CD,leg} = \frac{1}{2 \rho_p (1 - \alpha_{g,mf})} \left( \frac{W_s}{C_0 A_0} \right)^2 \quad (10.90)$$

where  $C_0 = 0.5$ .

# Chapter 11

## Packed Bed Reactors

The discovery of solid catalysts led to a breakthrough of the chemical process industry. Today most commercial gas-phase catalytic processes are carried out in fixed packed bed reactors.<sup>1</sup> A fixed packed bed reactor consists of a compact, immobile stack of catalyst pellets within a generally vertical vessel. On macroscopic scales the catalyst bed behaves as a porous media. The fixed beds are thus employed as continuous tubular reactors in which the reactive species in the mobile fluid (gas) phase are reacting over the catalyst surface (interior or exterior) in the stationary packed bed. Compared to other reactor types or designs utilizing heterogeneous catalysts, the fixed packed bed reactors are preferred because of simpler technology and ease of operation.

### 11.1 Processes Operated in Packed Bed Reactors

Catalytic processes are carried out in several types of reactors like fixed bed, moving bed, trickle bed, two- and three phase fluidized beds, bubble columns, and stirred tanks. Examples of important fixed bed catalytic processes with only one fluid phase are given in Table 11.1. Other fixed bed processes with particular catalyst designs exist as well. Several packed bed reactors (PBRs) are employed by the petroleum refining industries utilizing natural gas as feedstock. Different compositions of synthesis gas (mixtures of carbon monoxide and hydrogen) or syngas are important intermediate feedstocks for the production of large volume chemicals such as ammonia, methanol, hydrogen and synthetic hydrocarbon liquids. The fixed bed reactors used today are thus mainly large-capacity units due to the vast market demand.

---

<sup>1</sup> The word *fixed* is used to distinguish this particular reactor design from moving bed reactors. The moving bed reactors also consists of a stack of catalyst pellets inside a vessel. In this reactor the force of gravity causes the catalyst pellets to move with respect to the wall from top to bottom while maintaining their relative positions to one another. The moving bed thus offers the ability to withdraw catalyst for regeneration outside the reactor in a continuous mode. A survey of the moving bed technology is given by Trambouze and Euzen [14].

**Table 11.1** Examples of fixed bed processes [3, 14]

| Basic chemical industry     | Petrochemical industry | Petroleum refining     |
|-----------------------------|------------------------|------------------------|
| Primary steam reforming     | Ethylene oxide         | Catalytic reforming    |
| Secondary steam reforming   | Ethylene dichloride    | Isomerization          |
| Carbon monoxide conversion  | Vinylacetate           | Polymerization         |
| Carbon monoxide methanation | Butadiene              | (Hydro)desulfurization |
| Ammonia synthesis           | Maleic anhydride       | Hydrocracking          |

| Oxo synthesis               | Styrene                |                        |
|                             | Hydrodealkylation      |                        |

## 11.2 Packed Bed Reactor Design

Typical for strongly exothermic processes is that at some location in the reactor an extreme temperature occur, frequently named the *hot spot*. In some processes with very strong exothermic reactions the hot spot temperature can raise beyond permissible limits. This phenomenon is called *runaway*. An important task in reactor design and operation is thus to limit the hot spot and avoid excessive sensitivity of the reactor performance to variations in the temperature. The value of the temperature at the hot spot is determined mainly by the reaction rate sensitivity to changes in temperature, the heat of reaction potential of the process, and the heat transfer potential of the heat exchanger units employed. A heat exchanger is characterized by the heat transfer coefficient and heat transfer areas. The selection of an appropriate fixed bed reactor design for a given process is performed assessing the main limitations of these reactors. The fixed packed bed reactors can be malfunctioning due to in-proper temperature control, pressure drop for processes with low tolerance, and deactivation of the catalyst.

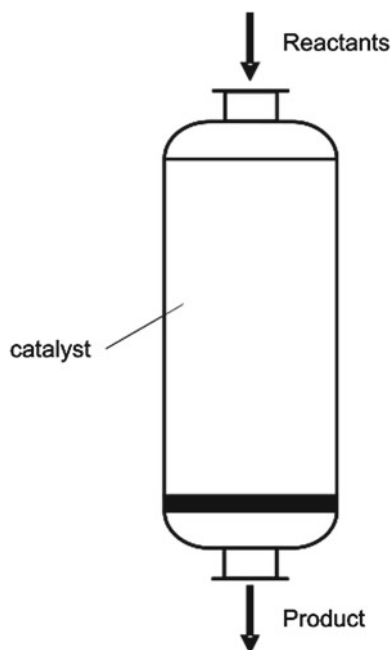

To optimize the performance of the fixed bed reactor operation several constructions of fixed bed reactors have been investigated over the years. Three of the most common reactor designs are:

- single-bed units
- multi-bed units
- multi-tube units

The single bed reactor is simply a vessel of relatively large diameter, as sketched in Fig. 11.1. This simple reactor design is best suited for adiabatic processes and not applicable for very exothermic or endothermic processes. If the reaction is very endothermic, the temperature change may be such as to extinguish the reaction before the desired conversion is attained. Strongly exothermic reactions, on the other hand, can lead to a temperature rise that is prohibitive due to its unfavorable influence on the equilibrium conversion, the product selectivity, the catalyst stability, and in extreme cases unsafe operation.

**Fig. 11.1** Sketch of a single bed reactor

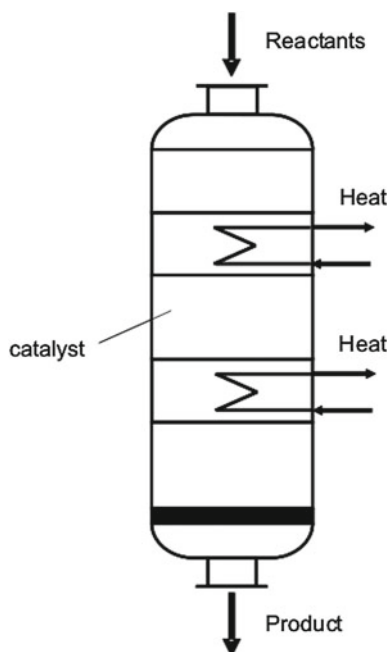

For endothermic reactions the problem can be solved by dividing the reactor into multiple stages, with intermediate heat exchangers, defining a multi-bed reactor. In exothermic processes, the intermediate cooling may be achieved by mean of heat exchangers or by injection of cold feed. A schematic illustration of a multi-bed reactor is shown in Fig. 11.2.

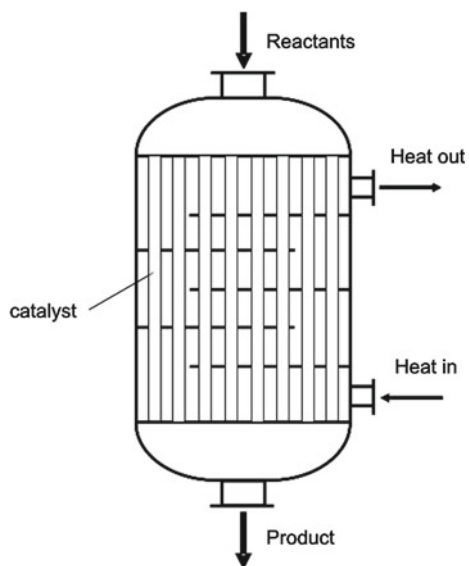

With very exothermic reactions the number of beds would have to be uneconomically large to limit the temperature increase per bed. This problem has been solved by introducing the multi-tube reactor. A schematic illustration of a multi-tube reactor is shown in Fig. 11.3. A representative multi-tube reactor can contain hundreds or thousands of tubes with an inside diameter of a few centimeters [3]. The diameter is limited to this small size to avoid excessive temperature and hot spots. The multi-tube reactor is more common than the other two fixed bed designs because many of the important heterogeneous catalytic processes require effective heat transfer between the mobile fluid, catalyst bed and heating/cooling media.

### 11.3 Modeling and Simulation of Packed Bed Reactors

In industrial reactors there are normally gradients in the species mass concentrations, temperature, pressure and velocity in all space directions. The fundamental microscopic equations give a detailed description of all the known mechanisms involved.

**Fig. 11.2** Sketch of a multi-bed reactor

**Fig. 11.3** Sketch of a multi-tube reactor

In the chemical reactor engineering approach we desire to eliminate the mechanisms that is not essential for the reactor performance from the equations to reduce the computational demand. An appropriate engineering packed bed reactor model is thus tailored for its main purpose. It is as simple as possible, but still include a sufficient representation of essential mechanisms involved. The conventional classification of reactor models contains two main categories: The pseudo-homogeneous and heterogeneous models. The pseudo-homogeneous models are mixture models and do not account explicitly for the presence of catalyst, in contrast to the heterogeneous models which consist of separate conservation equations for the interstitial fluid and catalyst phases. The catalyst phase in this context refers to a region which may include both gas and solid material. The solids mass is stagnant and inert thus disregarded in both the pseudo-homogeneous and heterogeneous mass and momentum balances, but retained in the heat balances because the heat transfer processes are generally much more effective in the solid material than in the gas. The pseudo-homogeneous models are sufficient and can be used instead of heterogeneous models for processes where the intra-particle heat and mass transfer limitations are small. Heterogeneous models are required for processes with significant temperature and concentration differences between the phases. The axial dispersion terms may be required to account for the mixing phenomena created by a non-ideal flow. However, the ideal plug flow model is often appropriate for packed bed reactors because the axial mixing is negligible compared to the convective flux for many processes. The basis for the modeling of fixed packed bed reactors are thus the cross sectional average homogeneous and heterogeneous model formulations. The homogeneous cross sectional average model equations were derived in Sect. 1.2.6 and simplified to the conventional single phase dispersion model in Sect. 1.2.7. The microscopic species mass balance reduces to (1.307) and the corresponding heat or temperature equation is given by (1.308). The heterogeneous two-phase cross sectional average model equations were derived in Sect. 3.4.6 and simplified to the two-phase dispersion model in Sect. 3.4.7. In this case the microscopic species mass balance reduces to (3.505) and the corresponding heat or temperature equation is given by (3.506). However, this formulation is used for the interstitial gas only. For the pellet similar equations are used for the gas in the pores, whereas the inert solid mass is disregarded in the species mass balances. The temperature equations for the pore gas and solid material are normally added together which collectively amount to a single mixture balance. The pseudo-homogeneous model equations are based on the classical mixture model derived in Sect. 3.4.5. In this concept the multiphase mixture is treated as a single homogeneous continuum. Thereby the balance principle can be applied to derive conservation laws for the macroscopic pseudo-fluid in analogy to the single phase formulation. The multiphase mixture properties are postulated or approximated by a volume fraction weighted sum of the phasic properties.

### 11.3.1 Fixed Bed Dispersion Models

The pseudo-homogeneous fixed bed dispersion models are divided into three categories: The axial dispersion model, the conventional two-dimensional dispersion model, and the full two-dimensional axi-symmetrical model formulation. The heterogeneous fixed bed dispersion models can be grouped in a similar way, but one dimensional formulations are employed in most cases. Assuming that the bed packing is uniform, the local void fraction equals the overall holdup thus the void parameter can be canceled out in several model equations.

#### 11.3.1.1 Pseudo-Homogeneous Axial Dispersion Model

For reactive flows in packed beds a set of cross sectional average balance equations is written for the gas–solid multiphase mixture [3, 5].

Continuity for the interstitial gas phase:

$$\varepsilon \frac{\partial \rho_g}{\partial t} + \frac{\partial(\rho_g v_g^s)}{\partial z} = 0 \quad (11.1)$$

Momentum balance for the interstitial gas phase:

$$\begin{aligned} \frac{\partial}{\partial t}(\rho_g \frac{v_g^s}{\varepsilon}) + \frac{\partial}{\partial z}(\rho_g \frac{v_g^s v_g^s}{\varepsilon^2}) = & - \frac{\partial p}{\partial z} - f \frac{\rho |v_g^s| v_g^s}{d_p} + 2 \frac{\partial}{\partial z}(\mu \frac{\partial v_g^s}{\partial z}) + \rho_g g_z \\ & - \frac{1}{2} \rho_g \frac{f_D}{d_t} |v_g^s| v_g^s \end{aligned} \quad (11.2)$$

Within a porous body the flow of a fluid is resisted by viscous and geometric (tortuosity) effects. A porous media friction term is therefore added to the right hand side of the momentum equation. The physical meaning of different terms in the equation is explained in Sect. 3.4.6.

For flows through a porous packed bed the pressure drop is generally dominated by the bed friction and for fixed bed processes the velocity is normally not very large, hence the momentum balance for the bulk gas phase can be reduced to (6.14):

$$\frac{dp}{dz} = -f \frac{\rho_g (v_g^s)^2}{d_p} \quad (11.3)$$

Several parameterizations for the friction factor,  $f$ , are given in the literature. A parameterization valid for spheres over a relatively broad range of particle Reynolds numbers is frequently used [3]:

$$f = 6.8 \frac{(1 - \varepsilon)^{1.2}}{\varepsilon^3} Re_p^{-0.2} \quad \text{where} \quad Re_p = \frac{d_p \rho |v_g^s|}{\mu_g} \quad (11.4)$$

Species mass balance for the interstitial gas phase:

$$\varepsilon \frac{\partial(\rho_g \omega_c)}{\partial t} + \frac{\partial(\rho_g \omega_c v_g^s)}{\partial z} = \frac{\partial}{\partial z} (\rho_g D_{ez} \frac{\partial \omega_c}{\partial z}) + R_c \rho_{cat} (1 - \varepsilon) \quad (11.5)$$

Enthalpy balance for the gas–solid multiphase mixture:

$$\begin{aligned} & \left( \varepsilon \rho_g C_{p_g} + (1 - \varepsilon) \rho_{cat} C_{p_{cat}} \right) \frac{\partial T}{\partial t} + \rho_g C_{p_g} v_g^s \frac{\partial T}{\partial z} \\ &= \frac{\partial}{\partial z} (k_{ez} \frac{\partial T}{\partial z}) - \frac{4 U_i}{d_t} (T - T_a) + \sum_r (-\Delta H_{R,r}) r_r \rho_{cat} (1 - \varepsilon) \end{aligned} \quad (11.6)$$

in which  $T_a$  represent the ambient temperature in the heating/cooling media.

In the current notation, the transport coefficients for heat and species mass are defined in terms of the superficial flow velocity. The species mass diffusivity—and the heat conductivity parameters may alternatively be expressed in terms of the interstitial gas flow velocity applying the following relations [3]:  $D_{ez} = \varepsilon D'_{ez}$  and  $k_{ez} = \varepsilon k'_{ez}$ .

The gas pressure or the gas mixture density can be calculated from an appropriate EOS, frequently the ideal gas law is employed in fixed bed simulations:

$$P = \rho_{mix} R T / M_{\omega_{mix}} \quad (11.7)$$

To solve these model equations appropriate initial and boundary conditions are required. Several conditions may be possible, a set of conditions for the rigorous case, in which (11.2) is used instead of (11.3), is listed below.

Initial conditions ( $t = 0$ ):

Initially there is no flow in the reactor, the tube is filled with a stagnant gas mixture having prescribed composition and temperature. The bed packing has the same temperature as the gas.

$$\left. \begin{aligned} \rho_g &= \rho_{g,0} \\ v_g^s &= v_{g,0}^s = 0 \\ p &= p_0 \\ T &= T_0 \\ \omega_c &= \omega_{c,0} \end{aligned} \right\} \quad \text{for all } z \quad (11.8)$$

Boundary conditions ( $t > 0$ ):

$$\left. \begin{array}{l} \rho_g = \rho_{g,0} \\ v_g^s = v_{g,0}^s \\ T = T_0 \\ \omega_c = \omega_{c,0} \end{array} \right\} \quad \text{for } z = 0 \quad (11.9)$$

$$\frac{\partial \rho_c}{\partial z} = \frac{dT}{dz} = 0 \quad \text{and} \quad p = p_0 \quad \text{for } z = L \quad (11.10)$$

In specific cases the gas mixture is almost isotherm and the chemical process are not altering the mixture molecular mass very much, thus the system and transport properties may be considered constant. Otherwise, the system and transport properties have to be considered temperature and composition dependent and calculated from approximate parameterizations or kinetic theory relations.

### 11.3.1.2 Pseudo-Homogeneous Two-dimensional Dispersion Model

The conventional two-dimensional pseudo-homogeneous reactor model consists of the continuity equation (11.1) and the simplified momentum equation (11.3) defined in connection with the pseudo-homogeneous dispersion model. The species mass and temperature equations are extended to 2D by adding postulated diffusion terms in the radial space dimension [3].

Species mass balance for the interstitial gas phase:

$$\begin{aligned} \varepsilon \frac{\partial(\rho_g \omega_c)}{\partial t} + \frac{\partial(\rho_g \omega_c v_g^s)}{\partial z} &= \frac{\partial}{\partial z} (\rho_g D_{ez} \frac{\partial \omega_c}{\partial z}) + \frac{1}{r} \frac{\partial}{\partial r} (r \rho_g D_{er} \frac{\partial \omega_c}{\partial r}) \\ &\quad + R_c \rho_{cat} (1 - \varepsilon) \end{aligned} \quad (11.11)$$

Enthalpy balance for the gas–solid multiphase mixture:

$$\begin{aligned} \left( \varepsilon \rho_g C_{p_g} + (1 - \varepsilon) \rho_{cat} C_{p_{cat}} \right) \frac{\partial T}{\partial t} + \rho_g C_{p_g} v_g^s \frac{\partial T}{\partial z} \\ = \frac{\partial}{\partial z} (k_{ez} \frac{\partial T}{\partial z}) + \frac{1}{r} \frac{\partial}{\partial r} (k_{er} r \frac{\partial T}{\partial r}) + \sum_r (-\Delta H_{R,r}) r_r \rho_{cat} (1 - \varepsilon) \end{aligned} \quad (11.12)$$

To solve these model equations appropriate initial and boundary conditions are required. Several conditions may be possible, a frequently used a set of conditions for the classical formulation, in which (11.3) is used instead of (11.2), is listed below.

Initial conditions ( $t = 0$ ):

Initially there is a steady-state flow in the reactor, and the tube contains a gas mixture having prescribed composition and temperature. The bed packing has the same

temperature as the gas.

$$\left. \begin{aligned} \rho_g &= \rho_{g,0} \\ v_g^s &= v_{g,0}^s \\ p &= p_0 \\ T &= T_0 \\ \omega_c &= \omega_{c,0} \end{aligned} \right\} \quad \text{for all } z \text{ and } r \quad (11.13)$$

Boundary conditions ( $t > 0$ ) are given as:

$$\left. \begin{aligned} \rho_g &= \rho_{g,0} \\ v_g^s &= v_{g,0}^s \\ p &= p_0 \\ T &= T_0 \\ \omega_c &= \omega_{c,0} \end{aligned} \right\} \quad \text{at } z = 0 \quad 0 \leq r \leq R \quad (11.14)$$

$$\frac{\partial \omega_c}{\partial z} = \frac{\partial T}{\partial z} = 0 \quad \text{at } z = L \quad 0 \leq r \leq R \quad (11.15)$$

$$\frac{\partial \omega_c}{\partial r} = 0 \quad \text{at } r = 0 \text{ and } r = R \quad \text{all } z \quad (11.16)$$

$$\frac{\partial T}{\partial r} = 0 \quad \text{at } r = 0 \quad \text{all } z \quad (11.17)$$

$$\frac{\partial T}{\partial r} = -\frac{U_i}{k_{er}\rho_g C_p}(T - T_a) \quad \text{at } r = R \quad \text{all } z \quad (11.18)$$

The gas pressure or the gas mixture density can be calculated from an appropriate EOS like (11.7).

This pseudo-homogeneous two-dimensional dispersion model formulation is strictly not consistent with the cross sectional averaging procedure outlined in Sects. 3.4.6 and 1.2.7 and should be treated with prudence and/or avoided. It is noticed that this model is only valid for particular flow situations. That is, the resulting 2D dispersion model is consistent with an unaveraged but simplified 2D model for a particular flow with a flat velocity profile being constant over the  $r$ -dimension. Following the model simplification approach, the reduced model will contain a local axial velocity  $v_g(z, r)$  rather than the superficial velocity,  $v_g^s(r)$ . On the other hand, for such flat flow profile situations the local axial velocity  $v_g(z, r)$  is frequently approximated by the superficial velocity  $v_g^s(z)$ . In the past many process simulations were performed keeping  $v_g^s$ ,  $\rho_g$ , and the system and transport properties constant to reduce the problem complexity [3]. These assumptions (i.e., especially for  $v_g^s$  and  $\rho_g$ ) are not accurate and may lead to large errors in the model predictions.

### 11.3.1.3 Full Pseudo-Homogeneous Two-Dimensional Axi-Symmetric Model

A more rigorous pseudo-homogeneous two-dimensional axi-symmetric model can be obtained reducing the governing averaged equations, that can be derived using any of the local averaging procedures described in Sect. 3.4, for the particular axi-symmetric tube flow problem.

Continuity for the interstitial gas phase:

$$\frac{\partial \rho_g}{\partial t} + \frac{\partial(\rho_g v_{g,z})}{\partial z} + \frac{1}{r} \frac{\partial(r \rho_g v_{g,r})}{\partial r} = 0 \quad (11.19)$$

Momentum balances for the interstitial gas phase:

$$\begin{aligned} & \frac{\partial}{\partial t}(\rho_g v_r) + \frac{1}{r} \frac{\partial}{\partial r}(r \rho_g v_r v_r) + \frac{\partial}{\partial z}(\rho_g v_z v_r) \\ &= -\frac{\partial p}{\partial r} - f \frac{\rho |\mathbf{v}| v_r}{d_p} + \frac{2}{r} \frac{\partial}{\partial r}(r \mu \frac{\partial v_r}{\partial r}) + \frac{\partial}{\partial z}(\mu \frac{\partial v_r}{\partial z}) - 2\mu \frac{v_r}{r^2} + \frac{\partial}{\partial z}(\mu \frac{\partial v_z}{\partial r}) \end{aligned} \quad (11.20)$$

and

$$\begin{aligned} & \frac{\partial}{\partial t}(\rho_g v_z) + \frac{1}{r} \frac{\partial}{\partial r}(r \rho_g v_r v_z) + \frac{\partial}{\partial z}(\rho_g v_z v_z) \\ &= -\frac{\partial p}{\partial z} - f \frac{\rho |\mathbf{v}| v_z}{d_p} + \rho_g g_z + \frac{1}{r} \frac{\partial}{\partial r}(r \mu \frac{\partial v_z}{\partial r}) + 2 \frac{\partial}{\partial z}(\mu \frac{\partial v_z}{\partial z}) + \frac{1}{r} \frac{\partial}{\partial r}(r \mu \frac{\partial v_r}{\partial z}) \end{aligned} \quad (11.21)$$

Species mass balances for the interstitial gas phase:

$$\begin{aligned} & \frac{\partial(\rho_g \omega_c)}{\partial t} + \frac{\partial(\rho_g \omega_c v_{g,z})}{\partial z} + \frac{1}{r} \frac{\partial(r \rho_g \omega_c v_{g,r})}{\partial r} \\ &= \frac{\partial}{\partial z}(\rho_g D'_{ez} \frac{\partial \omega_c}{\partial z}) + \frac{1}{r} \frac{\partial}{\partial r}(r \rho_g D'_{er} \frac{\partial \omega_c}{\partial r}) + R_c \rho_{cat} \frac{(1-\varepsilon)}{\varepsilon} \end{aligned} \quad (11.22)$$

Enthalpy balance for the gas–solid multiphase mixture:

$$\begin{aligned} & \left( \rho_g C p_g + \frac{(1-\varepsilon)}{\varepsilon} \rho_{cat} C p_{cat} \right) \frac{\partial T}{\partial t} + \rho_g C p_g v_{g,z} \frac{\partial T}{\partial z} + \rho_g C p_g v_{g,r} \frac{\partial T}{\partial r} \\ &= \frac{\partial}{\partial z}(k'_{ez} \frac{\partial T}{\partial z}) + \frac{1}{r} \frac{\partial}{\partial r}(r k'_{er} \frac{\partial T}{\partial r}) + \sum_r (-\Delta H_{R,r}) r_r \rho_{cat} \frac{(1-\varepsilon)}{\varepsilon} \end{aligned} \quad (11.23)$$

The gas pressure or the gas mixture density can be calculated from an appropriate EOS like (11.7).

The standard initial and boundary conditions for two-dimensional axi-symmetric flows in a tube are generally used.

Initial conditions ( $t = 0$ ):

Initially there is no flow in the reactor ( $v_r = v_{r0} = v_z = v_{z0} = 0$ ), the tube is filled with stagnant gas having prescribed composition and temperature, as for the 2D dispersion model simulations.

Boundary conditions ( $t > 0$ ):

The standard conditions for axi-symmetric flow in a 2D tube can be specified in the following manner. There is no flow through the reactor wall. The normal velocity component is set to zero at the symmetry boundary. Plug flow is assumed at the inlet. A prescribed pressure is specified at the reactor outlet. For the scalar variables Dirichlet boundary conditions are used at the inlet, whereas Neumann conditions are used at the other boundaries, as for the 2D dispersion model simulations.

#### 11.3.1.4 Full Heterogeneous Axial Dispersion Model

For reactive flows in packed porous beds a heterogeneous two-phase model consists of two sets of model equations, one set for the interstitial gas phase and one set for the pellet phase. The governing equations used by Rusten et al. [13] are outlined below.

##### *Interstitial gas phase*

Continuity for the bulk gas phase:

$$\varepsilon \frac{\partial \rho_g}{\partial t} + \frac{\partial(\rho_g v_g^s)}{\partial z} = 0 \quad (11.24)$$

Momentum balance for the bulk gas phase:

$$\begin{aligned} \frac{\partial}{\partial t}(\rho_g \frac{v_g^s}{\varepsilon}) + \frac{\partial}{\partial z}(\rho_g \frac{v_g^s v_g^s}{\varepsilon^2}) = & - \frac{\partial p}{\partial z} - f \frac{\rho |v_g^s| v_g^s}{d_p} + 2 \frac{\partial}{\partial z}(\mu \frac{\partial v_g^s}{\partial z}) + \rho_g g_z \\ & - \frac{1}{2} \rho_g \frac{f_D}{d_t} |v_g^s| v_g^s \end{aligned} \quad (11.25)$$

Species mass balance for the bulk gas phase:

$$\varepsilon \frac{\partial(\rho_g \omega_c)}{\partial t} + \frac{\partial(\rho_g \omega_c v_g^s)}{\partial z} = \frac{\partial}{\partial z}(\rho_g D_{ez} \frac{\partial \omega_c}{\partial z}) + a_s k_c \rho_g (\omega_{s,c} - \omega_c) \quad (11.26)$$

Enthalpy balance for the bulk gas phase:

$$\begin{aligned} \left( \varepsilon \rho_g C_{p_g} + (1 - \varepsilon) \rho_{cat} C_{p_{cat}} \right) \frac{\partial T}{\partial t} + \rho_g C_{p_g} v_g^s \frac{\partial T}{\partial z} \\ = \frac{\partial}{\partial z} (k_{ez} \frac{\partial T}{\partial z}) - \frac{4 U_i}{d_i} (T - T_a) + a_s h (T_s - T) \end{aligned} \quad (11.27)$$

### *Pellet equations*

Inside the pores of the catalyst pellets the convective terms are assumedly not significant, hence the species mass balance equations for the porous gas are expressed by:

$$\varepsilon_p \frac{\partial \rho_g \omega_{p,c}}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \frac{D_{cm} \varepsilon_p}{\tau} \rho_g \frac{\partial \omega_{p,c}}{\partial r}) + (1 - \varepsilon_p) \rho_p R_c \quad (11.28)$$

The multicomponent diffusivities are generally calculated from the Wilke equation, the Maxwell-Stefan model or the dusty gas model. The diffusion flux models are outlined in Chap. 2 and further investigated by Solsvik and Jakobsen [15] and Solsvik et al. [17].  $\tau$  represents the tortuosity factor for the pellet.

The pellet temperature equation for the multiphase gas–solid mixture can be expressed as:

$$\begin{aligned} (\varepsilon_p \rho_g C_{p_g} + (1 - \varepsilon_p) \rho_p C_{p_p}) \frac{\partial T_p}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 k_{p,g} \frac{\partial T_p}{\partial r}) \\ + (1 - \varepsilon_p) \rho_p \sum_r (-\Delta H_{R,r}) r_r \end{aligned} \quad (11.29)$$

The gas pressure or the gas mixture density can be calculated from an appropriate EOS like (11.7).

To solve these model equations appropriate initial and boundary conditions are required. Several conditions may be possible, a set of conditions for the rigorous case, in which (11.25) is used instead of (11.3), is listed below.

Initial conditions ( $t = 0$ ):

Initially there is no flow in the reactor, the tube is filled with a stagnant gas mixture having prescribed composition and temperature. The bed packing has the same temperature as the gas.

$$\left. \begin{aligned} v_g^s &= v_{g,0}^s = 0 \\ \rho_g &= \rho_{g,0} \\ p &= p_0 \\ T &= T_0 \\ \omega_c &= \omega_{c,0} \end{aligned} \right\} \quad \text{for all } z \text{ and } r \quad (11.30)$$

Boundary conditions ( $t > 0$ ):

$$\left. \begin{aligned} v_g^s &= v_{g,0}^s \\ \rho_g &= \rho_{g,0} \\ T &= T_0 \\ \omega_c &= \omega_{c,0} \end{aligned} \right\} \quad \text{for } z = 0 \quad (11.31)$$

$$\frac{\partial \omega_c}{\partial z} = \frac{dT}{dz} = 0 \quad \text{and} \quad p = p_0 \quad \text{for } z = L \quad (11.32)$$

Mixed boundary conditions are employed for the pellet equations. Robin boundary conditions are used for gas species mass and pellet temperature at the particle surface. Neumann boundary conditions are specified at the pellet center. These are generally defined for all  $z$  and  $t$ :

$$-\frac{D_{cm}\varepsilon_p}{\tau} \frac{\partial \omega_c}{\partial r} \bigg|_{r=r_p} = k_c(\omega_{p,c} - \omega_c) \quad (11.33)$$

$$-k_{p,g} \frac{\partial T_p}{\partial r} \bigg|_{r=r_p} = h(T_p - T) \quad (11.34)$$

$$\frac{\partial \omega_c}{\partial r} \bigg|_{r=0} = 0 \quad (11.35)$$

$$\frac{\partial T_p}{\partial r} \bigg|_{r=0} = 0 \quad (11.36)$$

### 11.3.2 Reactor Process Simulations

In the subsequent sections three examples of fixed bed reactor modeling are given, summarizing the work of Jakobsen et al. [5] and Lindborg et al. [7] investigating the steam methane reforming (SMR) and methanol production processes, and the simulations of the hydrogen production by sorption enhanced steam reforming of methane by Rusten et al. [13].

### 11.3.2.1 Methanol Production Process

The last decades the discoveries of natural gas reserves are considerable, hence the oil and gas companies are looking into the economics and technical feasibility of building huge gas conversion plants to take fully advantage of the economics of scale [9]. Among the most interesting gas conversion processes are the methanol process, where natural gas is converted into fuel. It is expected that the methanol market will develop into a fuel market in the future. Methanol can be used as a hydrogen source in future automobiles based on fuel cell technology. It can also be used as an alternative to oil and LNG for power generation.

Model simulations of reactor operation are convenient in order to study:

- The effect on products of changes in feed and catalyst.
- Scale up from laboratory to industry scales.
- Optimalization of the reactor performance.
- Optimization of the operating conditions.
- Interpretations of laboratory measurements.

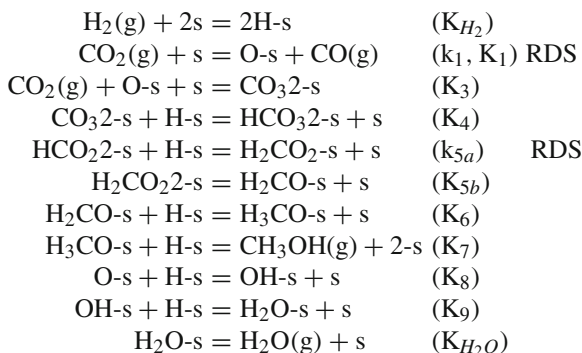

In this study the steady-state kinetic model for the methanol synthesis on a commercial Cu/ZnO/Al<sub>2</sub>O<sub>3</sub> catalyst as proposed by Van den Bussche and Froment [18] are used.

The chemistry mechanism is based on three overall reactions:

The first and the second reaction are hydrogenation reactions of CO<sub>2</sub> and CO, respectively. The last reaction is the water gas shift reaction (WGS).

The reaction steps considered developing the reaction kinetics were given, and the rate determining steps (RDS) are identified:

in which the pressures are given in bar and the reactions in mol/kg<sub>cat</sub>s.

The kinetic rate models for the conversion of synthesis gas over a Cu/ZnO/Al<sub>2</sub>O<sub>3</sub> catalyst is thus given by:

$$r_{MeOH} = \frac{k'_{5a} K'_2 K_3 K_4 K_{H_2} p_{CO_2} p_{H_2} \left( 1 - \frac{1}{K_1^*} \frac{p_{H_2O} p_{CH_3OH}}{p_{H_2}^3 p_{CO_2}} \right)}{\left( 1 + \frac{K_{H_2O}}{K_8 K_9 K_{H_2}} \frac{p_{H_2O}}{p_{H_2}} + \sqrt{K_{H_2} p_{H_2}} + K_{H_2O} p_{H_2O} \right)^3} \quad (11.37)$$

$$r_{RWGS} = \frac{k'_1 p_{CO_2} \left( 1 - K_3^* \frac{p_{H_2O} p_{CO}}{p_{H_2} p_{CO_2}} \right)}{1 + \frac{K_{H_2O}}{K_8 K_9 K_{H_2}} \frac{p_{H_2O}}{p_{H_2}} + \sqrt{K_{H_2} p_{H_2}} + K_{H_2O} p_{H_2O}} \quad (11.38)$$

The production of methanol is given by  $r_{MeOH}$  and the production of CO is given by the expression for the reversed water gas shift reaction  $r_{RWGS}$ . These expressions can be re-written as:

$$r_{MeOH} = \frac{F_4 p_{CO_2} p_{H_2} \left( 1 - \frac{1}{K_1^*} \frac{p_{H_2O} p_{CH_3OH}}{p_{H_2}^3 p_{CO_2}} \right)}{DENOM^3} \quad (11.39)$$

$$r_{RWGS} = \frac{F_5 p_{CO_2} \left( 1 - K_3^* \frac{p_{H_2O} p_{CO}}{p_{H_2} p_{CO_2}} \right)}{DENOM} \quad (11.40)$$

The denominator is defined by:

$$DENOM = 1 + F_3 \frac{p_{H_2O}}{p_{H_2}} + F_1 \sqrt{p_{H_2}} + F_2 p_{H_2O} \quad (11.41)$$

The factors  $F_i$  were calculated from the Arrhenius or Van't Hoff equation:

$$F_i = A_i \times e^{\frac{B_i}{RT}} \quad (11.42)$$

in which  $B_i$  represents either the activation energy  $E$ , or the reaction enthalpy ( $-\Delta H$ ), or a combination of those. The parameter values for  $A_i$  and  $B_i$  are given in Table 11.2.

To calculate the equilibrium constants  $K_1^*$  and  $K_3^*$ , the following expressions were applied [18]:

$$\log_{10}(K_1^*) = \frac{3066}{T} - 10.592 \quad (11.43)$$

$$\log_{10}\left(\frac{1}{K_3^*}\right) = \frac{-2073}{T} + 2.029 \quad (11.44)$$

**Table 11.2** Parameters for the methanol synthesis

|                |                                    |                |                        |                                              |

| Void fraction in the bulk region      | 0.5              |

Van den Bussche and Froment [18] did assume that CO<sub>2</sub> is the main source of carbon in methanol, thus only reactions (I) and (III) are considered. Hence, the rates of formation of the different components in the system are given as:

$$\begin{aligned}
 r_{CH_3OH} &= r_{MeOH} \\
 r_{CO} &= r_{RWGS} \\
 r_{CO_2} &= -r_{RWGS} - r_{MeOH} \\

 \end{aligned} \tag{11.45}$$

The reaction enthalpies were calculated from the the heat of formation for the species in the hydrogenation of CO<sub>2</sub> and water gas shift reactions. The overall process is strongly exothermic. Due to the cooling requirement, the industrial scale fixed bed reactors used for this process are normally constructed based on the multi-tube design.

The operating conditions used for the methanol Bench Scale Reactor simulations are listed in the Tables 11.3, 11.4 and 11.5.

**Table 11.5** Gas data

|                                     | Methanol process    |
|-------------------------------------|---------------------|
| Mass fraction of CH <sub>4</sub>    | 0.1490 (6.00 mol%)  |
| Mass fraction of CH <sub>3</sub> OH | 0 (0.00 mol%)       |
| Mass fraction of CO                 | 0.1734 (4.00 mol%)  |
| Mass fraction of CO <sub>2</sub>    | 0.2044 (3.00 mol%)  |
| Mass fraction of H <sub>2</sub>     | 0.2564 (82.00 mol%) |
| Mass fraction of H <sub>2</sub> O   | 0 (0.00 mol%)       |
| Mass fraction of N <sub>2</sub>     | 0.2168 (5.00 mol%)  |
| Superficial inlet velocity (m/s)    | 0.0067184           |
| Inlet temperature (K)               | 493.2               |
| Inlet pressure (bar)                | 50                  |

The pseudo-homogeneous two-dimensional dispersion model, consisting of (11.11) to (11.18) and the pressure drop relations (11.3) and (11.4), was solved for the methanol production process under non-adiabatic conditions.

The results from a simulation of the methanol process with external cooling (non-adiabatic process) are given in Fig. 11.4. The predicted profiles show that methanol is produced at the expense of CO, CO<sub>2</sub> and H<sub>2</sub>. The temperature gradient at the reactor entrance is very steep. The temperature increases to about 550 K in the center of the tube, but near the walls the maximum temperature is approximately 530 K. The temperature decreases further away from the reactor inlet, and the radial profiles are almost flat at  $z = 0.3$  meters downstream from the inlet.

Van den Bussche and Froment [18] simulated an adiabatic Bench Scale Reactor using a pseudo-homogeneous one-dimensional model. Using a similar pseudo-homogeneous axial dispersion model Jakobsen et al. [5] obtained axial concentration and temperature profiles that were hardly distinguishable from the pseudo-homogeneous one-dimensional model results of Van den Bussche and Froment [18]. The adiabatic reactor case was used as a validation test for the two-dimensional model.

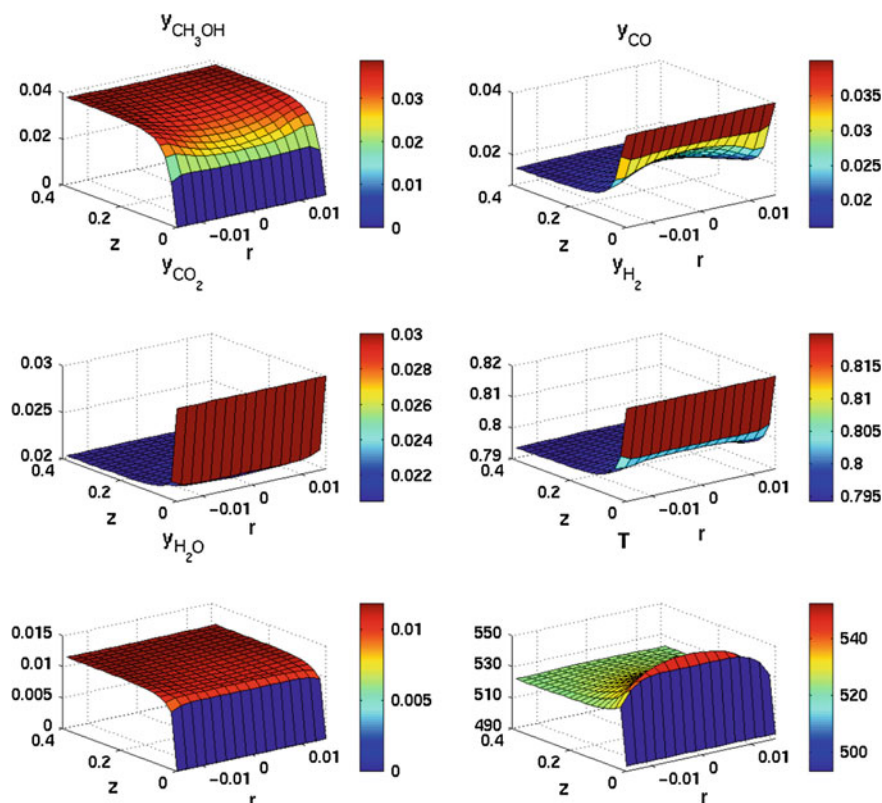

### 11.3.2.2 Conventional Steam Methane Reforming

The most important reactions taking place in the catalytic steam methane reforming process are the endothermic methane steam reforming reaction and the parallel exothermic water gas shift reaction, respectively [4]:

The endothermic CO<sub>2</sub> reforming reaction is frequently considered:

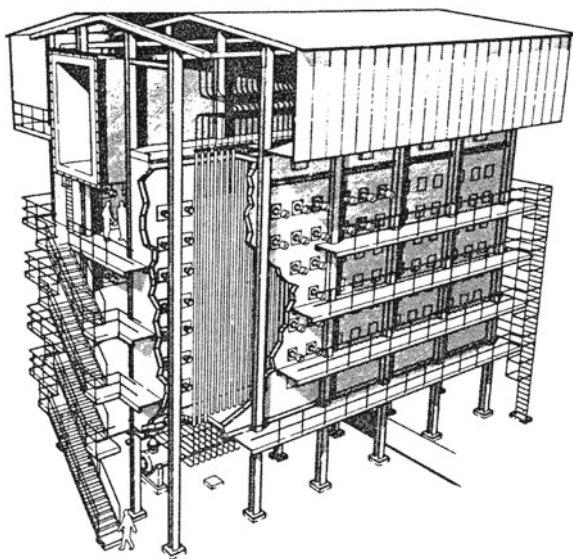

**Fig. 11.4** Species mole fractions and temperature profiles predicted for the non-adiabatic methanol process by the pseudo-homogeneous two-dimensional dispersion model. Note, as a 2D axis-symmetric tube has been simulated, the model is solved for positive  $r$ -values only. Reprinted from [5] with permission from Elsevier

These three reactions are not independent because the third reaction equals the sum of the other two reactions. The reactions are catalyzed by pellets coated with nickel ( $\text{Ni/MgAl}_2\text{O}_3$ ) and are highly endothermic overall. The operating process conditions are typically 20–40 bar with inlet temperature of 300–650 °C and outlet temperature of 700–950 °C. The kinetics, physical data, correlations and operating conditions used for the conventional steam methane reforming process are taken from Froment and Bischoff [3], De Groote and Froment [1] and Xu and Froment [19, 20].

Coking reactions occur in parallel with the reforming reactions and are undesirable as they cause poisoning of the surface of the catalyst pellets. This leads to lower catalyst activity and the need for more frequently catalyst reloading. The coking reactions are the CO-reduction, methane cracking and Boudouard reaction, given by the respective equilibrium reactions [4]:

**Fig. 11.5** The Topsøe reformer design with tube and burner arrangement. Reprinted from Rostrup-Nielsen [10] with permission from Springer

It can be seen from these reaction equations that low steam excess can lead to critical conditions causing coke formation, according to the principle of Le Chatelier.

The most common reactor concept for steam reforming of natural gas is the fired steam reformer that is a multi-tube fixed bed design [2]. The Topsøe reformer design with tube and burner arrangement is shown in Fig. 11.5. A Natural gas and the tail gas from the synthesis loop are burned in a firebox where several tubes packed with catalyst pellets are placed in rows with a number of 40–400 tubes. The reactor tubes are about 10–12 m long, with diameters of about 10 cm. The reactions for conversion of natural gas to syngas take place over the catalytic surfaces in the reactor tubes. The burners can be located in different places: On the roof, on the floor, on levelled terraces on the walls, or on the walls. The top fired reformer is characterized by a defiant peak in the tube wall temperature in the upper part of the reformer, and it has the highest heat flux where the metal temperature is at its maximum. The bottom fired type has an almost constant heat flux profile along the length of the tube. The terrace wall fired reformer is a modification of the bottom fired reformer and has some smaller problem with high metal temperatures. The side fired reformer has the most effective design and is also the most flexible reformer, both in design and in operation.

**Table 11.6** Reactor tube data

|                                        | Syngas process |
|----------------------------------------|----------------|
| Inner tube diameter (m)                | 0.102          |
| Outer tube diameter (m)                | 0.132          |
| Tube length (m)                        | 8              |
| Temperature outside the wall (K)       | 1100           |
| Heat coefficient for the metal (J/msK) | 52             |

**Table 11.7** Catalyst data

|                                       | Syngas process |
|---------------------------------------|----------------|
| Catalyst density (kg/m <sup>3</sup> ) | 2355.2         |
| Particle diameter (m)                 | 0.0173         |
| Void fraction in the bulk region      | 0.528          |

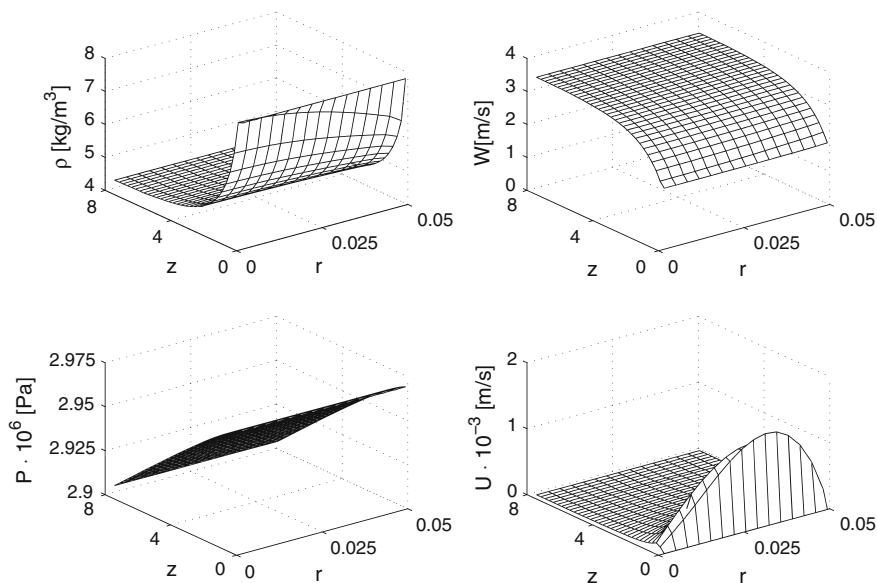

**Table 11.8** Gas data

|                                   | Syngas process |
|-----------------------------------|----------------|
| Mass fraction of CH <sub>4</sub>  | 0.1911         |
| Mass fraction of CO               | 0.0001         |
| Mass fraction of CO <sub>2</sub>  | 0.0200         |
| Mass fraction of H <sub>2</sub>   | 0.0029         |
| Mass fraction of H <sub>2</sub> O | 0.7218         |
| Mass fraction of N <sub>2</sub>   | 0.0641         |
| Superficial inlet velocity (m/s)  | 1.89           |
| Inlet temperature (K)             | 793            |
| Inlet pressure (bar)              | 29             |

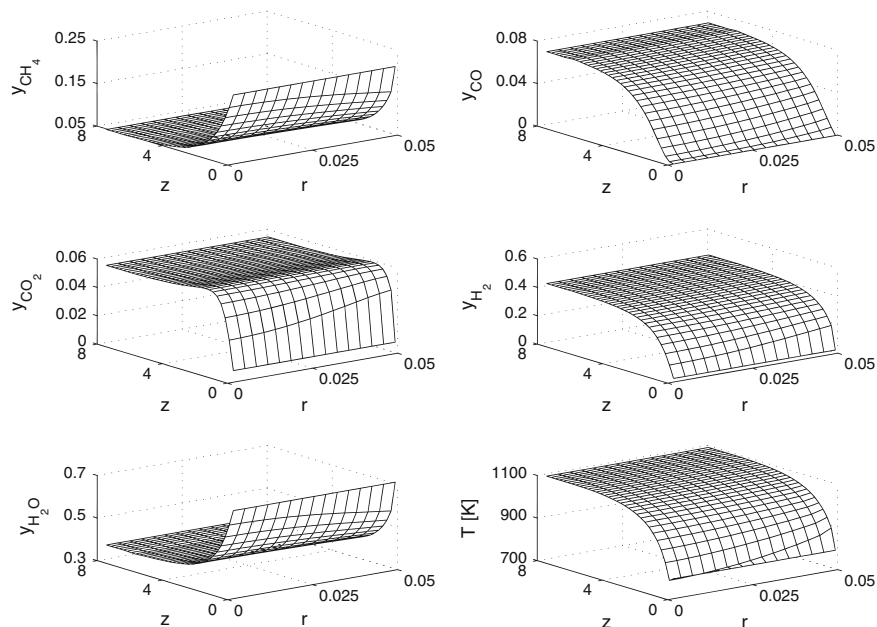

The operating conditions used in the simulations of the syngas process are listed in the Tables 11.6, 11.7 and 11.8.

For steam methane reforming, both heterogeneous and pseudo-homogeneous models have been used to simulate the process. However, since the steam methane reforming process is strongly intra-particle diffusion-controlled [3], an appropriate reactor simulation generally requires a heterogeneous model. Nevertheless, the use of pseudo-homogeneous models in which the diffusion resistances are taken into account through efficiency factors can also be a sufficient option provided that appropriate values of these factors are known. Froment and Bischoff [3] and Solsvik and Jakobsen [15] did solve the pellet equations and determined the efficiency factors for the SMR reactions.

The full pseudo-homogeneous 2D axis-symmetric model, consisting of (11.19) to (11.23), was used to simulate the synthesis gas process. The model was simulated with a grid  $17 \times 257$  for 3 s until the steady state solution was obtained. The time increment in the simulations was  $\Delta t = 10^{-3}$  s. To ensure mass conservation the convergence criteria was set to an error limit of  $10^{-18}$  of the residual error. The results obtained from the 2D simulations with a uniform void distribution are given in Figs. 11.6 and 11.7.

**Fig. 11.6** Velocity, density, pressure and temperature profiles from a 2D simulation of the SMR process with a uniform void fraction profile. Reprinted from [7] with permission from Elsevier

**Fig. 11.7** Mole fraction profiles for the components from a 2D simulation of the SMR process with a uniform void fraction distribution. Reprinted from [7] with permission from Elsevier

The axial velocity component is close to uniform and the radial velocity component is very small, hence the flow pattern can be characterized as plug flow.

In the synthesis gas process CO is produced from  $\text{CH}_4$  and  $\text{H}_2\text{O}$ . The reversed water gas shift reaction consumes CO in the  $z$ -interval from 0–1.5 m. The mole fraction of  $\text{CO}_2$  is increasing from the reactor entrance and reaches a maximum at a distance of 1.5 m from the inlet. At  $z = 1.5$  m the reaction is reversed, and a maximum occurs in the  $\text{CO}_2$  profile. Then there is a slight decrease to the point where equilibrium is achieved. A radial temperature gradient with a maximum at the wall is observed at the reactor entrance. Further away from the reactor entrance, the radial profile is flat. The mole fraction profiles also contain marked radial gradients within the first 1.5 m of the reactor. The radial gradients observed in the species concentration profiles are caused by the limited heat flux added to the reactor through the wall. The reactions are endothermic and the heat transferred through the wall and/or from the wall into the bed is not sufficient to smooth out the temperature profile, thus the chemical conversion becomes non-uniform.

The use of a full 2D pseudo-homogeneous axi-symmetric model has the advantage, compared to the conventional 2D pseudo-homogeneous dispersion model, that it enables an evaluation of the influence of a non-uniform void distribution in the reactor. To evaluate the importance of the radial variations in the void fraction profiles, simulations with prescribed radial variations in the bed structure were performed for the synthesis gas process. The velocity and pressure profiles were significantly altered. Higher void fractions at the wall induces less friction from the bed, thus the gas flow increases and the pressure drop decreases. However, the influence on the temperature and mole fraction profiles were very small but noticeable. This particular process consists of very fast reactions that are very much controlled by the operational temperature, hence provided that sufficient heat is added the non-uniform bed packing has very little impact on the conversion. A customary simplification is to run the conventional dispersion model simulations adopting prescribed values for the superficial velocity and the mixture density throughout the reactor, in conjunction with a linear pressure profile as represented by (11.3). The superficial velocity and the mixture density values are then generally set to the inlet values. However, solving the full 2D pseudo-homogeneous model formulation for the synthesis gas process, it is shown that the axial gradients predicted in the axial velocity component and mixture density profiles are considerable and should be taken into account. However, the chemical species concentration and temperature profiles obtained in the rigorous 2D simulations do not vary much from the corresponding results obtained by use of a conventional 2D pseudo-homogeneous dispersion model.

### 11.3.2.3 Sorption Enhanced Steam Methane Reforming

Hydrogen is an important raw material in the chemical and petroleum industries. Large quantities are used in the manufacture of ammonia and methanol and in a variety of petroleum hydro treating processes. In addition, hydrogen might become a

new generation clean energy source for transport, especially for fuel cell application, which would cause a huge increase in hydrogen demand.

Steam methane reforming (SMR) is currently the major process for large-scale production of hydrogen. For hydrogen production a more cost effective process is desirable. Within the last few years the concept of multi-functional reactors combining reaction and separation, especially the concept of sorption enhanced reaction process (SERP), have received increased attention. A  $\text{CO}_2$ -acceptor can be installed together with catalyst to remove  $\text{CO}_2$  from the gas phase, normal equilibrium limits of reforming and shift reactions are changed, and a product containing more than 98 %  $\text{H}_2$  (dry basis) is possible [8]. The steam reforming can be run at a much lower temperature (450–630 °C) than conventional steam reforming, which will significantly lower investment and operation cost.

A fixed bed reactor for production of hydrogen by sorption enhanced steam methane reforming (SE-SMR) using  $\text{Li}_2\text{ZrO}_3$  as  $\text{CO}_2$ -acceptor was investigated by Rusten et al. [13]:

The capture process is represented by an exothermic reaction (i.e.,  $\Delta H_{848K} = 15 \text{ kJ/mol}$ ), contrary to the endothermic steam reforming process, and the heat of sorption makes the need for external heating less than for the traditional steam methane reforming process.

An empirical parameterization of the sorption kinetics was employed:

$$\frac{dx}{dt} = k_1(p_{\text{CO}_2} - p_{eq, \text{CO}_2})^2(1 - x) \quad (11.46)$$

in which  $x$  is the fractional conversion, defined by  $x = q/q_{max}$ , where  $q$  is the mass of  $\text{CO}_2$  captured per unit mass of lithium zirconate,  $q_{max}$  is  $q$  at maximum capture found to be 0.22 for  $\text{Li}_2\text{ZrO}_3$ . Moreover, the equilibrium partial pressure of  $\text{CO}_2$ ,  $p_{eq, \text{CO}_2}$ , was modeled using thermodynamical data [6].

The  $k_1$  is the effective reaction rate constant for which an Arrhenius expression is used for the temperature dependence:

$$k_1 = k_{10} e^{-\frac{E}{R}(\frac{1}{T} - \frac{1}{T_0})} \quad (11.47)$$

The parameters in (11.47) have the values  $k_{10} = 8.07 \times 10^{-13} \text{ (s}^{-1}\text{)}$  and  $E = 7.7 \times 10^4 \text{ (J/mol)}$ .

The sorption rate thus yields:

$$R_{cap} = R_{\text{CO}_2} = q_{max} \frac{dx}{dt} \left( \frac{kg}{kgs} \right) \quad (11.48)$$

Transient one-dimensional reactor models with axial dispersion were used to simulate the fixed bed reactor process. Transient models were chosen because the capture

of  $\text{CO}_2$  has a time-dependent nature, and the axial dispersion term was included because of the relatively low gas velocities that were used in the simulations. Three different versions of the basic one dimensional model were developed, two heterogeneous models and a pseudo-homogeneous model. The difference in the two heterogeneous models is the way the sorbent was installed in the reactor bed. One model version considers that  $\text{Li}_2\text{ZrO}_3$  and the reforming catalyst are coated on two different particles, while in the other case there is one particle with both catalytic and capture properties. The steam methane reforming and the water-gas shift reaction kinetics are taken from Xu and Froment [19], but corrected for different properties of the catalyst.

Using the pseudo-homogeneous axial dispersion model as a reference, the governing equations are defined by (11.1) to (11.10). The species mass balance (11.5) was solved for  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CH}_4$  and  $\text{CO}_2$ . The mass fraction of  $\text{H}_2\text{O}$ , the dominating species in the mixture, was calculated from (11.49):

$$\sum_{c=1}^5 \omega_c = 1 \quad (11.49)$$

To define the alternative model versions the effective reaction term  $S_c = M_{\omega_c} r_c \rho_{cat}(1 - \varepsilon) = R_c \rho_{cat}(1 - \varepsilon)$  in the basic model species mass balance is substituted with a modified source term  $S_c$  being different in the various model versions:

- For the heterogeneous one particle model, we can see from (11.26) that the source term is a conventional particle-bulk interstitial gas phase mass transfer term is defined by:

$$S_c = a_s k_c \rho_g (\omega_{s,c} - \omega_c) \quad (11.50)$$

- For the two-particle heterogeneous model the source term in the bulk gas phase equation is given as the sum of the conventional particle-bulk phase mass transfer terms for both the catalyst and  $\text{CO}_2$ -acceptor particles. The net source term is thus defined by:

$$S_c = a_{s,cat} k_c \rho_g (\omega_{s,c}^{cat} - \omega_c) + a_{s,cap} k_c \rho_g (\omega_{s,c}^{cap} - \omega_c) \quad (11.51)$$

- For the pseudo-homogeneous model  $S_c$  represents an effective reaction rate. For  $\text{CO}_2$  the source term for the pseudo-homogeneous model consists of two effective reaction rate terms, one for the reforming reactions and one for the  $\text{CO}_2$ -capture kinetics:

$$S_{\text{CO}_2} = \frac{1 - \epsilon_b}{1 + \alpha \frac{\epsilon_p^{cap}}{\epsilon_p^{cat}}} (1 - \epsilon_p^{cat}) \rho_{cat} R_{\text{CO}_2} + \frac{1 - \epsilon_b}{1 - \frac{\epsilon_p^{cat}}{\epsilon_p^{cap} + \epsilon_p^{cap} \alpha}} (1 - \epsilon_p^{cap}) \rho_{cap} R_{\text{CO}_2, cap} \quad (11.52)$$

The  $\alpha$  represents the ratio between the solid mass of the CO<sub>2</sub>-acceptor and the catalyst.

For the other species, the capture rate is zero so the source terms in these equations reduce to the form:

$$S_c = \frac{1 - \epsilon_b}{1 + \alpha \frac{\epsilon_p^{cap}}{\epsilon_p^{cat}}} (1 - \epsilon_p^{cat}) \rho_{cat} R_c \quad (11.53)$$

The corresponding temperature equation for the interstitial gas is given by (11.6). To define the alternative model versions the effective heat of reaction term  $S_T = \rho_{cat}(1 - \epsilon) \sum_r (-\Delta H_{R,r}) r_r$  in the basic model heat balance is substituted with a modified source term  $S_T$  being different in the various model versions:

- For the heterogeneous one particle model, we see from (11.27) that the source term equals the conventional particle-bulk gas phase heat transfer term, defined by:

$$S_T = a_s h (T_s - T) \quad (11.54)$$

- For the two-particle heterogeneous model the source term in the bulk gas phase equation is given as the sum of the conventional particle-bulk phase heat transfer terms for both the catalyst and CO<sub>2</sub>-acceptor particles.

$$S_T = a_{s,cat} h (T - T_s^{cat}) + a_{s,cap} h (T_s^{cap} - T) \quad (11.55)$$

- For the pseudo-homogeneous model  $S_T$  denotes an effective heat of reaction term. The source term for the pseudo-homogeneous model consists of two effective heat of reaction terms, one for the reforming reactions and one for the CO<sub>2</sub>-acceptor kinetics:

$$S_T = \frac{1 - \epsilon_b}{1 + \alpha \frac{\epsilon_p^{cap}}{\epsilon_p^{cat}}} (1 - \epsilon_p^{cat}) \rho_{cat} \sum_r^3 (-\Delta H_{R,r}) r_r - \frac{1 - \epsilon_b}{1 - \frac{\epsilon_p^{cat}}{\epsilon_p^{cat} + \epsilon_p^{cap} \alpha}} (1 - \epsilon_p^{cap}) \rho_{cap} (-\Delta H_{cap}) R_{cap} / M_{\omega_{cap}} \quad (11.56)$$

The cross sectional average momentum and continuity equations were solved for the velocity and pressure, respectively. The heterogeneous momentum equation for the interstitial gas phase is written like (11.2). The pseudo-homogeneous continuity equation was written as:

$$\epsilon_b \frac{\partial \rho_g}{\partial t} + \frac{\partial}{\partial z} (\rho_g v_g^s) = -R_{cap} \quad (11.57)$$

The net acceptor reaction  $R_{cap}$  is included in the continuity equation since the  $\text{CO}_2$  mass captured is removed from the interstitial gas phase. The pseudo-homogeneous continuity equation was used for the heterogeneous models as well due to numerical convergency problems. A truly heterogeneous continuity equation should not contain the sorption reaction rate but the sum of all the species mass balance interfacial mass transfer terms. The sorption rate should then be included in the pellet continuity equation instead.

The impact of two different ways of designing the packed bed were investigated, one case with one particle having both the sorbent and the catalyst properties, and a second case with two different particle types each of them having only one property.

The species mass balance for the gas mixture in the pellet pores are written on the form (11.28). To define the alternative model versions, the effective reaction term  $S_c = R_c \rho_{cat}(1 - \varepsilon)$  in the basic model species mass balance is substituted with a modified source term  $S_c$  being different in the various model versions:

- For the model with one type of particle the term  $S_{\text{CO}_2}$  consists of both the reforming reaction rates and the capture reaction rate. The net source term in the  $S_{\text{CO}_2}$ -balance yields:

$$S_{\text{CO}_2} = \frac{1 - \varepsilon_p}{1 + \alpha} \rho_{cat} R_{\text{CO}_2} - \frac{1 - \varepsilon_p}{1 - \frac{1}{1 + \alpha}} \rho_{cap} R_{\text{CO}_2, cap} \quad (11.58)$$

For the other species the capture rate is zero, hence the effective reaction rate in the pellet reduces to:

$$S_c = \frac{1 - \varepsilon_p}{1 + \alpha} \rho_{cat} R_c \quad (11.59)$$

- In the model with two types of particles, (11.28) is solved for both of them. The catalyst particles are solved for all components, with the reforming kinetics. Like the equations for the bulk transport, (11.28) is solved for four components and  $\text{H}_2\text{O}$  is calculated from the sum of the mass fractions (11.49). The source term is then defined by:

$$S_c = (1 - \varepsilon_{p, cat}) \rho_{cat} R_c \quad (11.60)$$

In the sorbent particle, all components but  $\text{CO}_2$  are inert, hence only one component equation is solved. The source term is defined by:

$$S_{\text{CO}_2} = -(1 - \varepsilon_{p, cap}) \rho_{cap} R_{\text{CO}_2, cap} \quad (11.61)$$

The pellet temperature equation considering the multiphase gas–solid mixture was expressed on the form (11.29).

To define the two model versions, the effective heat of reaction term  $S_T = (1 - \varepsilon_{p, cat}) \rho_{cat} \sum_r (-\Delta H_{R, r}) r_r$  in the basic pellet model heat balance is substituted with a modified source term  $S_T$ :

**Table 11.9** Physical parameters used in the simulations

|                                          |                           |
|------------------------------------------|---------------------------|
| Pellet diameter, $d_p$                   | 0.005 (m)                 |
| Reactor tube inner diameter, $d_t$       | 0.1 (m)                   |
| Reactor length, $L$                      | 4 (m)                     |
| Gas holdup, $\varepsilon$                | 0.5 (–)                   |
| Tortuosity, $\tau$                       | 3 (–)                     |
| Acceptor density, $\rho_{cap,p}$         | 2500 (kg/m <sup>3</sup> ) |
| Catalyst density, $\rho_{cat,p}$         | 2300 (kg/m <sup>3</sup> ) |
| Pellet effective conductivity, $k_{p,g}$ | 0.2 (W/mK)                |
| Solids heat capacity, $Cp_p$             | 1000 (J/kg K)             |

- For the model with one type of particle the  $S_T$  term consists of both the reforming heat of reaction and the capture heat of reaction. The net source term  $S_T$  yields:

$$S_T = \frac{1 - \varepsilon_p}{1 + \alpha} \rho_{cat} \sum_r^3 (-\Delta H_{R_r}) r_r + \frac{1 - \varepsilon_p}{1 - \frac{1}{1 + \alpha}} \rho_{cap} r_{CO_2, cap} (-\Delta H_{r, cap}) \quad (11.62)$$

- In the model with two types of particles, (11.29) is solved for both of them. For the catalyst particles the source term is defined by:

$$S_T = (1 - \varepsilon_{p, cat}) \rho_{cat} \sum_r^3 (-\Delta H_{R, r}) r_r \quad (11.63)$$

For the acceptor particles the source term is defined by:

$$S_T = (1 - \varepsilon_{p, cap}) \rho_{cap} (-\Delta H_{R, cap}) r_{CO_2, cap} \quad (11.64)$$

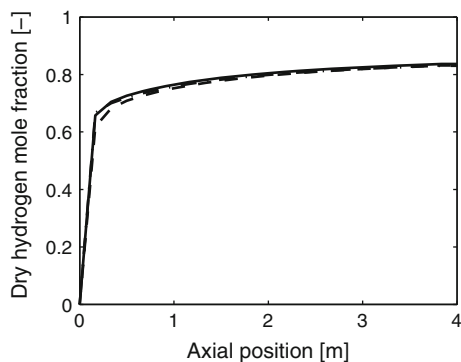

For the bulk gas phase Dirichlet boundary conditions were specified at the reactor inlet for all the variables, and Neumann boundary condition were employed at the outlet for all the variables except for the pressure which is specified by a Dirichlet boundary condition.

A tube reactor with dimensions given in Table 11.9 was simulated. A high ratio between CO<sub>2</sub>-acceptor and catalyst was used because the reforming kinetics are fast compared to the sorption rate. The reactor was filled with steam (97 mole %) and a small amount of hydrogen at the desired temperature, 848 K, at start-up. The input to the reactor was methane and steam, in which the steam to methane ratio is set to 6. A high steam to carbon ratio is necessary to reach high conversions. Physical properties of the reactor and materials are given in Table 11.9. A typical set of reactor conditions are presented in Table 11.10. The inlet mass flux, which is set to 0.77 kg/m<sup>2</sup>s in the simulations, corresponds to a superficial gas velocity of 0.3 m/s.

A measure used for the performance of the reactor is the dry hydrogen mole fraction, which is the hydrogen mole fraction of the gas after steam is removed. The dry mole fractions are calculated as:

$$y_c^{dry} = \frac{y_c}{1 - y_{H_2O}} \quad (11.65)$$

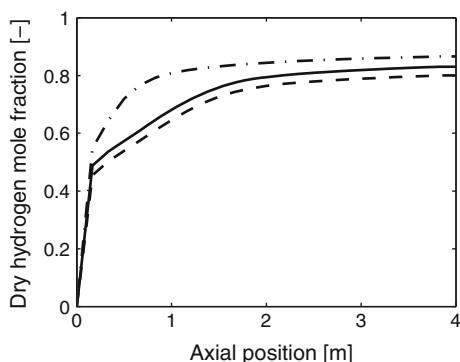

The dry hydrogen mole fractions at  $t = 200$  s predicted by the pseudo homogeneous, one-particle heterogeneous and two-particle heterogeneous models are shown in Fig. 11.8. No significant differences were observed in the reactor performances as simulated by the three models. The pseudo-homogeneous model gives appropriate results for the particle size used. The capture of  $CO_2$  is the limiting step of the process. With larger particles the process may change behavior as the intra-particle diffusion resistance increases. The conversion in the reactor decreases with larger particles. The effect is greater for the two-particle model and occurs at smaller particle sizes. The reason for this is that for two particles the  $CO_2$  have to diffuse out of the catalyst particle, through the bulk phase, and into the sorbent and this becomes the limiting step. For one particle the diffusion to and from the bulk phase becomes the limiting step at larger particle diameters.

A tube reactor of 20 m was simulated to show the performance of the reactor as a function of the length. The thermodynamic upper limit of hydrogen purity on dry basis at 10 bar total pressure and a temperature of 848 K with lithium zirconate as acceptor is 91 mole %. Very long reactors and low space velocities are required to reach the equilibrium composition due to the limitations of the  $CO_2$ -capture kinetics. A contour plot of the dry hydrogen fraction is shown in Fig. 11.9. It is observed that

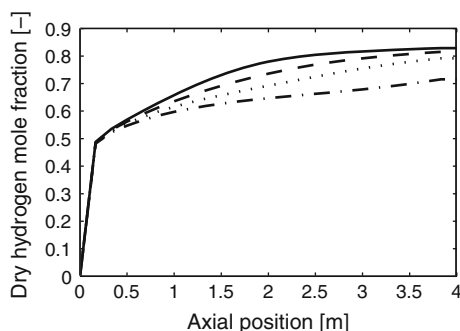

**Fig. 11.10** Results of SE-SMR simulations. Comparison in dry hydrogen mole fraction at different inlet superficial gas velocities.  $v_g^s = 0.6$  m/s (—), 0.3 m/s (— · —), 0.1 m/s (· —) at  $t = 200$  s. Reprinted with permission from [13]. Copyright 2007 American Chemistry Society

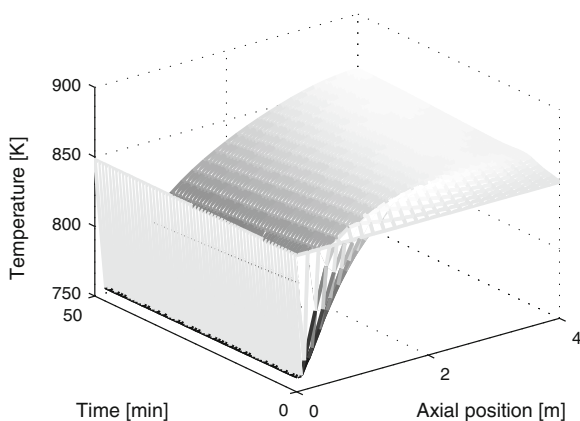

a dry hydrogen mole fraction of 0.8 is reached just after 2 m of the reactor, but to get close to the thermodynamical limit a significantly longer reactor is needed. At 10 m a dry mole fraction of 0.88 is reached, but after ten more meters the dry hydrogen fraction has only increased by about 0.02 and equilibrium conversion is not reached. The main reason for this is the slow capture kinetics at low partial pressures of  $\text{CO}_2$ . A reaction order of 2 with respect to partial pressures of  $\text{CO}_2$  in (11.46) makes the process slow as it reaches the thermodynamical limitation. The same tendency as with longer reactors is observed when lowering the gas velocity. Figure 11.10 shows dry hydrogen purity as function of axial position in a 4 meter long reactor at  $t = 200$  s, and the conversion is strongly dependent of the gas velocity. The  $\text{CO}_2$ -capture kinetics are dependent on the fractional conversion of the  $\text{CO}_2$ -acceptor. Thus, the sorption kinetics will be slower with time. This lead to lower conversion in the reactor as shown in Fig. 11.11.

Figure 11.11 shows that a dry hydrogen mole fraction above 0.84 only is reached in the first minutes. After that the hydrogen content decreases, and after 50 min it is down to just above 70 %, which is close to the thermodynamic limit for steam methane reforming without  $\text{CO}_2$ -acceptor at these conditions. The lower dry hydrogen mole fraction in the reactor is due to the decreasing capture kinetics. The decrease in kinetics is mainly because of the dependence of fractional conversion, but also because

**Fig. 11.11** Results of SE-SMR simulations. Dry hydrogen mole fraction as a function of axial position at different times: (—) after 5 min, (---) after 20 min, (...) after 40 min, and (- · -) after 70 min). Reprinted with permission from [13]. Copyright 2007 American Chemistry Society

**Fig. 11.12** Results of SE-SMR simulations. Temperature in the reactor as function of time and axial position. Reprinted with permission from [13]. Copyright 2007 American Chemistry Society

the temperature in the reactor is lowered. The reactor is heated with a constant temperature at the wall which is set equal to the inlet gas temperature. As observed in Fig. 11.12 this is not sufficient to sustain the temperature in the reactor. This leads to slower sorption kinetics and hence lower conversion. Dry hydrogen mole fractions over 90 % can be reached in SE-SMR with  $\text{Li}_2\text{ZrO}_3$  (s) as  $\text{CO}_2$ -acceptor, but require long reactors and low gas velocities. Simulations show that the kinetics of the  $\text{CO}_2$ -capture is the rate-determining step in the process at the given conditions and indicate that there are no significant intra-particle resistances. This means that a pseudo-homogeneous model with efficiency factor of one can be used instead of more rigorous heterogeneous models.

Recently, numerous investigations of SE-SMR processes have been performed with different sorbent particle designs. Rout et al. [11, 12] and Solsvik and Jakobsen [16] did study the impact of multi-component diffusion fluxes (i.e., bulk multi-component diffusion, Knudsen diffusion, and product layer diffusion) in CaO based sorbent particle and pellets using both natural and synthetic sorbents.

## Chapter 12

# Numerical Solution Methods

In this chapter several numerical methods frequently employed in reactor engineering are introduced. To simulate the important phenomena determining single- and multiphase reactive flows, mathematical equations with different characteristics have to be solved. The relevant equations considered are the governing equations of single phase fluid mechanics, the multi-fluid model equations for multiphase flows, and the population balance equation.

Computers generally make the study of fluid flow easier, more effective and cheaper than using experimental analysis solely. Once the power of numerical simulations was recognized, the interest in numerical techniques increased dramatically and the work of developing numerical solution methods for the governing equations of fluid mechanics now constitutes a separate field of research known as *computational fluid dynamics* (CFD). In engineering practice, the basic conservation equations of fluid mechanics are normally solved by the Finite Difference- and the Finite Volume Methods. Other methods may be more appropriate for equations with particular mathematical characteristics or when more accurate, robust, stable and efficient solutions are required. The alternative spectral methods can be classified as subgroups of the general approximation technique for solving differential equations named the *method of weighted residuals* (MWR) [59]. The relevant spectral methods are called the collocation-, Galerkin, Tau- and Least squares methods. These methods can also be applied to subdomains. The subdomain methods are generally divided into two categories, named spectral element- [41, 103], and finite element [42, 89, 98] methods. In the spectral element methods, the solution on each subdomain (or element) is approximated by a high order polynomial expansion. In the finite element methods, on the other hand, the solution on each element is normally approximated by a first order (low order) polynomial expansion [28].

The CFD market is currently dominated by four codes CFX, FLUENT, PHOENICS and STAR-CD, that are all based on the finite volume method [248]. A few commercial CFD codes based on the finite element method have entered the market

(e.g., FIDAP,<sup>1</sup> COMSOL Multiphysics/FEMLAB<sup>2</sup>), but in general only research codes are developed based on the spectral methods. In this chapter, the elementary theory required for the effective use of this type of commercial codes to simulate single- and multiphase reactive flows in chemical reactors is outlined. However, this chapter is not primarily aimed at supporting those who have access to a commercial package, rather the theory is explored in greater depth so that the interested reader is able to start developing codes from scratch or to extend open source codes. During the last decade the use of open source CFD codes (e.g., OPEN FOAM, CFDLIB, MFIX, etc) are continuously expanding both in academia and industry.

A brief summary of the relevant families of numerical methods are given in the introductory sections. This survey thus comprises the finite difference method, the finite volume method and the weighted residual methods. Due to its relevance in solving multiphase reactor models, a more detailed description of the finite volume method is presented. The multi-fluid model is generally solved by methods that are representing extensions of the techniques used in single phase fluid dynamics. The main extensions are related to the treatment of the volume fraction-pressure-velocity coupling and the calculation of the phase distribution phenomena. When the two-fluid- and multi-fluid models are combined with population balance models (PBEs), a particular method for solving the latter integro-differential equation is required. A synopsis of several methods for solving the PBE is given.

## 12.1 Limitations of Numerical Methods

Due to the strong coupling and the non-linearity of the transport equations determining a reactor model, the usefulness of the numerical methods are conditional on being able to solve the set of PDEs accurately. This is difficult for most flows of engineering interest. There are several reasons for observing differences between the computed results and experimental data. Errors arise from the modeling, discretization and simulation sub-tasks performed to produce numerical solutions. First, approximations are made formulating the governing differential equations. Secondly, approximations are made in the discretization process. Thirdly, the discretized non-linear equations are solved by iterative methods. Fourthly, the limiting machine accuracy and the approximate convergence criteria employed to stop the iterative process also introduce errors in the solution. The solution obtained in a numerical simulation is thus never exact. Hence, in order to validate the models, we have to rely on experimental data. The experimental data used for model validation is representing the reality,

---

<sup>1</sup> FIDAP is a general purpose finite element code for simulating two-dimensional, axisymmetric, or full three dimensional equations of viscous incompressible Newtonian or non-Newtonian fluid flow, including the effects of heat transfer.

<sup>2</sup> COMSOL Multiphysics/FEMLAB is an interactive FEM-based environment for modeling, implementation and solving scientific and engineering problems involving PDEs. This simulation software offers interface to MATLAB with toolboxes which gives MATLAB the ability to solve 2D PDEs by the Finite Element Method, including meshing, preprocessing and post processing capabilities.

but the measurements are also containing errors or uncertainties. These errors have to be taken into consideration comparing the experimental data and the model predictions. A proper model validation procedure consists of a model verification part and a part where the model predictions are compared to experimental data [75]. The model verification may be performed by the *method of manufactured solutions* [180, 202]. The method of manufactured solutions consists in proposing an analytical solution, preferably one that is infinitely differentiable and not trivially reproduced by the numerical approximation, and the produced residuals are simply treated as source terms that produce the desired or prescribed solution. These source terms or residuals are referred to as the consistent forcing functions. This method can be used to confirm that there are no programming errors in the code and to monitor the truncation error behavior during the iteration process. Visualization of numerical solutions is generally the most effective means of interpreting the huge amount of data produced by an unsteady reactor simulation. In many ways these movies resembles the informative weather forecasts on TV. However, there is the danger that an erroneous solution may look good but may not correspond to the actual boundary conditions, fluid properties, and so forth. Unexperienced users of commercial CFD codes must thus be careful. Nice color pictures and videos make a great impression but are of no value if they are not quantitatively or even qualitatively correct. Numerical results must therefore be examined critically before they are believed. In engineering practice, CFD simulations are thus commonly used as advanced learning aids because one may need to postulate expected trends and unknown physics, and estimate the numerical errors in a simulation to find realistic outcomes on which we base our process design decisions. Our physical understanding is then to a large extent improved by the work analyzing the actual flow problem to define a proper benchmark test for model validation, and not by the model predictions in itself solely.

## 12.2 Building Blocks of a Numerical Solution Method

The important ingredients of a numerical solution method are outlined in this section [56, 164, 248]. The basis for any numerical reactor performance simulation is a *mathematical model*, consisting of a set of ordinary differential-, partial differential- or integro-differential equations and initial and boundary conditions. An optimized solution method must then be designed for this particular set of equations. The transport equations can be written in many different forms, depending on the *coordinate system* used. Generally, we may select the orthogonal curvilinear Cartesian-, cylindrical-, and spherical coordinate systems, or the non-orthogonal curvilinear coordinate systems, which may be fixed or moving. In reactor engineering we frequently apply the simple curvilinear cylindrical- or Cartesian coordinates as most reactors have circular, quadratic or rectangular cross sectional geometries. Spherical coordinates are generally employed simulating the reactions and transport processes taking place in spherical catalyst pellets. By *numerical grid* generation we define the discrete locations at which the variables are to be located. The numerical grid is

essentially a discrete representation of the geometric domain on which the problem is solved. It divides the solution domain into a finite number of sub-domains named elements or grid volumes. For reactors with quadratic and rectangular cross sectional geometries structured (regular) grids are generally appropriate, but for the more complex geometries like cylindrical reactors unstructured grids may be required. The ill conditioned or singular points in origo at the center axis are difficult to deal with in an accurate manner employing a cylindrical coordinate representation. Similar problems may occur simulating the transport phenomena taking place in spherical catalyst pellets. The selected mathematical model is represented by a *discretization method* for approximating the differential equations by a system of algebraic equations for the variables at some set of discrete locations in space and time. Many different approaches are used in reactor engineering, but the most important of them are the simple finite difference methods (FDMs), the flux conservative finite volume methods (FVMs), and the accurate high order weighted residual methods (MWRs). The *finite approximations* to be used in the discretization process have to be selected. In a finite difference method, approximations for the solution function derivatives at the grid points have to be selected. In a finite volume method, one has to select the methods of approximating surface and volume integrals in addition to the function derivatives at the cell nodes and surfaces. In a weighted residual method, one has to select appropriate quadrature rules, solution function approximations, and trial- and weighting functions. A compromise between simplicity, ease of implementation, accuracy and computational efficiency has to be made. For the low order finite difference- and finite volume methods, at least second order discretization schemes (both in time and space) are recommended. For the WRMs, high order approximations are normally employed. The discretization process generally gives rise to a large system of non-linear algebraic equations, which has to be solved by an efficient and convergent *solution method*. For linear 1D problems discretized by the low order FDMs and FVMs the direct Tri-Diagonal-Matrix-Algorithm (TDMA) is frequently used [164, 249]. For multi-dimensional problems the *multigrid solvers* [25, 249, 256] and the Krylov sub-space methods like the *conjugate gradient solver* [84, 205] are quite efficient. The problems that are discretized by the low order methods generally give rise to large systems of linear equations whose coefficient matrices are sparse,<sup>3</sup> thus a sparse matrix solver is required. Non-linear equations are solved by an iteration scheme and successive linearization of the equations. A proper *convergence criterion* is important, from both the accuracy and efficiency points of view, because it is deciding when to stop the iterative process. Research codes are generally iterating until the machine accuracy is reached, whereas the commercial codes are less accurate as efficiency is commonly desired by the customers. In commercial CFD codes, a convergence criterion defined by the reduction of the normalized residual, as calculated from the initial guess variable values, by a factor of  $10^{-3}$  is frequently considered sufficient by contract research- and salespersons. However, for complex multiphase reactive flows this approach may easily lead to unphysical solutions.

---

<sup>3</sup> A matrix which is  $n \times m$  with  $k$  non-zero entries is sparse if  $k \ll n \times m$ .

## 12.3 Properties of Discretization Schemes

For most multiphase reactive flow problems, it is not possible to analyze all the operators in the complete solution method simultaneously. Instead the different operators of the method are analyzed separately one by one. The working hypothesis is that if the operators do not possess the desired properties solely, neither will the complete method. Unfortunately, the reverse is not necessarily true. In practical calculation we can only use a finite grid resolution, and the numerical results will only be physically realistic when the discretization schemes have certain fundamental properties. The usual numerical terminology employed in the CFD literature is outlined in this section [56, 164, 249]. A *consistent numerical scheme* produces a system of algebraic equations which can be shown to be equivalent to the original model equations as the grid spacing tends to zero. The *truncation error* represents the difference between the discretized equation and the exact one. For low order finite difference methods the error is usually estimated by replacing all the nodal values in the discrete approximation by a Taylor series expansion about a single point. As a result one recovers the original differential equation plus a remainder, which represents the truncation error. A numerical solution method is said to be *stable* if the method does not magnify the errors that appear during the numerical solution process. This property is relevant as a consistent discretization scheme provides no guarantee that the solution of the discretized equation system will become an accurate solution of the differential equation in the limit of small step size. The stability of low order numerical schemes applied to idealized problems can be analyzed by the *von Neumann's method*. However, when solving relevant, non-linear and coupled reactor model equations with complex boundary conditions, there are no methods available for stability analysis so we have to rely on experience and intuition. A numerical method is *convergent* if the solution of the discretized equations tends to the exact solution of the differential equation as the grid spacing tends to zero. For simple problems convergence is frequently checked using numerical experiments repeating the calculation on a series of successively refined grids. If the method is stable and if all approximations used in the discretization process are consistent, we may experience that the solution does converge to a grid-independent solution. The overall order of the method can then be estimated from the convergence behavior of the error in the solution. For industrial multiphase reactive flows we generally do not have the computational resources available to perform numerical experiments repeating the calculation on a series of successively refined grids. In this case we are stuck and have to rely on experience, intuition, and experimental data. In the cases where the transport equations to be solved express a conservation law, the numerical scheme should also both on a local and a global basis represent *conservative* properties. Conservative schemes are normally preferred. Numerical solution methods should also produce realistic results. In the absence of sources, the model equations require that the minimum and maximum values of the variables should be found on the boundaries of the domain. These conditions should be reflected by the numerical approximation as well. Only a few first order schemes guarantee the so-called

*boundedness property*, but the higher-order schemes generally produce unbounded solutions. Closure models for the unresolved phenomena, which we cannot describe directly due to computational restrictions, should be designed to guarantee physically realistic solutions. Basically, this is a modeling issue, but models that are not *realizable* generally result in unphysical solutions or cause the numerical methods to diverge. In multiphase reactor models realizability is particularly important considering the interfacial coupling terms in the average multi-fluid models and the kernels in the population balance equation. Numerical simulations of any non-linear reactive flow problem provide only approximate solutions. Errors in the solution might be introduced by mistakes when deriving the solution algorithm, in programming, and in setting up the boundary conditions. In addition, there are systematic errors caused by approximations in the model derivation, discretization, and convergence criteria [56]. An *accurate* solution is customarily said to be achieved when the overall truncation error in the solution is small and less than a prescribed threshold. From a Taylor series analysis this means that a fine grid resolution provides accurate solutions. The different errors may also cancel each other, so that sometimes a solution obtained on a coarse grid may agree better with the experiment than a solution on a finer grid, which by definition should be more accurate.

## 12.4 Initial and Boundary Condition Requirements

The formulation of initial- and boundary conditions for a given mathematical problem is of course basically a modeling issue, but models that are not solved with correct type, number and composition of conditions will result in unphysical solutions or cause the numerical methods to diverge. It is recognized that both the formulation of proper initial and/or boundary conditions for a given equation and the choice of an appropriate numerical method that can be used to solve a given PDE, are intimately tied to the mathematical character of the governing equations. The classification of a PDE problem may be difficult as the equation may be an initial value problem with respect to one variable and a boundary value problem in another. However, the overall classification of a PDE is generally governed by the behavior of the terms containing the highest order derivatives. The elementary theory concerning the character of partial differential equations has developed mainly from the study of the simplified two dimensional, quasi-linear second order equation defined by [64, 215]:

$$a \frac{\partial^2 \psi}{\partial x^2} + b \frac{\partial^2 \psi}{\partial x \partial y} + c \frac{\partial^2 \psi}{\partial y^2} + d \frac{\partial \psi}{\partial x} + e \frac{\partial \psi}{\partial y} + f \phi + g = 0 \quad (12.1)$$

where  $a, b, c, d, e, f$ , and  $g$  may be non-linear functions of the independent variables  $x, y, \psi, \frac{\partial \psi}{\partial x}$  and  $\frac{\partial \psi}{\partial y}$ , but not of the second derivative of  $\psi$  (hence the term quasi-linear in the second derivative).

Based on mathematical analysis it has been found that the character of this equation changes depending upon the sign of the function<sup>4</sup>  $b^2 - 4ac$ :

$$\text{if } b^2 - 4ac \begin{cases} < 0 & \text{the equation is } \textit{elliptic} \\ = 0 & \text{the equation is } \textit{parabolic} \\ > 0 & \text{the equation is } \textit{hyperbolic} \end{cases} \quad (12.2)$$

A method for more advanced analysis of the eigenvalues of the governing equation matrix is examined by Flescher [61], Jiang [98], Sect. 4.7, Roache [196], among many others. We generally distinguish between two principal categories of physical behavior, represented by equilibrium and marching problems [249]. The problems in the first category are governed by elliptic equations. Elliptic equations have no real characteristics. These problems, which are called *boundary-value problems*, require boundary conditions over the entire boundary of the calculation domain. An important feature of elliptic boundary value problems is that a disturbance in the interior of the solution changes the solution everywhere else. Many steady-state viscous fluid flow problems belong to this group. Supersonic steady-state inviscid fluid flow problems may behave differently because the fluid velocity is greater than the propagation speed of disturbances and the pressure is unable to influence events in the upstream direction. Supersonic steady-state inviscid fluid flow problems are generally hyperbolic. Subsonic steady-state inviscid flows are normally elliptic because the pressure can propagate disturbances at the speed of sound, which is greater than the flow speed. The problems in the second category of physical behavior are governed by parabolic or hyperbolic equations. Most unsteady viscous fluid flow problems are parabolic, whereas many unsteady inviscid flow problems are hyperbolic with discontinuous solutions. It is noted that the viscous marching problems contain dissipation terms, whereas the inviscid marching problems contain no dissipation terms. Hyperbolic equations have two sets of real characteristics and arise in systems with finite propagation speeds. These problems, which are termed *initial-boundary-value problems*, may be classified as an initial value problem with respect to one variable and boundary value problems in the other variables. The spatial domain may or may not be bounded. If the spatial region is bounded, there may also be boundary conditions (one at each boundary). Otherwise, we have a pure *initial value problem*. An initial value problem requires only an initial condition at one boundary, that is within the domain of dependence of the solution. Thus, hyperbolic equations are always posed in domains that extend to infinity in a time like coordinate. Parabolic equations can be regarded as the limiting case of hyperbolic equations in which the propagation speed of the signals becomes infinite. Such equations are often obtained when it is assumed that the propagation speed (e.g., the speed of sound) is very large compared to any other velocity in the problem, so that the propagation speed may be set to infinity (e.g., the incompressible limit in gas dynamics). The initial and boundary conditions typically applied to parabolic equations are similar to those for hyperbolic

---

<sup>4</sup> The names elliptic, parabolic, and hyperbolic that denote the different characters of the equation, have arisen by analogy with the conic sections of analytic geometry [215, 257].

problems with one important exception. Only one initial condition in time or space is necessary. This is related to the fact that there is only one set of characteristics. However, the spatial domain may be open or closed. In the case of a closed spatial domain, the boundary conditions are the same as those applied in the hyperbolic case. Recall, however, that for hyperbolic equations the signals propagate at a finite speed over a finite region. This property distinguishes hyperbolic equations from the two other types. Compressible flows at speeds close to and above the speed of sound exhibit shock-waves and it turns out that the inviscid flow equations are hyperbolic (i.e., not parabolic) at these speeds. The shock-wave discontinuities are manifestations of the hyperbolic nature of such flows. Numerical solution algorithms for hyperbolic problems are designed for the need to allow for the possible existence of such discontinuities in the interior of the solution. In contrast algorithms designed for parabolic and elliptic problems assume infinite propagation speeds. The mathematical character of the transport equations determining reactive flows are often too complicated to fit into the generalized form of the quasi-linear second order PDE. For a reactive mixture the equations are often strongly coupled through the variable thermodynamic properties and transport coefficients, and may be elliptic, parabolic, hyperbolic or mixtures of all three types of equations, depending on the specific chemical process, flow conditions and geometry. For multiphase flows, additional complications are observed making the multi-fluid equations ill-posed under certain conditions, as mentioned in Sect. 3.5.

## 12.5 Discretization Approaches

In this section an outline of a selection of discretization methods frequently used in chemical reactor engineering is provided.

### 12.5.1 *The Finite Difference Method*

The finite difference method is the oldest method for numerical solution of PDEs, presumably introduced by Euler in the 18th century [56, 85, 208, 215]. It is a convenient method to use for simple geometries. The starting point for the FDM discretization is the transport equation in differential form. The first step in obtaining a numerical solution is to discretize the geometric domain by defining a numerical grid. The domain of interest is replaced by a set of discrete points. In FDMs the grid is normally structured. At each grid point, the differential equation is approximated by replacing the partial derivatives by approximations in terms of the nodal values of the functions. On staggered grids, interpolation is used to obtain variable values that are required at locations other than grid nodes. The result is one algebraic equation per grid node, in which the variable value at that and a few neighboring nodes appear as unknowns. Taylor series expansions can be used to obtain approximations to the

first and second order derivatives of the variables with respect to the coordinates. When necessary, these methods are used to obtain variable values at locations other than grid nodes (interpolation). The Taylor series expansion can be defined by:

$$\psi(z \pm \Delta z) \approx \psi(z) \pm \Delta z \left. \frac{\partial \psi}{\partial z} \right|_z + \frac{(\Delta z)^2}{2!} \left. \frac{\partial^2 \psi}{\partial z^2} \right|_z \pm \cdots + \frac{(\Delta z)^k}{k!} \left. \frac{\partial^k \psi}{\partial z^k} \right|_z \quad (12.3)$$

By forming linear combinations of the values of the function at various grid points  $z, z \pm \Delta z, z \pm 2\Delta z$ , and so on, we can obtain approximations to the derivatives.

The truncation error is usually proportional to a power of the grid spacing  $\Delta x_i$  and/or the time step  $\Delta t$ . If the most important error term is proportional to  $(\Delta x_i)^n$  or  $(\Delta t)^n$  we call the method an  $n$ th-order approximation, often simply indicated by  $O(\Delta x_i^n)$  or  $O(\Delta t^n)$ , respectively.  $n > 0$  is required to obtain an accurate solution as the grid spacing tends to zero. Ideally, all terms should be discretized with approximations of the same order of accuracy. However, certain terms may be dominant in a particular flow and it may be reasonable to treat them with more accuracy than the others. The order of the approximation tell us the rate at which the error decreases as the mesh spacing is reduced. It gives no information about the error on a single grid.

The simplest approximations for the first derivative are given below.

*Forward differences, first order explicit Euler method:*

$$\left. \frac{\partial \psi}{\partial z} \right|_z \approx \frac{\psi(z + \Delta z) - \psi(z)}{\Delta z} + O(\Delta z) \quad (12.4)$$

*Backward differences, first order implicit Euler method:*

$$\left. \frac{\partial \psi}{\partial z} \right|_z \approx \frac{\psi(z) - \psi(z - \Delta z)}{\Delta z} + O(\Delta z) \quad (12.5)$$

*Central differences, second order:*

$$\left. \frac{\partial \psi}{\partial z} \right|_z \approx \frac{\psi(z + \Delta z) - \psi(z - \Delta z)}{2\Delta z} + O(\Delta z^2) \quad (12.6)$$

The simplest approximation for the second derivative can be obtained in a similar manner.

*Central differences, second order:*

$$\left. \frac{\partial^2 \psi}{\partial z^2} \right|_z \approx \frac{\psi(z + \Delta z) - 2\psi(z) + \psi(z - \Delta z)}{(\Delta z)^2} + O(\Delta z^2) \quad (12.7)$$

Any approximation of the derivative of a function in terms of values of that function at a discrete set of points is called a *finite difference approximation*. There are several ways of constructing such approximations, the Taylor series approach illustrated

above is frequently used in numerical analysis because it supplies the added benefit that information about the error is obtained. Another method uses interpolation to provide estimates of derivatives. In particular, we use interpolation to fit a smooth curve through the data points and differentiate the resulting curve to get the desired result. A collection of low order approximations (i.e., first to fourth order polynomial approximations) of first and second order derivative terms can be found in textbooks like [56, 57, 208].

At boundary nodes where the variable values are given by Dirichlet conditions, no model equations are solved. When the boundary condition involve derivatives as defined by Neumann conditions, the boundary condition must be discretized to provide the required equation. The governing equation is thus solved on internal points only, not on the boundaries. Robin conditions can also be used. These conditions consist of linear combinations of the variable value and its gradient at the boundary. A common problem does arise when higher order approximations of the derivatives are used at interior nodes in the vicinity of the boundaries, because these approximations may demand data at points beyond the boundary. It may then be necessary to use one-sided (i.e., upwind, and sometimes even down-wind) or lower order approximations for the derivatives at points close to the boundaries. For many problems the solution changes rapidly in some parts of the solution domain and more gradually in others, hence it is required to use a grid in which the discretization points are more concentrated where the derivatives of the function are larger to distribute the error uniformly over the domain. On such non-uniform grids it is more difficult to construct finite difference approximations to derivatives and the errors tend to be larger. An introduction to finite difference approximations on non-uniform grids can for example be found in books like [56, 57, 85]. The main disadvantages of FDMs are low accuracy, low convergency rates and that the conservation is not enforced unless special care is taken. The restriction to simple geometries is a significant disadvantages in complex flows.

### ***12.5.2 The Finite Volume Method***

The finite volume method has become a very popular method of deriving discretizations of partial differential equations because these schemes preserve the conservation properties of the differential equation better than the schemes based on the finite difference method. The FVM uses the integral form of the conservation or transport equations as its starting point. The solution domain is subdivided into a number of continuous grid of cell volumes, and the equations are applied to each cell volume. At the centroid of each cell volume lies a computational node at which the values are to be calculated. *Interpolation* is used to express variable values at the cell surface in terms of the nodal (cell volume-center) values. Surface and volume integrals are approximated using a suitable *quadrature formula*. As a result, one obtains an algebraic equation for each cell volume, in which a few of the neighboring nodal values appear. The FVM can accommodate any type of grid, so it is suitable for

complex geometries. The method is conservative by construction, so long as the surface integrals which represent convective and diffusive fluxes are the same for the cell volumes sharing the boundary.

The main disadvantages of FVMs are low accuracy and low convergence rates. Compared to FDMs, the main disadvantage of the FVM is that methods of order higher than second are more difficult to develop in 3D because the FVM approach requires two levels of approximation considering the interpolation and integration processes. The FDM only requires approximations of the derivatives and interpolation.

### 12.5.3 The Method of Weighted Residuals

In some sense the method of weighted residuals (MWR) uses the integral form of the conservation or transport equations as its starting point. In particular, the MWR is a general concept for minimizing a residual defined based on the integral form of the governing equations [59, 103]. The key elements of the MWR are the *expansion functions* (also called the trial-, basis- or approximating functions) and the *weight functions* (also known as test functions). The trial functions are used as the basis functions for a truncated series expansion of the solution, which, when substituted into the differential equation, produces the residual. The test functions are used to ensure that the differential equation is satisfied as closely as possible by the truncated series expansion. This is achieved by minimizing the residual, i.e., the error in the differential equation produced by using the truncated expansion instead of the exact solution, with respect to a suitable norm. An equivalent requirement is that the residual satisfy a suitable orthogonality condition with respect to each of the test functions. The choice of test function distinguishes between the most commonly used spectral schemes, the Galerkin, tau, collocation, and least squares versions [28, 59, 98, 103] (see also [22, 63, 74, 152]). In the Galerkin approach, the test functions are the same as the trial functions, whereas in the collocation approach the test functions are translated Dirac delta functions centered at special, so-called collocation points. The collocation approach thus requires that the differential equation is satisfied exactly at the collocation points. Spectral tau methods are close to Galerkin methods, but they differ in the treatment of boundary conditions. For particular problems, it is possible to formulate spectral methods starting out from variational principles [98, 103]. The variational methods provide a means to obtain approximate solutions to differential equations based on minimizing the functional of the equation. A variational method that is based on the principle of minimum potential energy, is known as the *Rayleigh-Ritz method* or just the Ritz method. Many attempts have been made to formulate variational principles patterned after Hamilton's principle (i.e., the *principle of least action*), which governs the equations of mechanics and dynamics of discrete particles as outlined in Chap. 2. The form of the Lagrangian is thus common to many of the variational principles and given by the kinetic energy minus the potential energy. However, the variational method cannot always be applied because there are no variational

principle that can be employed for many problems. The *Galerkin method*, on the other hand, represents a sub-class of the method of residuals and is always applicable because it does not depend on the existence of a variational principle. Hence, in some cases both the Rayleigh-Ritz method and the Galerkin method are applicable for the same problem. In these situations the Galerkin method is thus associated with the *variational principle*. In one view, the Galerkin methods may thus be interpreted as either variational principles or regular methods of weighted residual. To distinguish the two methods, a system of equations is said to be self-adjoint when we can formulate a variational principle for the corresponding problem. Because the Rayleigh-Ritz method is applicable only for equations with self-adjoint operators, the Galerkin method is commonly considered a more universal approach to construction of spectral methods. The variational and Galerkin methods give identical results. However, the self-adjointness can be destroyed by combining the equations or by improper non-dimensionalization. There may be several ways to apply the Galerkin method, but only one of which corresponds to the variational methods. There is always a Galerkin method that corresponds to the variational method, but the reverse is not true. The *orthogonal collocation* method generally employed in the chemical engineering literature refers to the family of collocation methods in which the discretization points are chosen as the zeros of certain orthogonal polynomials (e.g., a polynomial in the family of Jacobi-polynomials) [41, 253]. In the chemical engineering community the collocation method is sometimes also referred to as the pseudo-spectral method. In other engineering branches, on the other hand, the name pseudo-spectral method refers to a particular method related to the fast Fourier transform (FFT) in which spatial derivative terms are effectively solved in spectral space and the products and time derivative terms are solved in physical space [169]. The latter pseudo-spectral method was initially implemented via the collocation method thus the names collocation and pseudo-spectral method are sometimes used as if they are interchangeable. The sub-groups of MWR methods also exist in different versions. The choice of local or global trial functions is the features which distinguishes the *spectral methods* (SMs) from the *spectral element Methods* (SEMs). The *finite element methods* (FEMs) can thus be regarded as SEMs with linear expansion- and weight functions. The trial functions for spectral methods are infinitely differentiable global functions. In the case of spectral element methods, the domain is divided into small elements, and the trial function is specified in each element. The trial and test functions are thus local in character, and well suited for handling complex geometries. It has been shown that several spectral, spectral element, finite volume, and finite difference methods are related [59, 103, 119]. The comparison of MWR-, finite difference- and finite volume calculations may in some cases be best revealed through a spectral element method because in this framework the calculation domain is divided into small elements so the trial and test functions are local in character. The finite difference- and finite volume trial functions are likewise local [103]. With particular trial functions certain SEMs may be regarded as equivalent to finite difference methods. In other cases certain spectral element methods may be regarded as equivalent to particular finite volume methods [56, 164]. However, no formal mathematical generalization of these methods has been defined yet. Nevertheless, in engineering analysis and notation such a heuristic

generalization may sometimes be useful, in which the FDMs and FVMs may be considered members of a broader class of methods called spectral- or spectral element methods. The general method of weighted residuals (MWRs) is outlined next in terms of a simple one dimensional model example [59, 103, 119]. A linear differential operator  $\mathcal{L}$ , that acts on a function  $f$  to produce a function  $g$ , is defined. The function  $f(z)$  represents the solution function. The generalized problem is thus defined as:

$$\mathcal{L}f(z) = g(z), \quad \forall z \in \Omega \quad (12.8)$$

$$Bf(z) = f_0 = 0, \quad \forall z \in \Gamma \quad (12.9)$$

where  $\Omega$  represents the domain of the region governed by  $f(z)$  and  $\Gamma$  represents the boundary of  $\Omega$ .

In the general method of weighted residuals, it is desired to approximate  $f(z)$  by a function  $\tilde{f}(z; a_1, a_2, a_3, \dots, a_N)$ , which is a linear combination of the basis functions chosen from a linearly independent set. That is, the approximation of the solution is generally written as [76]:

$$f(z) \approx \tilde{f}(z; a_1, a_2, a_3, \dots, a_N) = \sum_{i=1}^N a_i \varphi_i(z) \quad (12.10)$$

in which  $N$  is the number of basis functions used. The solution function,  $\tilde{f}(z; a_1, a_2, a_3, \dots, a_N)$ , has one or more unknown parameters,  $a_i$ , that are constant.

For certain MWRs the coefficients are required to satisfy exactly the boundary conditions. Then, when substituted into the differential operator  $\mathcal{L}$ , the result of the operations is not, in general,  $g(z)$ . Hence, a residual error will exist:

$$R(z; a_1, a_2, a_3, \dots, a_N) = \mathcal{L}\tilde{f}(z; a_1, a_2, a_3, \dots, a_N) - g(z) \neq 0 \quad (12.11)$$

The notation in the MWR literature is to force the residual to zero in some average sense over the domain. That is, the MWR requires that the parameters  $a_i$  are determined satisfying the integral:

$$\int_{\Omega} R(z; a_1, a_2, \dots, a_N) W_i(z) d\Omega = 0 \quad (12.12)$$

where  $W_i(z)$ ,  $i = 1, \dots, N$  are the  $N$  arbitrary weighting functions. The number of weighting functions  $W_i(z)$  is exactly equal to the number of unknown constants  $a_i$  in  $\tilde{f}(z; a_1, a_2, a_3, \dots, a_N)$ . The result is a set of  $N$  algebraic equations for the unknown constants  $a_i$ .

There are several sub-groups of MWR methods, according to the particular choices for the weighting function  $W_i(z)$  employed. The performance of the resulting MWR is to a certain extent tied to the properties of the resulting coefficient matrix. To enable an efficient solution process it is desired that the coefficient matrix is symmetric, positive definite and characterized by a small condition number. At the same time the work needed to assemble the coefficient values should be minimized.

The most popular weighted residual methods are:

- *The collocation method*

In this method, the weighting functions  $W_i(z)$  are taken from the family of Dirac  $\delta$  functions in the domain. That is,  $W_i(z) = \delta(z - z_i)$ . The Dirac  $\delta$  functions are defined such that:

$$\int_a^b \delta(z - z_i) dz = 1 \quad (12.13)$$

Substitution of this choice of  $W_i(z)$  into (12.12) gives:

$$\int_{\Omega} R(z; a_1, a_2, \dots, a_n) \delta(z - z_i) d\Omega = 0 \quad \text{for } i = 1, 2, \dots, n \quad (12.14)$$

If this integral relation is evaluated at  $N$  collocation points  $z_1, z_2, \dots, z_N$ ,  $N$  algebraic equations in  $N$  unknowns are obtained:

$$R(z_1; a_1, a_2, \dots, a_N) = 0 \quad (12.15)$$

$$R(z_2; a_1, a_2, \dots, a_N) = 0 \quad (12.16)$$

.

.

.

$$R(z_N; a_1, a_2, \dots, a_N) = 0 \quad (12.17)$$

Hence, the integration of the weighted residual statement results in the forcing of the residuals to zero at specific points in the domain.

The collocation methods can be shown to give rise to symmetric, positive definite coefficient matrices that is characterized with a acceptable condition number for diffusion dominated problems or other higher order even derivative terms. For convection dominated problems the collocation method produces non-symmetric coefficient matrices that are not positive definite and characterized with a large condition number. This method is thus frequently employed in reactor engineering solving problems containing second order derivatives of smooth functions. A typical example is the pellet equations in heterogeneous dispersion models.

The work needed to assemble the coefficient values is generally minimized when the collocation points are chosen freely. However, better convergence performance is normally achieved by the orthogonal collocation methods because a more optimal distribution of the collocation points is achieved. In the orthogonal collocation methods the discretization points are chosen as the zeros in certain orthogonal polynomials. In the historical survey of the spectral methods given by Canuto et al. [28], it was assumed that Lanczos [118] was the first to reveal that a proper choice of trial functions and distribution of collocation points is crucial to the accuracy of the solution of ordinary differential equations. Villadsen and

Stewart [251] developed this method for boundary value problems. The earliest applications of the spectral collocation method to partial differential equations were made for spatially periodic problems by Kreiss and Oliger [109] and Orszag [161].

A particular form of the collocation method, named the Fourier *pseudo-spectral* method [169, 206], is considered to elucidate the background for the strange notation frequently found in the engineering literature. Actually, the Fourier spectral methods have become very popular in recent years due to the availability of the fast transform methods solving hydraulic engineering wave propagating problems [207]. The discrete Fourier transform (DFT) related pseudo-spectral method (PsM) was thus designed for the numerical solution of initial value problems simulating wave propagation. According to Fornberg and Sloan [62, 63] the current popularity of the PsM dates back to the early 1970s and the works of Kreiss and Oliger [109] and Orszag [161]. The Fourier method was first used for PDEs with periodic solution functions by Kreiss and Oliger [109], and it was referred to as the PsM by Orszag [161]. Due to its universality, high efficiency and accuracy, the PsM can be applied for the solution of a large variety of problems. To examine the basic ideas of the PsM, some mathematical operations required in order to solve PDEs numerically are outlined. First, one major task in a numerical method is that the partial derivatives with respect to the time and space coordinates must be approximated. In the WRMs the function is approximated by a truncated series expansion expressed as a sum of basis functions. The derivative of the function can thus be calculated analytically from the solution function expansion as these operators correspond to a weighted sum of derivatives of the basis functions. For the solution of wave propagation problems, it is often convenient to choose trigonometric functions as the set of basis functions, because the *fast Fourier transform* (FFT) is an efficient and widely used algorithm. A FFT is an algorithm to compute the discrete Fourier transform (DFT) and its inverse. A Fourier transform converts time or space to frequency and vice versa. The key issue is that an FFT rapidly computes such transformations. Hence, if some numerical operations are more efficiently computed in spectral space than in physical space (or time), the FFTs are used to transform the operators between the two space representations. In other words, the FFT-related cosine series are often employed as basis functions in order to approximate a *periodic function* as  $f(x)$ . The solution function approximation might thus be expressed as [206]:

$$f(x) \approx \sum_{k=0}^N a_k \cos(kx + \phi_k) \quad (12.18)$$

It is mentioned that integrals of  $f(x)$  can be calculated from this solution expansion and a suitable quadrature rule. In the current context the discrete Fourier transform is convenient due to the following properties. For a function  $f(x, t)$  being periodic in space and given on the interval  $0 \leq x \leq 2\pi$  and the space grid being formed by  $N$  points with space step  $\Delta x = 2\pi/N$ , the DFT is defined by [206]:

$$\tilde{f}(k, t) = Ff = \sum_{j=0}^{N-1} f(j\Delta x, t) \exp\left(-\frac{2\pi ijk}{N}\right) \quad (12.19)$$

and the inverse DFT by:

$$f(j\Delta x, t) = F^{-1}\tilde{f} = \frac{1}{N} \sum_k \tilde{f}(k, t) \exp\left(-\frac{2\pi ijk}{N}\right) \quad (12.20)$$

in which  $F$  denotes the DFT and  $F^{-1}$  the inverse DFT,  $i$  is the imaginary unit and the wave numbers are:

$$k = 0, \pm 1, \pm 2, \dots, \pm(N/2 - 1), -N/2. \quad (12.21)$$

As a rule the FFT algorithm is used for the calculation of the DFT in scientific computing. Making use of the properties of the DFT, the space derivatives of the periodic function  $f(x, t)$  can be calculated as [206]:

$$\begin{aligned} \frac{\partial f(x, t)}{\partial x} &= F^{-1}[ikFf], \\ \frac{\partial^2 f(x, t)}{\partial^2 x} &= -F^{-1}[k^2Ff], \end{aligned} \quad (12.22)$$

$$\begin{aligned} \frac{\partial^3 f(x, t)}{\partial^3 x} &= -F^{-1}[ik^3Ff], \\ &\dots \\ \frac{\partial^n f(x, t)}{\partial^n x} &= F^{-1}[(ik)^n Ff] \end{aligned} \quad (12.23)$$

and integrals as:

$$\int f(x, t) dx = F^{-1} \frac{Ff}{ik} + C \quad (12.24)$$

where  $C$  is the integration constant. If the length of the space period for  $f(x, t)$  is not  $2\pi$  but  $2m\pi$ , then one must use the quantity  $k/m$  instead of  $k$  in the formulas (12.22) and formula (12.24).

The essential idea of the PsM is that by making use of the numerical differential operators<sup>5</sup> (12.22), a PDE problem on the general form:

$$\frac{\partial f(x, t)}{\partial t} = \Phi\left(f(x, t), \frac{\partial f(x, t)}{\partial x}, \frac{\partial^2 f(x, t)}{\partial^2 x}, \dots\right). \quad (12.25)$$

---

<sup>5</sup> In the case of solving integro-PDE problems, the operator defined by formula (12.24) must also be used.

With sufficient initial and boundary conditions, the PBE can be reduced to an ODE (thus representing a kind of method of lines [208]):

$$\frac{\partial f(x, t)}{\partial t} = \Psi(f). \quad (12.26)$$

The resulting initial value problem is completed by introducing an initial condition on the form:

$$f(x, t = 0) = f(x), \quad (12.27)$$

To solve the resulting initial value problem in time, standard ODE solvers can be applied. In the original PsM proposed by Kreiss and Oliger [109], the finite difference *leap-frog scheme*, which is still commonly employed in meteorology, was used to approximate the time derivative term. The PsM is generally applied to compute linear and non-linear spatial derivative terms in conjunction with an explicit time discretization scheme. It is further noticed that the application of the Fourier PsM is restricted as the use of the DFT requires that the boundary conditions must be periodic and the length of the space period must be  $2m\pi$ , where  $m$  is a positive integer. Non-periodic boundary conditions may, however, be incorporated if Chebyshev polynomials were used as basis functions instead of the cosine series [36, 169, 207].

The numerical approach is named the *pseudo-spectral* method because the integration with respect to time is carried out in the physical space, and the Fourier transform related quantities which are solved in spectral space are used only for the calculation of the spatial derivatives. The main advantage of the PsM compared to the FDM is the low cost of the computations, as for the same accuracy the PsM required a much smaller number of space grid points. Moreover, when using the PsM, the DFT of the variable  $f$  is computed at every discrete time step. The major disadvantage of the method is the time step restrictions that must be imposed to maintain stability due to the explicit time integration scheme employed. Another disadvantage of the Fourier PsM is related to the periodic boundary conditions required. However, as mentioned earlier, non-periodic boundary conditions can be incorporated if Chebyshev polynomials are used as basis functions.

It seems that the pseudo-spectral method was originally implemented via collocation. That is, the PsM can be seen either as a particular method using FFT to switch the computations of particular terms between the spectral and physical spaces or as a particular collocation method. However, the PsM has also been implemented via the Galerkin method [161, 162]. For this reason, the PsM is a general approach thus from this viewpoint the names pseudo-spectral and orthogonal collocation methods are surely not interchangeable. Moreover, researchers in other engineering branches use the term pseudo-spectral method referring to a particular form of the collocation method [1, 63, 74], while in the chemical engineering literature the term orthogonal collocation is normally used referring to different collocation methods than the Fourier pseudo-spectral collocation method [251, 253]. The names collocation and pseudo-spectral methods have also been used as synonyms.

- *Least Squares method*

The Least Squares method (LSM) requires that the integral  $I$  of the Square of the residuals  $R(z)$  is minimized:

$$I = \int_{\Omega} [R(z; a_1, a_2, \dots, a_N)]^2 d\Omega \quad (12.28)$$

In order to achieve a minimum of this scalar function, the derivatives of  $I$  with respect to all the unknown parameters must approach zero:

$$\begin{aligned} \frac{\partial I}{\partial a_i} &= \frac{\partial}{\partial a_i} \int_{\Omega} [R(z; a_1, a_2, \dots, a_N)]^2 d\Omega = \int_{\Omega} \frac{\partial}{\partial a_i} [R(z; a_1, a_2, \dots, a_N)]^2 d\Omega \\ &= 2 \int_{\Omega} R(z; a_1, a_2, \dots, a_N) \frac{\partial}{\partial a_i} R(z; a_1, a_2, \dots, a_N) d\Omega = 0 \end{aligned} \quad (12.29)$$

Compared to (12.12), the weight functions are found to be:

$$W_i(z) = 2 \frac{\partial}{\partial a_i} R(z; a_1, a_2, \dots, a_N), \quad i = 1, 2, \dots, N \quad (12.30)$$

The constant pre-factor 2 can be dropped, since it cancels out in the equation. Therefore, the weight functions for the Least Squares Method are just the derivatives of the residual with respect to the unknown constants:

$$W_i(z) = \frac{\partial R(z; a_1, a_2, \dots, a_N)}{\partial a_i}, \quad i = 1, 2, \dots, N \quad (12.31)$$

The determination of  $a_i$  is achieved from the solution of the general MWR integral statement (12.12):

$$\int_{\Omega} R(z; a_1, a_2, \dots, a_N) \frac{\partial R(z; a_1, a_2, \dots, a_N)}{\partial a_i} d\Omega = 0 \quad (12.32)$$

where  $i = 1, \dots, N$ .

According to Jiang [98], the major disadvantage of the LSMs is the high condition number of the resulting system matrix generally obtained with this method making numerical solutions difficult. The major advantages of the LSMs is that the formulation is independent of the underlying problem equation. The LSM always leads to symmetric positive-definite algebraic systems. Particularly simple and efficient algebraic solvers can thus be employed. The LSM is a robust method in the sense that method manipulations like upwinding, staggered grid, artificial dissipation, etc. may not be necessary. This is a major advantage of the

LSMs compared to the conventional Galerkin, Tau, and collocation methods as applied to fluid mechanical problems. The weak formulation of the LSMs is universal to all types of differential equations. Thus, the LSM can be formulated in a very general setting and the implementation can be done in a systematic manner. However, for performance optimization strong form implementations might be advantageous. The SEM least squares method is generally applied to problems containing first order derivatives. A differential equation containing second order derivatives is thus re-written as a set of two equations containing only first order derivatives. The LSMs can be shown to give rise to symmetric, positive definite coefficient matrices that are characterized with a acceptable condition number for convection dominated problems or other higher order odd derivative terms. For diffusion (even derivatives) dominated problems the LSMs still produce symmetric and positive definite coefficient matrices but these are now generally characterized with large condition numbers. In SEM this reformulation is required in order to achieve a  $C^0$  continuity of the functions across the element borders. In particular, the errors in these LSM solutions grow faster with the condition number than the error induced by the other MWR methods. The LSMs might thus be best suited solving convection dominated problems. However, in reactor engineering a few successful attempts have been made applying this method to solve convection-diffusion problems, by reformulating the second order derivatives into a set of two first order derivative equations. Applications and evaluations of the LSMs to single phase flow and PBE problems describing bubbly flows have been performed by Dorao [43], Dorao and Jakobsen [44–49], Zhu [265], Zhu et al. [264, 266], Nayak et al. [156], Sporleder [225], Sporleder et al. [226], Solsvik and Jakobsen [218] and to drop-gas separation analysis by Patruno [168] and Patruno et al. [165–167]. In chemical reactor engineering the LSM has been adopted for the solution of the pellet and fixed packed bed equations, as well as for the engineering Kunii-Levenspiel type bubbling fluidized bed reactor model equations [201, 217, 224].

- *The Galerkin method*

This method may be viewed as a modification of the least squares method. In that is the case, rather than using the derivatives of the residual with respect to the unknown  $a_i$ , the derivative of the approximating function is used. That is, since the approximation of the  $f(z)$  function is given by (12.10), the weight functions are:

$$W_i(z) = \frac{\partial \tilde{f}(z; a_1, a_2, \dots, a_N)}{\partial a_i}, \quad i = 1, 2, \dots, N \quad (12.33)$$

We note that these weights are identical to the original basis functions appearing in (12.10):

$$W_i(z) = \frac{\partial \tilde{\psi}}{\partial a_i} = \varphi_i(z), \quad i = 1, 2, \dots, N \quad (12.34)$$

The Galerkin methods have many of the same characteristics as the collocation methods because both of them give rise to symmetric, positive definite coefficient matrices that are characterized with an acceptable condition number for diffusion dominated problems. An important advantage is that the basis functions used in the Galerkin methods satisfy the boundary conditions (and sometimes other useful properties too). However, it may not always be feasible to require that the basis functions also satisfy the boundary conditions. The way around this problem is to derive formulas for the boundary coefficients requiring that the solution satisfies the boundary conditions instead of the PDEs. This method was invented by Cornelius Lanczos [118] in 1938 and is called the (Lanczos) tau method.<sup>6</sup> For convection dominated problems the Galerkin methods produce non-symmetric coefficient matrices that are not positive definite and characterized with a large condition number. Several upwind-like modifications of the original Galerkin method have been introduced (e.g., the Petrov-Galerkin method [42, 98]) to overcome this limitation. Nevertheless, this method has rarely been employed in reactor engineering even for solving problems containing second order derivatives of smooth functions.

Fernandino et al. [55] did study the use of Galerkin methods for solving typical convection-diffusion reaction engineering models expressed in spherical and cylindrical coordinate systems containing singular points at the origo. In particular, cylindrical and spherical coordinates can lead to a degeneracy in the global system of equations. This difficulty was removed by incorporating the factor  $r$  into the weight function which is introduced naturally by using Jacobi polynomials  $P_k^{\alpha,\beta}$  with  $\alpha = 0$  and  $\beta = 1, 2$ . In this way, an unified framework is obtained for treating the typical reactor geometries.

### • *Method of Moments*

In this method, the weight functions are chosen from the family of polynomials. That is:

$$W_i(z) = z^i \quad i = 0, 1, 2, \dots, N - 1 \quad (12.35)$$

In the event that the basis functions for the approximation, the  $\varphi$ 's, were chosen as polynomials, then the method of moments may be identical to the Galerkin method.

In the finite element and spectral element methods the entire domain  $\Omega$  is divided into sub-domains or elements. Piecewise continuous trail (expansion) functions are then defined for each element instead of using only one global trail function. Different continuity requirements for connecting the elements can be used.

---

<sup>6</sup> The (Lanczos) method was named the *tau* method because Lanczos used the letter  $\tau$  to represent the error.

### 12.5.4 The Finite Element Method

The finite element method originated in the 1950s from the needs for solving complex elasticity, structural analysis problems in civil engineering and aeronautical engineering. The standard nomenclature thus comes from the mechanics of solids, the field in which the method was first developed. The early development of the finite element method in these fields was based on the finite element form of the Rayleigh-Ritz method [42, 98, 103]. This method is based on an energy principle (i.e., the minimum total potential energy principle), and in these particular applications this concept provides a general, intuitive and physical basis that has a great appeal to structural engineers. In the early 1970s, the standard finite element approximations were based upon the Galerkin formulation of the method of weighted residuals. This technique did emerge as a powerful numerical procedure for solving elliptic boundary value problems [22, 42, 57, 61, 89, 98, 103, 119]. The Galerkin finite element methods are preferable for solving Laplace-, Poisson- and diffusion equations because they do not require that a variational principle exists for the problem to be analyzed. However, the power of the method is still best utilized in systems for which a variational principle exists, and it is the preferred method for such problems. In reactor modeling, the balance equations frequently used for analyzing the heat and species mass transport phenomena in porous catalyst pellets constitute an elliptic boundary value problem, provided there are no fluid convection through the pores of the particles. However, most of the classical reactor models consist of convection dominated species mass balances and temperature equations. For self-adjoint problems it is generally possible to define an energy norm of the Galerkin method that result in symmetric coefficient matrices. With regard to simulating convection-dominated transport phenomena by the finite element method, severe problems frequently occur due to the presence of non-symmetric convection operators. Solutions to convection dominated transport problems by the Galerkin method are thus often corrupted by spurious oscillations. These can only be removed by severe grid and time refinements. A remedy is to exchange the standard Galerkin formulation with alternative formulations, called stabilization techniques, avoiding these oscillations without requiring mesh or time step refinement. In recent years, generalized finite element methods of the Petrov-Galerkin type have been designed to produce stable and accurate results in the presence of highly convective effects. Adequate FEMs for solving convection-diffusion transport equations have thus been established and are to some extent used to simulate the performance of chemical reactor processes. However, very few single- and multiphase reactive flow models have been solved by the FEM yet. The finite element method is similar to the finite volume method in that it describes the behavior of a continuum using a subdivision of the continuum domain into smaller sub-regions. In the FEM nomenclature each sub-region of the domain is referred to as an *element* and the process of subdividing a domain into a finite number of simple elements is referred to as *discretization*. In 1D line element can be used. In 2D the elements are usually triangles or quadrilaterals, while in 3D tetrahedrals or hexahedrals are most often used. The basic idea of the

FEM is piecewise approximation, in which the solution of a complex problem is approximated by piecewise linear functions in each element. The function used to approximate the solution in each element is called the interpolation function, basis function, shape function or approximating function, depending upon the discipline in which the method is being applied. The overall accuracy of the finite element solution depends on the choice of the approximating function. Polynomial type of interpolation functions are most widely used in the finite element method literature. In selecting the order of the polynomials, a compromise has to be made between accuracy and computational effort. A higher order polynomial usually approximates an arbitrary function better, hence it may be desirable to use a higher order polynomial. However, a low order polynomial simplifies the computations. The simplest method of approximation is to assume a linear distribution of the unknown function within the element domain. Besides, the accuracy is normally low when using only a few large elements, more accurate solutions are generally obtained with a large number of small elements. Computational costs, on the other hand, may increase significantly as the number of elements in a model increases. Thus, it may be more practical to use fewer elements, and ones that have a higher order of interpolation.

To illustrate the finite element method, the basic steps in the formulation of the standard Galerkin finite element method for solving a one-dimensional Poisson equation is outlined in the following.

The governing equations with boundary conditions are called the *strong form* of the problem, and can be defined by:

$$\frac{d^2 f(z)}{dz^2} = g_0 \quad (12.36)$$

$$\psi(0) = 0 \quad (12.37)$$

$$\left. \frac{df}{dz} \right|_{z=L} = 0 \quad (12.38)$$

The derivation of the governing FEM discretization equations is quite similar to the derivation of the spectral methods presented in the previous section. The first task is to reformulate the problem into the *weak form*. The weak form is a variational statement of the problem in which we integrate against a weighting function. This has the effect of relaxing the problem, meaning that instead of finding an exact solution everywhere we are requiring a solution that satisfies the strong form in an average manner over the domain.

Following the MWR framework, the residual function can be defined as:

$$R(z) = \frac{d^2 \tilde{f}(z)}{dz^2} - g_0 \quad (12.39)$$

Multiplying the residual function with a weighting function  $W(z)$  and integrate, the weak form is established:

$$\int_0^L R(z)W(z)dz = 0 \quad (12.40)$$

In the spectral form of the method we approximate  $f(z)$  by a function  $\tilde{f}(z; a_1, a_2, a_3, \dots, a_n)$ , representing a linear combination of the basis functions:

$$f(z) \approx \tilde{\psi}(z; a_1, a_2, a_3, \dots, a_n) = \sum_{i=1}^N a_i \varphi_i(z) \quad (12.41)$$

The  $a_i, i = 1, \dots, N$  are constants and  $\varphi_i$  are linearly independent basis functions of  $z$ , which are chosen to satisfy the boundary conditions and  $N$  is the total number of basis functions used.

In the Galerkin method, the weights  $W_i(z)$  are taken to be the basis functions  $\varphi_i(z)$  used in the approximate solution of (12.41). In this case, the continuous residual function (12.39) can be approximated by:

$$\tilde{R}(z; a_1, a_2, a_3, \dots, a_N) = \frac{d^2 \tilde{f}(z; a_1, a_2, a_3, \dots, a_N)}{dz^2} - g_0 \quad (12.42)$$

Thus, in the Galerkin method the weak form (12.40) becomes<sup>7</sup>:

$$\int_0^L \tilde{R}(z; a_1, a_2, \dots, a_N) \varphi_i(z) dz = 0, \quad i = 1, 2, \dots, N. \quad (12.43)$$

Equation (12.43) represents  $N$  simultaneous equations in the  $N$  unknowns  $a_1, a_2, \dots, a_N$ . Thus, the solution of (12.43) gives the approximation solution through (12.41).

In the next step the approximate solution (12.41) is substituted into the approximate weak form (12.43):

$$\int_0^L \left( \frac{d^2 \tilde{f}(z; a_1, a_2, a_3, \dots, a_N)}{dz^2} - g_0 \right) \varphi_j dz = \sum_{i=1}^n a_i \int_0^L \frac{d^2 \varphi_i}{dz^2} \varphi_j dz - \int_0^L g_0 \varphi_j dz \quad (12.44)$$

The integration by parts method can be used to simplify the first term on the LHS of the problem Eq. (12.36):

$$\int_0^L \frac{d^2 \varphi_i}{dz^2} \varphi_j dz = \left. \frac{d\varphi_i}{dz} \varphi_j \right|_{z=0}^{z=L} - \int_0^L \frac{d\varphi_i}{dz} \frac{d\varphi_j}{dz} dz = - \int_0^L \frac{d\varphi_i}{dz} \frac{d\varphi_j}{dz} dz \quad (12.45)$$

---

<sup>7</sup> This is an  $L_2$  inner product. The orthogonality condition states that the residual is orthogonal to the space of basis functions.

where the boundary conditions, requiring that the basis functions and the first derivative of the basis functions vanish at the respective global boundaries (12.37) and (12.38), are invoked.

The weak form for the spectral method becomes:

$$-\sum_{i=1}^n a_i \int_0^L \frac{d\varphi_i}{dz} \frac{d\varphi_j}{dz} dz = \int_0^L g_0 \varphi_j dz \quad \text{for all } j = 1, 2, \dots, n \quad (12.46)$$

If a FEM is to be used instead, the global basis functions are replaced with element basis functions. In this case, the domain must be discretized. In general, the domain  $z = [0, L]$  is discretized into  $K + 1$  elements with  $K$  internal node points in addition to the boundaries.

Next, a finite dimensional subspace  $\Omega_h$  consisting of piecewise linear functions must be constructed. The sub-intervals of length  $\Delta z = z_{j+1} - z_j, j = 1, 2, \dots, K$  are defined. As parameters to describe how the function change over the sub-intervals, the basis functions are chosen as the set of triangular functions defined as:

$$\varphi_j(z) = \begin{cases} \frac{1}{\Delta z}(z - z_{j-1}) & \text{for } z_{j-1} \leq z \leq z_j, \\ \frac{1}{\Delta z}(z_{j+1} - z) & \text{for } z_j \leq z \leq z_{j+1}, \\ 0 & \text{otherwise} \end{cases} \quad (12.47)$$

for  $j = 1, 2, \dots, K$ .

It is noticed that the basis functions have the following property:

$$\varphi_j(z_i) = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{otherwise} \end{cases} \quad (12.48)$$

where  $i, j \in [1, \dots, N]$ .

If the segments are equal, the interval  $[0, L]$  is divided into  $K + 1$  equal segments of length  $\Delta z$ . Each basis function is an isosceles triangle, displaced from the previous one by a distance equal to one-half of the length of the base line. This means that the solution to  $\psi$  between any two points  $z_j$  and  $z_{j+1}$  is approximated by a piecewise linear function:

$$\tilde{f}(z) = a_j \left(1 - \frac{z - z_j}{z_{j+1} - z_j}\right) + a_{j+1} \left(\frac{z - z_j}{z_{j+1} - z_j}\right) \quad (12.49)$$

where  $a_j$  has the physical meaning of being the value of  $f$  at the nodes  $z = z_j$ .

The first-order derivatives of the basis functions are:

$$\frac{d\varphi_j(z)}{dz} = \begin{cases} \frac{1}{\Delta z} & \text{for } z_{j-1} \leq z \leq z_j, \\ -\frac{1}{\Delta z} & \text{for } z_j \leq z \leq z_{j+1}, \\ 0 & \text{otherwise} \end{cases} \quad (12.50)$$

which have discontinuities for  $z = z_j, j = 1, 2, \dots, K$ .

Introducing (12.47) into (12.46), the result is:

$$\sum_{j=1}^n A_{ij} \tilde{f}_j = g_j \quad (12.51)$$

where  $A_{ij} = \int_0^L \frac{d\varphi_i}{dz} \frac{d\varphi_j}{dz} dz$  and  $f_j = \int_0^L g_0 \varphi_j dz$ .

The assembly of the complete system contributions to the discrete weak form results in a matrix equation of the form:

$$\mathcal{A} \tilde{\mathbf{f}} = \mathbf{g} \quad (12.52)$$

where  $\tilde{\mathbf{f}}$  is the vector of the unknown nodal value.

Due to the local nature of the basis functions chosen, the system can be assembled based on local element contributions. The result is an element matrix equation of the form:

$$\mathcal{A}_e \tilde{\mathbf{f}}_e = \mathbf{g}_e \quad (12.53)$$

where  $\tilde{\mathbf{f}}_e$  is the vector of the unknown nodal values in element  $e$ , and  $\mathcal{A}_e$  and  $\mathbf{g}_e$  are the element characteristic matrix and vector, respectively.

It is important to note that in order to combine each element approximation of the field variable to obtain a global solution certain *continuity* conditions must be satisfied at the element boundaries. The value of the field variable at a node must be the same for each element that shares that node. Such an approximation is said to have  $C^0$  continuity. If the first derivatives of the field variable were continuous between elements, then the approximation would have  $C^1$  continuity. In general, with  $N$  the highest order derivative that appears in the element equations, a function is  $C^N$  continuous if the derivatives up to the  $N$ -th order are continuous. The *compatibility* condition requires that  $C^{N-1}$  continuity exists at the element interfaces. The *completeness* condition requires that there is  $C^N$  continuity of the field variable within the element. It has been shown that the finite element solution will converge to the exact solution as the number of elements increases provided that the compatibility and completeness conditions are satisfied. It is further noted that the global system matrix  $\mathcal{A}$  and global system vector  $\mathbf{g}$  result from the assembly of element contributions. The addition of the element contributions to the appropriate locations in the global system matrix  $\mathcal{A}$  and global system vector  $\mathbf{g}$  can be represented through the action of an assembly operator acting on the local element matrix and nodal vector as follows:

$$\mathcal{A} = \sum_{e=1}^K \mathcal{A}_e \quad (12.54)$$

$$\mathbf{g} = \sum_{e=1}^K \mathbf{g}_e \quad (12.55)$$

where the summation sign indicates assembly over all finite elements. The summation does not indicate the usual algebraic summation, but is based on the requirement of compatibility at the element nodes. With the standard  $C^0$  continuity requirement at the element boundaries, this means that at the nodes where the elements are connected, the value of the unknown  $f_{e,i}$  is set to be equal for all the elements joining at the node. In the implementation of the method one may thus either assemble information obtained on an element by element basis into a global representation of the problem or assemble the information from the complete system form instead. Some assembling techniques are outlined by Jiang [98], Chap. 15. Finally, standard numerical techniques may be used to solve the global system matrix equation for the unknown field variables.

#### 12.5.4.1 The Basic Steps of a Standard Finite Element Analysis

- **Discretization of the Continuum Calculation Domain**  
The continuum domain is generally replaced by a series of interconnected sub-domains or elements. It must then be determined which types of elements are appropriate for a given problem and the density of elements required to sufficiently approximate the solution.
- **Selection of Interpolation Functions**  
Once an element shape has been chosen, it must be determined how the variation of the field variable across the element domain is to be represented or approximated. The method of approximating the solution across each element is referred to as *element interpolation*. In most cases, a polynomial interpolation function is used. The number of nodes assigned to an element dictates the order of the interpolation function which can be used. The degree to which the approximate solution is sufficient to accurately model the problem is affected by the type of interpolation function used. The simplest method of approximation is to assume a linear distribution of the unknown function within the element domain.
- **Find the Element Properties**  
Once the interpolation functions have been chosen, the field variables in the domain of the element are approximated in terms of the discrete values at the nodes. The Galerkin finite element spatial discretization of the boundary value problem is formulated as an equivalent weak or variational form to the strong form of the boundary value problem. A system of equations is formed which expresses the element properties in terms of the quantities at the nodes.
- **Assembly the Element Properties**  
The assembly procedure combines each element approximation of the field variable with the specified compatibility and completeness requirements between the elements to form a piecewise approximation of the behavior over the entire solution domain. A standard FEM requires  $C^0$  continuity at the element boundaries.
- **Apply the Boundary Conditions**  
The global system of equations created by the previous FEM steps cannot be solved, before a set of suitable boundary conditions are specified.

- Solve the System of Equations

Once the boundary conditions have been applied to the assembled matrix of equations, standard numerical techniques can be used to solve the global system matrix equation for the unknown field variables. The matrix equations generated by the finite element process are often sparse and sometimes also symmetrical.

Among the basic attributes of the method are the ease in modeling complex geometries, the consistent treatment of differential type boundary conditions and the possibility to be programmed in a flexible and general purpose format.

## 12.6 Basic Finite Volume Algorithms Used in Computational Fluid Dynamics

The purpose of this section is to outline the design of the basic finite volume solution algorithms used in computational fluid dynamics. The design of solution strategy for particular flow problems is strongly related to the mathematical characteristics of the governing equations. The mathematical nature of the governing equations for single phase flow was discussed in Sect. 12.4. For compressible flows, for which the pressure property equals the thermodynamic pressure, the continuity and momentum equations are strongly coupled to the energy equation through energy dissipation and reversible conversion of kinetic energy into internal energy. It is noticed that both the pressure gradient and the magnitude of the pressure are important properties in compressible flows. Transonic and greater Mach number flows usually exhibit shock-waves, which allow for nearly discontinuous changes in the flow field properties. The main difficulty encountered when constructing numerical methods for the compressible flow equations is thus the possible presence of discontinuities in the solution. One remedy devised to solve these equations is known as the shock-capturing methodology. One of the basic ingredients of the shock-capturing schemes is the high-resolution mechanism (implemented in the form of flux-limiters) that allows one to combine higher-order accuracy with shock-capturing capabilities to circumvent Gudunov's theorem [78]. The governing equations for compressible unsteady viscous flow collectively constitute an *incomplete parabolic* system of equations, as there are no second-order derivative terms in the continuity equation. The particular system form constituting the continuity, momentum, and temperature equations in addition to the ideal gas law is referred to as the *compressible Navier-Stokes equations*. The governing compressible equations for unsteady inviscid flows, called the *Euler equations*, are hyperbolic. This system admits discontinuous solutions, and it can also describe the transition from a subsonic flow (where  $|\mathbf{v}| < c$ ) to supersonic flow (where  $|\mathbf{v}| > c$ ), where  $c = (\gamma RT)^{1/2}$  is the speed of sound. The two basic sets of compressible equations are generally treated numerically within a generic system framework on the form of scalar convection laws [4, 86, 196, 214]. That is, the use of the *conservation form* of the unsteady governing conservation equations assures conservation of mass, momentum and energy so that the simulations performed may convergence to physically valid solutions [122]. The solution of the generic

conservation law form of all the governing equations (i.e., continuity, momentum, and energy) takes the form of a time-marching solution where the dependent flow field variables are solved progressively in steps of time. Note that in this formalism the computations provide the fluid density  $\rho$  and the flux variables  $\rho \mathbf{v}$  and  $\rho E$ , and not the primary variables  $\mathbf{v}$  and  $E$ . However, these methods are specifically designed for compressible flows and may become very inefficient when applied to incompressible flows [40, 86, 196]. In one view, the reason for this inefficiency is that in compressible flows the continuity equation contains a time derivative which drops out in the incompressible limit. As a result, the equations become extremely stiff in the limit of weak compressibility, necessitating the use of very small time steps or implicit methods. Another interpretation, of the same effects, is that the compressible equations support sound waves which have a definite speed associated with them. As some information propagates at the flow velocity, the larger of the two velocities determines the allowable time step in an explicit method. In the low speed limit, one is forced to take a time step inversely proportional to the sound speed for any fluid velocity. This step size may be much smaller than the one a method designed for incompressible flows (which support sound waves that propagate at an infinite speed) might allow. For incompressible flows, the pressure quantity acts as a surface force and the system of governing equations becomes parabolic (dynamic flow) or elliptic (steady-state flow), the continuity and momentum equations are not coupled to the energy equation because the fluid velocity is so low that no significant heat is produced thus the flow is isothermal. This means that only the pressure gradient, and not the magnitude of the pressure, is important characterizing the flow. Moreover, for these low Mach number flows, the pressure gradient required to force the fluid to move is so small that the density is not significantly affected. The density is thus almost constant and the transient term in the continuity equation drops out. For this reason, the continuity can no longer be considered as an equation for density but acts as a constraint on the velocity field. However, the pressure is closely connected to the velocity components in the continuity equation thus for a sequential solution of the equations, it is necessary to devise a mechanism to couple the continuity and momentum equations through the pressure field. It is further noted that for parabolic and elliptic equations the propagation speed of the signals is infinite. A Poisson-like equation for the pressure is frequently used to correct the intermediate velocity field and enforce continuity. In this formalism the computations provide the primary variables  $\rho$  and  $\mathbf{v}$ . In computational fluid dynamics, the central part of a solution algorithm for the governing equations denotes the procedure used to resolve the coupling that arises between the pressure, density and velocity. Two families of algorithms, the *pressure-based methods* and *density-based methods*, have been developed for solving the governing equations for single phase flow. Pressure-based methods use a Poisson-like equation for updating the pressure instead of the continuity equation in the fundamental form, while density-based methods use the continuity equation to update density. For this reason, for compressible fluids an equation of state is used to provide density in pressure based schemes and pressure in density based schemes. The pressure-based method was introduced by Harlow and Welch [81] and Chorin [35] for the calculation of unsteady incompressible viscous flows (parabolic

equations). In Chorin's *fractional step method*, an incomplete form of the momentum equations is integrated at each time step to yield an approximate velocity field, which will in general not be divergence free, then a correction is applied to that velocity field to produce a divergence free velocity field. The correction to the velocity field is an orthogonal projection in the sense that it projects the initial velocity field into the divergence free field without changing the vorticity. This step is called the projection step, and schemes that use this approach are often called *projection methods*. The original Chorin method was modified for use with finite volumes defined on a staggered grid by Kim and Moin [106]. An alternative to the basic projection method is the pressure correction method, which is similar to the basic projection method, but with the pressure gradient term retained in the momentum equations. The Poisson's equation is then solved for a pressure correction quantity which is used to correct the intermediate velocity field and enforce continuity. This approach was proposed by Patankar and Spalding [163] and Patankar [164]. In classical gas dynamics much research effort has been devoted to the development of accurate and efficient numerical algorithms suitable for solving flows in the different Mach number regimes. The magnitude of the Mach number dictates the type of algorithm to be employed in the solution procedure. The density-based methods are generally used for high Mach number flows, and the pressure-based methods for low Mach number flows. However, the fundamental equations of motion are uniformly valid as the Mach number ranges from zero (incompressible limit) to infinite (supersonic limit). During the years, many researchers have thus aimed at developing unified algorithms capable of solving flow problems in all the Mach number regimes. In any numerical method designed to be capable of predicting both incompressible and compressible fluid flows the pressure must play its dual role and act on both velocity and density to satisfy continuity. Several researchers have worked on extending the range of pressure-based methods, that were originally developed for incompressible flows at low Mach numbers, to high Mach numbers [40, 93, 101, 140, 154, 213, 240]. It is noted that Harlow and Amsden [82] developed one of the first pressure-based finite difference methods of this kind. On the other hand, the density-based methods were originally developed for compressible transonic flows and have been extended down to low Mach numbers through the use of preconditioning techniques [34, 50, 117, 147, 232]. Incompressible steady flows are commonly solved by pressure-based methods and methods based on the concept of artificial compressibility [50, 231]. The extension of pressure correction methods to steady flows, generally elliptic equations, has been performed by Patankar and Spalding [163] and Patankar [164]. The artificial compressibility method for calculating steady incompressible flows was proposed by Chorin [34]. In this method, an artificial compressibility term is introduced in the continuity equation, and the unsteady terms in the momentum equations are retained. Hence, the system of equations becomes hyperbolic and many of the methods developed for hyperbolic systems can be applied. Generally, the design of modern solution algorithms for fluid flow problems is associated with the choice of primitive variables, the grid arrangement, and the solution approach [154]. In the class of pressure-based solution algorithms, both fully coupled and segregated approaches have been proposed. In the coupled approach, the discretized forms of the momentum

and continuity equations are linked together and the resulting system of equations is solved simultaneously [29]. This technique thus ensures a close connection between the velocity components and pressure, which may enhance the convergence rate and hence the efficiency of the method. However, the memory required to store the coefficients and variables at all grid nodes is often prohibitive for multidimensional flows. This storage problem may be alleviated by subdividing the domain into parts and solving the system of equations over each sub-domain separately. However, these sub-domain solvers artificially decouple the equations in the various parts of the domain and may thus lead to reduced convergence rates. In the segregated approach, the discretized equations are solved separately, but over the whole domain. This has the advantage of requiring considerably less computer storage than the semi-coupled method in addition to providing the flexibility of easily solving additional PDEs when needed. Two different grid arrangements have been used in implementations of the numerical methods, staggered grids [81] with different grid cell volumes for velocities and pressure and collocated grids [145, 146, 191] with the same grid cell volume for all variables. For the collocated variable schemes special interpolation procedures for evaluating the grid cell volume face velocities are required. The use of staggered grids [81], in which pressure is stored at the grid cell center and velocities at the grid cell faces, removes the need for interpolation of pressure in the momentum equations and of velocity in the continuity equation. The primary disadvantage of the staggered grid arrangement is the greater complexity associated with the use of different grid systems for the various variables, which becomes overwhelming in curvilinear coordinates. In this book, emphasis is placed on describing elements of particular pressure-based methods originally developed for incompressible flows. The basic methods are extended and used to simulate reactive flows. The standard algorithms used to solve multi-fluid models are extensions of particular pressure-based methods for single phase flows.

## 12.7 Elements of the Finite Volume Method for Flow Simulations

In this section, a survey of the basic elements of the finite volume method, as applied to single phase flows, is provided [56, 164, 196, 248, 249]. The numerical issues considered are the approximations of surface and volume integrals, time discretizations, and space discretization of diffusive and convective (or advective) terms.

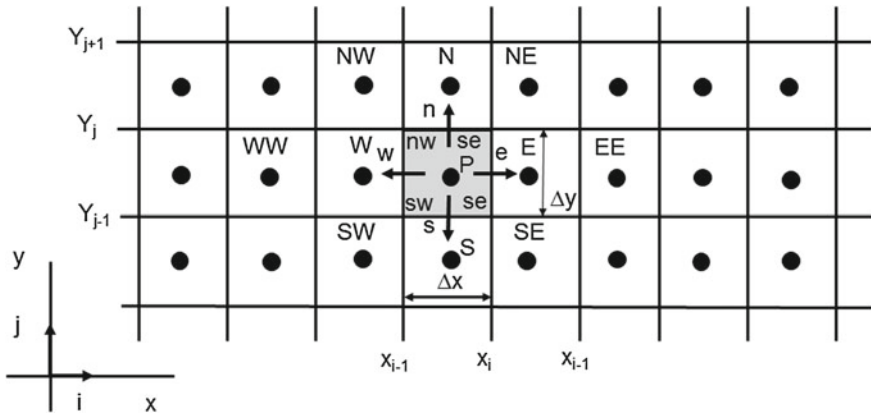

Consider the generic transport equation for the property  $\psi$  and assume that the velocity field and the fluid properties are known. The starting point for the FVM is the integral form of the balance equation:

$$\int_t \int_V \frac{\partial(\rho\psi)}{\partial t} dv dt + \int_t \int_A \rho\psi \mathbf{v} \cdot \mathbf{n} da dt = \int_t \int_A \Gamma_\psi \nabla\psi \cdot \mathbf{n} da dt + \int_t \int_V S_\psi dv dt \quad (12.56)$$

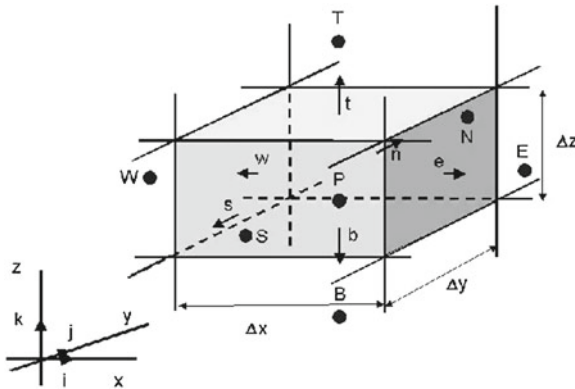

The finite volume integration of (12.56) over a grid volume is essentially the same for both steady and dynamic systems to treat convection, diffusion and source terms. The first observation is that for steady problems the transient term vanishes, and the finite volume integration consists of the space dimensions only. It makes sense to consider the common features first.

The first task is to discretize the domain. The computational domain is subdivided into a finite number of small grid cell volumes (GCVs) by a grid which defines both the grid cell volume boundaries and the computational nodes. Note that in the finite difference method, the grid defines the location of the computational nodes solely. In the FVM a general 3D cell containing the central node  $P$  has six neighboring nodes identified as west, east, south, north, bottom and top nodes ( $W, E, S, N, B, T$ ), as sketched in Fig. 12.2. The notation,  $w, e, s, n, b$  and  $t$  are used to refer to the west, east, south, north, bottom and top cell faces, respectively. The algorithms are illustrated using Cartesian grids.

The usual approach in the FVM is to define GCVs by a suitable grid and assign the computational node to the GCV center. However, one could as well define the nodal locations first and construct GCVs around them, so that GCV faces lie midway between nodes. The advantage of the first approach is that the nodal value represents the mean over GCV volume to higher accuracy (second order) than in the second approach, since the node is located at the centroid of the GCV. The advantage of the second approach is that CDS approximations of derivatives at GCV faces are more accurate when the face is midway between two nodes. The discretization principles are the same for both variants. One only has to take into account the relation between the various locations within the integration volume. The first variant is used more often than the second approach. The transport equation on the integral form (12.56) applies to each GCV, as well as to the solution domain as a whole. If we employ consistent discretization schemes and sum the equations for all GCVs, the global transport equation is obtained, since the surface integrals over the inner GCV faces cancel out. To obtain an algebraic equation for each GCV, the surface and volume integrals need to be approximated using appropriate *quadrature formulas* [57, 107, 155, 182]. In some cases, depending on the approximations used, these equations are equal to those obtained from the FDM. Special treatment of the boundary grid cells may be required for the implementation of boundary conditions. The volume integrals are calculated in the same way as for every GCV, but the fluxes through the GCV faces coinciding with the domain boundary require special treatment. These boundary fluxes must either be known, or be expressed as a combination of interior values and boundary data. The convective fluxes are normally prescribed at the inflow boundary. Convective fluxes are zero at impermeable walls and symmetry planes, and are generally assumed to be independent of the coordinate normal to an outflow boundary. Diffusive fluxes are sometimes specified at a wall or boundary values of variables are prescribed.

**Fig. 12.2** A typical grid volume and the notation used for a Cartesian 3D grid

### 12.7.1 Numerical Approximation of Surface and Volume Integrals

In Figs. 12.1 and 12.2, typical 2D and 3D Cartesian cell volumes are shown together with the notation commonly used. In 3D the GCV surface is subdivided into six plane surfaces, denoted by lower case letters corresponding to their direction ( $e$ ,  $w$ ,  $n$ ,  $s$ ,  $t$ , and  $b$ ) with respect to the central node  $P$ . The 2D case can be regarded as a special case of the 3D one in which the dependent variables are independent of  $z$ , hence the GCV surface is subdivided into four plane surfaces ( $e$ ,  $w$ ,  $n$ , and  $s$ ).

The net flux through the GCV boundary is the sum of integrals over the GCV faces:

$$\int_A f da = \sum_k \int_{A_k} f da \quad (12.57)$$

where  $f$  is the component of the convective ( $\rho\psi\mathbf{v} \cdot \mathbf{n}$ ) or diffusive ( $\Gamma_\psi\nabla\psi \cdot \mathbf{n}$ ) vector in the direction normal to the GCV face.

The only unknown is  $\psi$ , since the velocity field and the fluid properties are assumed known. If the velocity field is not prescribed, it can be calculated from a more complex problem involving non-linear coupled equations, which are examined shortly. To demonstrate the method, a representative GCV face labeled  $e$  in Fig. 12.2 is considered. Analogous expressions can be derived for all faces by making appropriate index substitutions. To calculate the surface integral in (12.57) accurately by a high order quadrature, the integrand  $f$  must be known at a large number of points on the surface  $A_e$ . This information is generally not available, rather only the nodal GCV center values are known so a low order quadrature approximation must suffice. The low order integral approximation consists in calculating the integral in terms of the variable values at one or only a few locations on the grid cell face. These cell face values are generally unknown and subsequently approximated by interpolation of the nodal GCV center values. The low order quadrature formula thus contains two levels of approximation.

Many quadrature formulas approximate the integral by a weighted sum of the values of the integrand at particular points on the interval of integration, that is, by [57, 107, 155, 182]:

$$\int_a^b f(x)dx = \sum_{i=1}^n w_i f(x_i) \quad (12.58)$$

$a \leq x_1 < x_2 < \dots < x_n \leq b$ . The numbers  $w_i$  are called the *weights* and the points  $x_i$  at which the function is evaluated are called the *abscissas*. Both the abscissas and weights depend on the method and on the number of intervals,  $n$ .

A quadrature formula is defined by the prescription of the weights and abscissas. One of the easiest ways to obtain useful quadrature formulas for our purpose is to use Lagrangian interpolation on an equally spaced mesh and integrate the result. This class of quadrature formulas is called the Newton-Cotes formulas. The closed quadrature formulas includes the endpoints of the range of integration as abscissas, whereas the open quadrature formulas do not include the endpoints of the range of integration as abscissas. The open formulas are not as accurate as the closed ones, hence most of the open formulas are rarely used. However, in engineering practice the simplest open formula, known as the *midpoint rule*, is frequently used as basis for the FVM. The midpoint rule is obtained by a polynomial of order zero which passes through the midpoint assuming that the function is constant over the integral of integration. The surface integral can thus be approximated as a product of the mean value over the surface and the cell face area [56]. The integrand at the cell face center is frequently used as an approximation to the mean value over the surface. In this case the surface integral is written as:

$$F_e = \int_{A_e} f da = \langle f \rangle A_e \approx f_e A_e \quad (12.59)$$

This integral approximation is of second order, provided that the value of  $f$  at location  $e$  is known. However, the value of  $f$  is generally not available at cell faces, hence they have to be obtained by interpolation from the node values. In order to preserve the second order accuracy of the midpoint rule approximation of the surface integral, the value of  $f_e$  must be obtained with at least second order accuracy. An alternative closed Newton-Cotes quadrature formula of second order can be obtained by a polynomial of degree 1 which passes through the end points. This quadrature formula is called the *trapezoid rule*. In 2D this surface integral approximation requires the integrand values at the GCV corners. For higher order approximations of the surface integrals, the integrand is needed at more than two locations. To apply the fourth-order Simpson's rule approximation, the values of  $f$  are required at three locations, the cell face center  $e$  and, the two corners  $ne$  and  $se$ . In order to retain the fourth order accuracy of the surface integral approximation, the corner values have to be obtained by interpolation of the nodal values providing the same or higher order accuracy.

Several terms in the transport equations require *integration over the volume of a grid cell*. The midpoint rule is again the simplest second order approximation available. The second-order approximation thus consists in replacing the volume integral by the product of the mean value and the GCV. The mean value is approximated as the value at the GCV center:

$$S_P = \int_{GCV} s dv = \langle s \rangle \Delta V \approx s_P \Delta V \quad (12.60)$$

where  $s_P$  is the value of  $s$  at the GCV center. Since all the variables are available at node  $P$ , no interpolation is necessary.

Higher order approximations are possible but require the value of  $s$  at more locations than just the GCV center. If the intervals between the interpolation points are allowed to vary, other groups of quadrature formulas can be used, such as the Gaussian-, Clenshaw-Curtis- and Fejér quadrature formulas. However, in engineering practice the simple second order midpoint approximation formulas are normally used for the surface and volume integrals in the FVM.

### 12.7.2 Solving Unsteady Problems

In transient problems the time coordinate must be discretized in a similar manner as the space coordinates [56, 80, 85, 86, 164, 196, 249]. The major difference between the space and time coordinates lies in the direction of influence. The time dependent variables will affect the flow only in the future, thus there is no backward influence. This has a strong influence on the choice of solution strategy. In general, two different solution strategies can be adopted for the time coordinate and used together with the finite volume space discretization of the generic unsteady transport equation. In one approach, the standard finite volume space integration is subsequently followed by discretization of the resulting ordinary differential equation in time. This approach is named the *numerical method of lines* [208]. Numerical methods for solving ODEs

are easily available in standard textbooks. However, a second alternative approach is commonly used in the basic textbooks on the finite volume method. In the standard finite volume discretization of the generic transport Eq. (12.56), integrations are performed over the GCV shown in Fig. 12.2 and over the time interval from  $t$  to  $t + \Delta t$ . In this framework the time integrals have to be approximated by use of appropriate quadrature formulas. These formulas may not be as easily accessible as the differential methods. To illuminate this topic, henceforth we follow the standard finite volume approach integrating both in time and space.

Integration of the convective flux terms over the GCV surface gives:

$$\begin{aligned} \int_A \mathbf{n} \cdot (\rho \mathbf{v} \psi) dA &= (\rho v_x \psi A)_e - (\rho v_x \psi A)_w + (\rho v_y \psi A)_n - (\rho v_y \psi A)_s \\ &\quad + (\rho v_z \psi A)_t - (\rho v_z \psi A)_b \end{aligned} \quad (12.61)$$

Integration of the diffusive flux terms over the GCV surface gives:

$$\begin{aligned} \int_A \mathbf{n} \cdot (\Gamma_\psi \nabla \psi) dA &= (\Gamma_\psi A \frac{\partial \psi}{\partial x})_e - (\Gamma_\psi A \frac{\partial \psi}{\partial x})_w + (\Gamma_\psi A \frac{\partial \psi}{\partial y})_n - (\Gamma_\psi A \frac{\partial \psi}{\partial y})_s \\ &\quad + (\Gamma_\psi A \frac{\partial \psi}{\partial z})_t - (\Gamma_\psi A \frac{\partial \psi}{\partial z})_b \end{aligned} \quad (12.62)$$

Introducing these standard finite volume space integrations, and changing the order of integration in the rate of change term, the result is:

$$\begin{aligned} &\int_t^{t+\Delta t} (\rho v_x \psi A)_e dt - \int_t^{t+\Delta t} (\rho v_x \psi A)_w dt + \int_t^{t+\Delta t} (\rho v_y \psi A)_n dt - \int_t^{t+\Delta t} (\rho v_y \psi A)_s dt \\ &\quad + \int_t^{t+\Delta t} (\rho v_z \psi A)_t dt - \int_t^{t+\Delta t} (\rho v_z \psi A)_b dt = - \left[ \int_t^{t+\Delta t} \frac{d(\rho \psi)}{dt} dt \right] \Delta V \\ &\quad + \int_t^{t+\Delta t} (\Gamma_\psi A \frac{\partial \psi}{\partial x})_e dt - \int_t^{t+\Delta t} (\Gamma_\psi A \frac{\partial \psi}{\partial x})_w dt + \int_t^{t+\Delta t} (\Gamma_\psi A \frac{\partial \psi}{\partial y})_n dt - \int_t^{t+\Delta t} (\Gamma_\psi A \frac{\partial \psi}{\partial y})_s dt \\ &\quad + \int_t^{t+\Delta t} (\Gamma_\psi A \frac{\partial \psi}{\partial z})_t dt - \int_t^{t+\Delta t} (\Gamma_\psi A \frac{\partial \psi}{\partial z})_b dt + \int_t^{t+\Delta t} \langle S_\psi \rangle \Delta V dt \end{aligned} \quad (12.63)$$

In the framework of the FVM it is generally assumed that the transient term prevails over the whole grid volume. To make further progress, approximate numerical techniques for evaluating the time integral from  $t_n$  to  $t_{n+1}$  are required.

It is observed that after the spatial terms have been approximated with appropriate discretizations, as outlined in the subsequent sections, the equation can be cast into the form of an ordinary differential equation on the form:

$$\int_{t_n}^{t_n+\Delta t} \frac{d\psi(t)}{dt} dt = \psi^{n+1} - \psi^n = \int_{t_n}^{t_n+\Delta t} f(t, \psi(t)) dt \quad (12.64)$$

where we have used the standard shorthand notation  $\psi^{n+1} = \psi(t_{n+1})$ .

Even though the time integration on the LHS is exact, the term on the RHS cannot be evaluated without knowing the solution<sup>8</sup> so some approximation is necessary. The time integral approximations are naturally viewed as obtained by use of some of the same quadrature rules as employed discussing the surface and volume integral approximations. However, there are more than one way to derive some of the time discretization methods considered in this section. Naturally, one way to derive these methods starts from the integrated form of differential equation, defining a quadrature problem. Nevertheless, another approach is to approximate the derivative in the differential equation, defining a numerical differentiation problem. Single-step methods can thus be introduced in a natural way by means of Taylor series. The Taylor series method is conceptually simple and capable of high accuracy. Its basis is truncated Taylor Series about a particular point. The family of backward differentiation formulas, BDFs, are primarily viewed as arising from numerical differentiation [211]. These methods employ previously computed information at more than two points.

### 12.7.2.1 Classes of ODE Methods

A brief survey of the different classes of ODE methods that are commonly applied solving the governing equations of fluid mechanics, is given in the following. The elementary notation and the basic properties of these ODE discretizations are briefly mentioned. Analysis of these methods can be found in numerous textbooks on the numerical solution of ordinary differential equations and will not be repeated here [33, 80, 107, 155, 193, 196, 211].

Several methods require the value of  $\psi(t)$  at some point other than  $t = t_n$  and these cannot be solved without further approximation or iteration. The class of methods that only require information from time level  $n$ , or previous time levels, is called *explicit* methods. The other class of methods that require information from time level  $n + 1$  and thus solved by an iterative procedure are named *implicit*. Explicit methods are relatively easy to program and use little computer memory and computation time per step but are unstable if the time step is large. On the other hand, implicit methods require iterative solution to obtain the values at the new time step. This makes them

---

<sup>8</sup> In an attempt to find an exact formula for the integral, we may resort to the *mean value theorem* of calculus. This theorem states that if the integrand is evaluated at a particular known instant  $t = \tau$  between  $t_n$  and  $t_{n+1}$ , the integral is equal to  $f(\tau, \psi(\tau))\Delta t$ . However, in the present case the theorem is of little use since the instant  $\tau$  is unknown.

harder to program and they use more computer memory and time per time step, but they are more stable. Problems including a wide range of time scales are called *stiff*. In general, for stiff problems implicit methods tend to behave well, whereas explicit methods often become unstable. For a single small time step it is possible to use Taylor series to estimate the order of the error for the methods. The order determines the rate at which the error goes to zero as the step size goes to zero, and this only after the step size has become small enough.

### Basic Single-Step Methods

The single-step methods<sup>9</sup> utilize the information at a single point on the solution curve to compute the next point. These methods are derived by use of low order quadrature formulas.

Four low order single-step approximations are frequently used:

- If the integral on the right side of (12.64) is estimated using the value of the integrand at the initial point, the result is:

$$\psi^{n+1} = \psi^n + f(t_n, \psi^n) \Delta t \quad (12.65)$$

which is known as the first order *explicit* or *forward Euler* method.

- If the integral on the right side of (12.64) is estimated using the value of the integrand at the final point, the first order *implicit* or *backward Euler* method is obtained:

$$\psi^{n+1} = \psi^n + f(t_{n+1}, \psi^{n+1}) \Delta t \quad (12.66)$$

- If the integral on the right side of (12.64) is estimated using the value of the integrand at the midpoint of the time interval, the *midpoint rule* is obtained:

$$\psi^{n+1} = \psi^n + f(t_{n+1/2}, \psi^{n+1/2}) \Delta t \quad (12.67)$$

Depending on what further approximations are employed, the midpoint rule may give rise to single-step or multistep methods. For example, the second order (two-step) *Leapfrog method* frequently used in meteorology and oceanography can be deduced from the midpoint rule [56, 80, 196]:

$$\psi^{n+1} = \psi^{n-1} + 2f(t_n, \psi^n) \Delta t \quad (12.68)$$

- Finally, if the integral on the right side of (12.64) is estimated using a value of the integrand that is obtained by a straight line interpolation between the initial and final points, the result is:

---

<sup>9</sup> In a few textbooks these methods are referred to as *two-level methods* because they involve the values of the unknown at two time levels [56].

$$\psi^{n+1} = \psi^n + \frac{1}{2}[f(t_n, \psi^n) + f(t_{n+1}, \psi^{n+1})]\Delta t \quad (12.69)$$

This approximation is called the *trapezoid rule* and is the basis for the popular second order Crank-Nicholson method.

### Runge-Kutta Methods

The *Runge-Kutta* methods are classified as a group of single-step methods that employs points between  $t_n$  and  $t_{n+1}$  to approximate the solution preferably with higher order accuracy. The Runge-Kutta methods are designed to imitate the desirable features of the Taylor series method, but with the replacement of the requirement for the evaluation of higher order derivatives of the original differential equation with the requirement to evaluate  $f(t, \psi)$  at some points within the step  $t_n$  to  $t_{n+1}$ . In one view, the Runge-Kutta methods arise from underlying quadrature formulas that use data only from  $[t_n, t_{n+1}]$ .

The basic idea of the Runge-Kutta methods is illustrated through a simple second order method that consists of two steps. The integration method is constructed by making an explicit Euler-like trail step to the midpoint of the time interval, and then using the values of  $t$  and  $\psi$  at the midpoint to make the real step across the whole time interval:

$$\psi_*^{n+1/2} = \psi^n + \frac{\Delta t}{2}f(t_n, \psi^n) \quad (12.70)$$

$$\psi^{n+1} = \psi^n + \Delta t f(t_{n+1/2}, \psi_*^{n+1/2}) \quad (12.71)$$

A major disadvantage with higher order Runge-Kutta methods is that the derivative must be calculated many times per time step, making these methods more expensive than midpoint methods of comparable order. However, the Runge-Kutta methods are more stable than the multistep methods of the same order and need no data other than the initial condition required by the differential equation itself (self-starting).

### Predictor-Corrector and Multistep Methods

Predictor-Corrector methods have been constructed attempting to combine the best properties of the explicit and implicit methods. The multistep methods are using information at more than two points. The additional points are ones at which data has already been computed. In one view, Adams methods arise from underlying quadrature formulas that use data outside of  $[t_n, t_{n+1}]$ , specifically approximate solutions computed prior to  $t_n$ .

Numerous predictor-corrector methods have been developed over the years. A simple second order predictor-corrector method can be constructed by first approximating the solution at the new time step using the first order explicit Euler method:

$$\psi_*^{n+1} = \psi^n + f(t_n, \psi^n) \Delta t \quad (12.72)$$

where the  $*$  indicates that this is not the final value of the solution at  $t_{n+1}$ .

Then, the solution is corrected by applying a second order trapezoid rule using  $\psi_*^{n+1}$  to compute the derivative:

$$\psi^{n+1} = \psi^n + \frac{1}{2}[f(t_n, \psi^n) + f(t_{n+1}, \psi_*^{n+1})] \Delta t \quad (12.73)$$

The formula is known both as the *improved Euler formula* and as *Heun's method* [211]. This method has roughly the stability of the explicit Euler method. Unfortunately, the stability may not be improved by iterating the corrector because this iteration procedure converges to the trapezoid rule solution only if  $\Delta t$  is small enough.

In order to construct higher-order approximations one must use information at more points. The group of multistep methods, called the *Adams methods*, are derived by fitting a polynomial to the derivatives at a number of points in time. If a Lagrange polynomial is fit to  $f(t_{n-m}, \psi^{n-m}), f(t_{n-m+1}, \psi^{n-m+1}), \dots, f(t_n, \psi^n)$ , and the result is used to compute the integrals in (12.64), we obtain an explicit method of order  $m+1$ . Methods of this type are called *Adams-Bashforth* methods. It is noted that only the lower order methods are used for the purpose of solving partial differential equations. The first order method coincides with the explicit Euler method, the second order method is defined by:

$$\psi^{n+1} = \psi^n + \frac{1}{2}[3f(t_n, \psi^n) - f(t_{n-1}, \psi^{n-1})] \Delta t \quad (12.74)$$

and, the third order method is expressed by:

$$\psi^{n+1} = \psi^n + \frac{1}{12}[23f(t_n, \psi^n) - 16f(t_{n-1}, \psi^{n-1}) + 5f(t_{n-2}, \psi^{n-2})] \Delta t \quad (12.75)$$

If data at  $t_{n+1}$  is included in the interpolation polynomial, implicit methods, known as *Adams-Moulton* methods, are obtained. The first order method coincides with the implicit Euler method, and the second order method coincides with the trapezoid rule. The third order method is written as:

$$\psi^{n+1} = \psi^n + \frac{1}{12}[5f(t_{n+1}, \psi^{n+1}) + 8f(t_n, \psi^n) - f(t_{n-1}, \psi^{n-1})] \Delta t \quad (12.76)$$

The Adam-Bashforth methods are frequently used as predictors and the Adam-Moulton methods are often used as correctors. The combination of the two formulas results in predictor-corrector schemes.

The multistep methods are quite cheap as they require only one evaluation of the derivative per time step. However, these methods require data from many points prior to the current one, thus they cannot be started using only data at the initial point. One has to use other methods to get the calculation started. A common approach is to

use a small step size and a lower order method to achieve the desired accuracy, and slowly increase the order as more data becomes available. Moreover, the multistep methods often give accurate solutions for some time and then begin to behave badly as they can produce non-physical solutions that may grow. A useful remedy for this problem is to restart the method at certain intervals. However, this trick may reduce the accuracy and/or the efficiency of the scheme.

### 12.7.3 Approximation of the Diffusive Transport Terms

In order to study the principles of spatial discretization, we consider the steady state diffusion of a property  $\psi$  in a one dimensional domain as sketched in Fig. 12.3.

In Cartesian coordinates the process is governed by:

$$\frac{d}{dx}(\Gamma_\psi \frac{d\psi}{dx}) + S_\psi = 0 \quad (12.77)$$

where  $\Gamma_\psi$  is a diffusion coefficient and  $S_\psi$  a source term. Boundary values of  $\psi$  at the end points are prescribed.

Considering the 1D system in x-direction, the west side face of the grid volume is referred to by  $w$  and the east side grid volume face by  $e$ . The distances between the nodes  $W$  and  $P$ , and between nodes  $P$  and  $E$ , are identified by  $\delta x_{WP}$  and  $\delta x_{PE}$ , respectively. Similarly, the distances between face  $w$  and point  $P$  and between  $P$  and face  $e$  are denoted by  $\delta x_{wP}$  and  $\delta x_{Pe}$ , respectively.

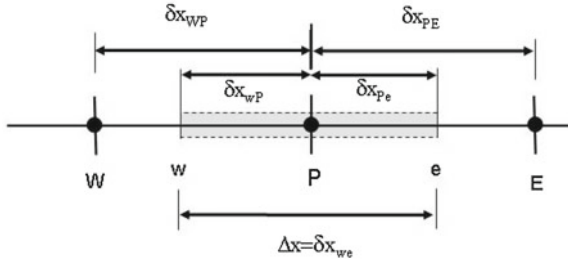

The key step of the finite volume method is the integration of the governing equation over the grid cell volume to form a discretized equation at the nodal point  $P$ . By use of the Gauss theorem and the midpoint quadrature formula, the result is:

$$\int_{\Delta V} \frac{d}{dx}(\Gamma_\psi \frac{d\psi}{dx}) dv + \int_{\Delta V} S_\psi dv = (\Gamma_\psi A \frac{d\psi}{dx})_e - (\Gamma_\psi A \frac{d\psi}{dx})_w + \langle S_\psi \rangle \Delta V \quad (12.78)$$

in which  $A$  is the cross section area of the GCV face,  $\Delta V$  is the grid cell volume and  $\langle S_\psi \rangle$  is the average value of  $S_\psi$  over the GCV.

In order to achieve useful forms of the discretized equation, the interface diffusion coefficient  $\Gamma_\psi$  and the property gradient  $d\psi/dx$  at the east  $e$  and west  $w$  faces are required. Linear approximations are frequently used to calculate the interface values and the gradients. The linear profile approximation of the property gradient is second order and widely used for the evaluation of the diffusive fluxes in (12.77). For the diffusive flux at position  $e$ , the approximation is then written as:

$$\Gamma_{\psi,e}(\frac{\partial \psi}{\partial x})_e \approx \Gamma_{\psi,e} \frac{(\psi_E - \psi_P)}{x_E - x_P} \quad (12.79)$$

**Fig. 12.3** A typical grid volume and the grid spacing notation used for a Cartesian 1D grid

The parameter value of  $\Gamma_{\psi,e}$  at the surface position  $e$  is determined by linear interpolation between points  $P$  and  $E$ . For uniform grids, and when the interface  $e$  is midway between the grid node points,  $\Gamma_{\psi,e}$  is approximated as the *arithmetic mean* of  $\Gamma_{\psi,P}$  and  $\Gamma_{\psi,E}$ , given by  $\Gamma_{\psi,e} \approx (\Gamma_{\psi,P} + \Gamma_{\psi,E})/2$ .

The source term  $\langle S_{\psi} \rangle$  may be a function of the dependent variable, hence a common practice in the FVM is to approximate the source term by means of a linear function:

$$\langle S_{\psi} \rangle \approx S_{\psi,u} + S_{\psi,p}\psi_P \quad (12.80)$$

The discretized equation can then be approximated by:

$$\Gamma_{\psi,e}A_e\left(\frac{\psi_E - \psi_P}{\delta x_{PE}}\right) - \Gamma_{\psi,w}A_w\left(\frac{\psi_P - \psi_W}{\delta x_{WP}}\right) + (S_{\psi,u} + S_{\psi,p}\psi_P) \Delta V \quad (12.81)$$

This relation can be rearranged and written on the following algebraic form:

$$a_P\psi_P = a_W\psi_W + a_E\psi_E + S_{\psi,u}\Delta V \quad (12.82)$$

The corresponding coefficients are defined as:

$$a_W = \frac{\Gamma_{\psi,w}}{\delta x_{WP}}A_w \quad (12.83)$$

$$a_E = \frac{\Gamma_{\psi,e}}{\delta x_{PE}}A_e \quad (12.84)$$

$$a_P = \frac{\Gamma_{\psi,e}}{\delta x_{PE}}A_e + \frac{\Gamma_{\psi,w}}{\delta x_{WP}}A_w - S_{\psi,p}\Delta V = a_W + a_E - S_{\psi,p}\Delta V \quad (12.85)$$

The truncation error of the linear approximation of the property gradient  $(\frac{\partial \psi}{\partial x})_e$  can be calculated in terms of two Taylor series expansions around  $\psi_e$ .

The Taylor series expansion of  $\psi_P$  about  $\psi_e$  yields [249]:

$$\psi_P = \psi_e - \delta x_{eP}\left(\frac{\partial \psi}{\partial x}\right)_e + \frac{(\delta x_{eP})^2}{2}\left(\frac{\partial^2 \psi}{\partial x^2}\right)_e - \frac{(\delta x_{eP})^3}{6}\left(\frac{\partial^3 \psi}{\partial x^3}\right)_e + O((\delta x_{eP})^4) \quad (12.86)$$

The Taylor series expansion of  $\psi_E$  about  $\psi_e$  yields:

$$\psi_E = \psi_e + \delta x_{Ee} \left( \frac{\partial \psi}{\partial x} \right)_e + \frac{(\delta x_{Ee})^2}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_e + \frac{(\delta x_{Ee})^3}{6} \left( \frac{\partial^3 \psi}{\partial x^3} \right)_e + O((\delta x_{Ee})^3) \quad (12.87)$$

Subtracting the first expansion formula from the second one, recognizing that  $\delta x_{EP} = \delta x_{eP} + \delta x_{Ee}$ , the result is:

$$\begin{aligned} \psi_E - \psi_P &= (\delta x_{eP} + \delta x_{Ee}) \left( \frac{\partial \psi}{\partial x} \right)_e + \left( \frac{(\delta x_{Ee})^2}{2} - \frac{(\delta x_{eP})^2}{2} \right) \left( \frac{\partial^2 \psi}{\partial x^2} \right)_e \\ &\quad + \left( \frac{(\delta x_{Ee})^3}{6} + \frac{(\delta x_{eP})^3}{6} \right) \left( \frac{\partial^3 \psi}{\partial x^3} \right)_e + O((\delta x_{Ee})^4) + O((\delta x_{eP})^4) \quad (12.88) \end{aligned}$$

The central difference approximation of the first derivative term becomes:

$$\begin{aligned} \left( \frac{\partial \psi}{\partial x} \right)_e &= \frac{\psi_E - \psi_P}{(\delta x_{eP} + \delta x_{Ee})} - \left( \frac{(\delta x_{Ee})^2 - (\delta x_{eP})^2}{2(\delta x_{eP} + \delta x_{Ee})} \right) \left( \frac{\partial^2 \psi}{\partial x^2} \right)_e \\ &\quad + \left( \frac{(\delta x_{Ee})^3 + (\delta x_{eP})^3}{6(\delta x_{eP} + \delta x_{Ee})} \right) \left( \frac{\partial^3 \psi}{\partial x^3} \right)_e + O((\delta x_{Ee})^4) - O((\delta x_{eP})^4) \quad (12.89) \end{aligned}$$

When the location  $e$  is midway between  $P$  and  $E$ , as for uniform grids, this scheme is of second order because the first error term on the RHS vanishes and the leading error term becomes proportional to the square of the grid spacing. For a non-uniform grid, the leading error term is proportional to the grid spacing  $\delta x_{EP}$  and this scheme is thus formally of first order.

### 12.7.4 Approximation of the Convective Transport Terms

An important aspect of Eulerian reactor models is the truncation errors caused by the numerical approximation of the convection/advection terms [96]. Very different numerical properties are built into the various schemes proposed for solving these operators. The numerical schemes chosen for a particular problem must be consistent with and reflect the actual physics represented by the model equations.

The transient equation describing the advection of a scalar property  $\psi$  yields:

$$\frac{\partial \psi}{\partial t} + \mathbf{v} \cdot \nabla \psi = 0 \quad (12.90)$$

The conservative form of the advection equation is obtained by use of the continuity equation, hence:

$$\frac{\partial(\rho\psi)}{\partial t} + \nabla \cdot (\mathbf{v}\rho\psi) = 0 \quad (12.91)$$

Numerical methods constructed based on the advective form (non-conservative form) of the transport operator are shape preserving, but not conservative [96]. Schemes constructed based on the conservative form (or flux form) of the transport operator are preferable when strict conservation is required.

The truncation error associated with convection/advection schemes can be analyzed by using the modified equation method [254]. By use of Taylor series all the time derivatives except the 1. order one are replaced by space derivatives. When the modified equation is compared with the basic advection equation, the right-hand side can be recognized as the error. The presence of  $\Delta x$  in the leading error term indicate the order of accuracy of the scheme. The even-ordered derivatives in the error represent the diffusion error, while the odd-ordered derivatives represent the dispersion (or phase speed) error. Another method for analyzing the truncation error of advection schemes is the Fourier (or von Neumann method) [157, 158, 215]. This method is used to study the effects of numerical diffusion on the solution.

A Taylor series analysis on the 1D transport equation shows that the transient artificial viscosity coefficients for explicit upwind differencing (i.e., a scheme that is 1. order in time and space) is given by [195, 196]:

$$\nu_{\text{numerical}} = \frac{v\Delta x}{2}(1 - \text{CFL}) \quad (12.92)$$

The corresponding implicit method gives:

$$\nu_{\text{numerical}} = \frac{v\Delta x}{2}(1 + \text{CFL}) \quad (12.93)$$

It can be noted that at least the explicit upwind method for the constant velocity equation model gives the exact answer for  $\text{CFL} = 1$ , whereas the implicit upwind differencing method never does. The numerical viscosity of the implicit method may increase a lot for  $\text{CFL} = 1$ . For this reason, many research codes for dynamic flows requiring high accuracy are solved using explicit time discretizations.

Over the years numerous discretization methods for the convection/advection terms have been proposed, some of them are stable for steady-state simulations solely, others were designed for transient simulations solely, but many techniques can be used for both types of problems. In order to study the numerical properties of these schemes, principally the steady state convection and diffusion of a property  $\psi$  with a source term in a one dimensional domain are considered as sketched Fig. 12.3 using a staggered grid for the velocity components so that the  $x$ -velocity components are located at the  $w$  and  $e$  GCV faces. Preliminary, it is assumed that the velocity is constant and the fluid properties are constants. The convective and diffusive processes are then governed by a balance equation of the form:

$$\frac{d}{dx}(\rho v_x \psi) = \frac{d}{dx}(\Gamma_\psi \frac{d\psi}{dx}) + S_\psi \quad (12.94)$$

where  $\rho$  denotes the mixture density and  $v_x$  the velocity component in the  $x$ -direction. Boundary values of  $\psi$  at the end points are prescribed.

The one dimensional flow must also satisfy the 1D continuity equation:

$$\frac{d}{dx}(\rho v_x) = 0 \quad (12.95)$$

As for the pure diffusion problem, the key step of the finite volume method is the integration of the governing equations over the grid cell volume to yield a set of discretized equations at the nodal point  $P$ . By use of the Gauss theorem and the midpoint quadrature formula, the result is:

$$(\rho v_x A \psi)_e - (\rho v_x A \psi)_w = (\Gamma_\psi A \frac{d\psi}{dx})_e - (\Gamma_\psi A \frac{d\psi}{dx})_w + \langle S_\psi \rangle \Delta V = 0 \quad (12.96)$$

The continuity yields:

$$(\rho v_x A)_e - (\rho v_x A)_w = 0 \quad (12.97)$$

In order to obtain useful forms of the discretized equations, the GCV surface terms at the east  $e$  and west  $w$  faces are required. As in the pure diffusion problem, the diffusive terms are approximated using linear approximations to calculate the surface values of the diffusion coefficients and the gradients. The result is:

$$F_e \psi_e - F_w \psi_w = D_e(\psi_E - \psi_P) - D_w(\psi_P - \psi_W) + S_{\psi,u} \Delta V \quad (12.98)$$

Temporarily, for convenience, the face values of the property  $\psi$  are kept unknown.

The continuity yields:

$$F_e - F_w = 0 \quad (12.99)$$

in which the two variables  $F$  and  $D$  are defined to represent the convective mass flux and the product of the diffusion conductance and cell face area  $F = \rho v_x A$  and  $D = \Gamma A / \delta x$ .

Assuming that the velocity and density fields are known, it follows that the unknown  $F_w$  and  $F_e$  terms can be determined. By that means (12.98) reduces to a transport equation for the property  $\psi$  with only one unknown variable. However, in order to solve the convection-diffusion equation we need to approximate the transport property  $\psi$  at the  $e$  and  $w$  faces. A few classical convection/advection schemes are outlined in the subsequent subsections.

#### 12.7.4.1 Upwind Differencing Scheme

The first order explicit upwind scheme was introduced by Courant et al. [37], and later on several extensions to second order accuracy and implicit time integrations have been developed.

In the upwind scheme  $\psi_e$  is approximated by the  $\psi$  value at the node upstream of the surface location  $e$ :

$$\psi_e = \begin{cases} \psi_P & \text{if } (\mathbf{v} \cdot \mathbf{n})_e > 0, \\ \psi_E & \text{if } (\mathbf{v} \cdot \mathbf{n})_e < 0. \end{cases} \quad (12.100)$$

By use of the Upwind Differencing Scheme (UDS), the coefficients in (12.98) can be defined as:

$$a_W = D_w + \max(F_w, 0) \quad (12.101)$$

$$a_E = D_e + \max(-F_e, 0) \quad (12.102)$$

$$a_P = a_W + a_E + (F_e - F_w) - S_{\psi,p} \Delta V \quad (12.103)$$

$$S_{\psi,u}^{UDS} \Delta V = S_{\psi,u} \Delta V \quad (12.104)$$

The main advantage of this scheme is that it satisfies the boundedness criteria unconditionally. A severe disadvantage associated with the UDS is that it is very numerically diffusive.

A Taylor series expansion about  $P$  gives (for Cartesian grid and  $(\mathbf{v} \cdot \mathbf{n})_e > 0$ ) [56]:

$$\psi_e = \psi_P + (x_e - x_P) \left( \frac{\partial \psi}{\partial x} \right)_P + \frac{(x_e - x_P)^2}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_P + \mathcal{O}((x_e - x_P)^3) \quad (12.105)$$

The UDS approximation retains only the first term on the right hand side, hence the leading truncation error term is of first order in the grid spacing,  $\delta x_{Pe} = (x_e - x_P)$ , so it is a first order scheme.

The leading truncation error term obtained discretizing the convective terms in the convection-diffusion equation (12.98) by use of the UDS resembles a diffusive flux. For  $(\mathbf{v} \cdot \mathbf{n})_e > 0$ , the UDS for the convective flux at the location  $e$  becomes:

$$\begin{aligned} (\rho v_x A)_e \psi_e &\approx (\rho v_x A)_e \psi_P + (\rho v_x A)_e \delta x_{Pe} \left( \frac{\partial \psi}{\partial x} \right)_P \\ &\approx (\rho v_x A)_e \psi_P + \Gamma_{\text{num},e} \left( \frac{\partial \psi}{\partial x} \right)_P \end{aligned} \quad (12.106)$$

in which the second term on the RHS represents the leading truncation error. In view of the diffusive form of this term, the numerical truncation error is sometimes named numerical-, artificial-, or false diffusion. The truncation error may be magnified in multi-dimensional problems if the flow is oblique to the grid.

#### 12.7.4.2 Central Difference Scheme

Another classical approximation for the value at GCV face center is obtained by linear interpolation between the two nearest nodes. The linear interpolation corresponds to the central difference approximation of the first derivative in FDMs. At location  $e$  on a non-uniform Cartesian grid we have [56, 249]:

$$\psi_e \approx \psi_P + \frac{(x_e - x_P)}{(x_E - x_P)}(\psi_E - \psi_P) \quad (12.107)$$

On a uniform grid the geometric pre-factor equals 1/2 and the Central Difference Scheme (CDS) reduces to the simple relation  $\psi_e \approx (\psi_P + \psi_E)/2$ . In this case, the coefficients in (12.98) are defined as:

$$a_W = D_w + \frac{F_w}{2} \quad (12.108)$$

$$a_E = D_e - \frac{F_e}{2} \quad (12.109)$$

$$a_P = a_W + a_E + (F_e - F_w) - S_{\psi,P} \Delta V \quad (12.110)$$

$$S_{\psi,u}^{CDS} \Delta V = S_{\psi,u} \Delta V \quad (12.111)$$

The main advantage of this scheme is that it is not numerically diffusive. However, the scheme is dispersive and a severe disadvantage associated with the CDS is that it does *not* always satisfy the boundedness criteria. The CDS may become unstable when  $F_e/D_e < 2$ , because the east coefficient will be negative. This scheme is thus conditionally stable. For this reason, the CDS may produce oscillatory solutions like all approximations of order higher than one.

For a non-uniform grid a Taylor series expansion of  $\psi_E$  about  $\psi_P$  is defined by:

$$\psi_E = \psi_P + (x_E - x_P) \left( \frac{\partial \psi}{\partial x} \right)_P + \frac{(x_E - x_P)^2}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_P + O((x_E - x_P)^3) \quad (12.112)$$

Using (12.112) to eliminate the first derivative in (12.105), the result is:

$$\psi_e = \psi_P + \frac{(x_e - x_P)}{(x_E - x_P)}(\psi_E - \psi_P) - \frac{(x_e - x_P)(x_E - x_P)}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_P + \dots \quad (12.113)$$

Comparing (12.107) and (12.113), it is seen that the leading truncation error term in CDS is proportional to the square of the grid spacing, hence the central difference scheme is second order accurate both on uniform and non-uniform grids.

### 12.7.4.3 Quadratic Upwind Interpolation for Convective Kinematics Scheme

The quadratic upstream interpolation for convective kinetics (QUICK) scheme of Leonard [123] uses a three-point upstream-weighted quadratic interpolation for the cell face values. In the third order QUICK scheme the variable profile between  $P$  and  $E$  is thus approximated by a parabola using three node values. At location  $e$  on a uniform Cartesian grids,  $\psi_e$  is approximated as:

$$\psi_e = \begin{cases} \frac{6}{8}\psi_P + \frac{3}{8}\psi_E - \frac{1}{8}\psi_W & \text{if } (\mathbf{v} \cdot \mathbf{n})_e > 0, \\ \frac{6}{8}\psi_W + \frac{3}{8}\psi_P - \frac{1}{8}\psi_{WW} & \text{if } (\mathbf{v} \cdot \mathbf{n})_e < 0. \end{cases} \quad (12.114)$$

The main advantage of this scheme is that it is less numerically diffusive than the UDS. However, the scheme is dispersive and a severe disadvantage associated with the QUICK scheme is that it does *not* satisfy the boundedness criteria unconditionally. The QUICK scheme is therefore conditionally stable. The explicit QUICK scheme is unstable in the absence of diffusion.

The implicit QUICK scheme may become unstable due to the possible appearance of negative coefficients in the coefficient matrix, hence a reallocation of the terms in the coefficient matrix is required to alleviate these stability problems. To retain positive coefficients in the coefficient matrix the troublesome negative terms (possibly amongst others) are placed in the source term. One approach is to put the upwind coefficients into the coefficient matrix and the deviation between the upwind and QUICK coefficient values into the source term. The corresponding coefficients in (12.98) are defined as:

$$a_W = D_w + \max(F_w, 0) \quad (12.115)$$

$$a_E = D_e + \max(0, -F_e) \quad (12.116)$$

$$a_P = a_W + a_E + (F_e - F_w) - S_{\psi,P} \Delta V \quad (12.117)$$

$$S_{\psi,u}^{QUICK} \Delta V = (S_{\psi,u} + S_{\psi,u}^{DCS}) \Delta V \quad (12.118)$$

By use of the *deferred correction method* some of the terms naturally belonging to the coefficient matrix are allocated to the source term because otherwise they may give rise to negative coefficients. The deferred correction method can only be applied when the scheme is being applied as part of an iterative loop structure. The iterative correction of these terms are thus deferred by one iteration, so at the  $\nu$ -th iteration the source term is evaluated using values known at the end of the previous  $(\nu-1)$ -th iteration. When convergence is reached, the solution is the same as without the deferred solution but the iterative process is usually more stable. The method was first introduced by Khosla and Rubin [105], and later outlined by several authors like [56, 132, 249].

The deferred correction source (DCS) term obtained for the QUICK implementation can be defined by:

$$\begin{aligned} S_{\psi,u}^{DCS} = \frac{1}{8} \bigg[ & (3\psi_P - 2\psi_W - \psi_{WW}) \max(F_w, 0) + (\psi_E + 2\psi_P - 3\psi_E) \max(F_e, 0) \\ & + (3\psi_W - 2\psi_P - \psi_E) \max(-F_w, 0) \\ & + (2\psi_E + \psi_{EE} - 3\psi_P) \max(-F_e, 0) \bigg] \end{aligned} \quad (12.119)$$

The advantage of this approach is that the main coefficients are positive and satisfy the requirement for conservativeness, boundedness and transportiveness.

The deferred correction method can also be employed in order to improve the convergence properties of high order schemes, rewriting a high order flux approximation as the sum of a stable low order flux and a higher order correction in the following manner:

$$(F_e^H)^{\nu+1} = (F_e^L)^{\nu+1} + (F_e^H - F_e^L)^\nu \quad (12.120)$$

in which  $F_e^L$  denotes a low order scheme like the upwind scheme consisting of a small computational molecule, and  $F_e^H$  represents a high order scheme leading to a larger computational molecule. The term in the bracket is moved to the source term and calculated using values from the previous iteration.

The quadratic interpolation has a third order truncation error on both uniform and non-uniform grids [56, 131]. However, when this interpolation scheme is used in conjunction with the midpoint rule approximation of the surface integral, the overall approximation is still of second order accuracy (i.e., the accuracy of the quadrature approximation). Although the QUICK approximation is slightly more accurate than CDS, both schemes converge asymptotically in a second order manner and the difference are rarely large [56]. It can be shown that the leading truncation error associated with the QUICK scheme is proportional to the grid spacing in the power 3. It is noted that, for cases where  $(\mathbf{v} \cdot \mathbf{n})_e > 0$ , for a general GCV on a uniform grid the QUICK scheme determines the value of  $\psi_e$  at the grid cell face  $e$  by the first approximation in (12.114).

The three relevant Taylor series expansions about the  $e$  face value in a Cartesian grid are given by [249]:

$$\psi_P = \psi_e - \frac{\Delta x}{2} \left( \frac{\partial \psi}{\partial x} \right)_e + \frac{(-\frac{\Delta x}{2})^2}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_e + \frac{(-\frac{\Delta x}{2})^3}{6} \left( \frac{\partial^3 \psi}{\partial x^3} \right)_e + \mathcal{O}\left(\left(\frac{\Delta x}{2}\right)^4\right) \quad (12.121)$$

$$\psi_E = \psi_e + \frac{\Delta x}{2} \left( \frac{\partial \psi}{\partial x} \right)_e + \frac{(\frac{\Delta x}{2})^2}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_e + \frac{(\frac{\Delta x}{2})^3}{6} \left( \frac{\partial^3 \psi}{\partial x^3} \right)_e + \mathcal{O}\left(\left(\frac{\Delta x}{2}\right)^4\right) \quad (12.122)$$

$$\psi_W = \psi_e - \frac{3}{2} \Delta x \left( \frac{\partial \psi}{\partial x} \right)_e + \frac{(-\frac{3}{2} \Delta x)^2}{2} \left( \frac{\partial^2 \psi}{\partial x^2} \right)_e + \frac{(-\frac{3}{2} \Delta x)^3}{6} \left( \frac{\partial^3 \psi}{\partial x^3} \right)_e + \mathcal{O}\left(\left(\frac{3}{2} \Delta x\right)^4\right) \quad (12.123)$$

By some manipulation yields:

$$\psi_e = \frac{6}{8} \psi_P + \frac{3}{8} \psi_E - \frac{1}{8} \psi_W - \frac{3}{48} \Delta x^3 + \mathcal{O}(\Delta x^4) \quad (12.124)$$

For non-uniform grids, the coefficients of the three nodal values involved in the interpolation are much more complex [56].

#### 12.7.4.4 Bounded High Resolution Convection schemes

A large number of numerical approximations to the convective fluxes have been proposed on structured grids within the framework of the finite volume method. The main challenge of the numerical approximation of hyperbolic transport equations is to obtain high accuracy of the solution in both discontinuous and smooth regions. The upwind scheme eliminates possible spurious oscillations in the neighborhood of sharp gradients and guarantees the resolution of discontinuities without wiggles. However, as already mentioned, the UDS possesses a strong numerical diffusion which spreads discontinuities over many grid nodes, hence it produces a low accuracy in the smooth region of the solution. The central difference scheme, on the other hand, gives good resolution in smooth regions, but introduces spurious oscillations near steep gradients that may lead to nonlinear instability. To avoid these difficulties, various high resolution schemes have been developed in recent years. These schemes, often called shock-capturing schemes in gas dynamics, are at least of second order accuracy in the smooth part of the solution and sharply resolve discontinuities without generating spurious oscillations. The high-resolution schemes often use flux/slope limiters to limit the gradient around shocks or discontinuities. One such approach is based on the concepts of non-linear flux limiters introduced by van Leer [241] and Boris and Book [18]. The work of Boris and Book [18] and Zalesak [263] determine the basis for a group of methods called flux correction transport (FCT) schemes. The schemes of Smolarkiewicz [216] is representative for this group. In the FCT schemes a first order accurate monotone scheme is converted to a high resolution scheme by adding limited amounts of an anti-diffusive flux. The work of van Leer [241, 243], on the other hand, represents an extension of the ideas of Godunov [78] to higher order accuracy.

In 1959, Godunov [78] introduced a novel finite volume approach to compute approximate solutions to the Euler equations of gas dynamics that applies quite generally to compute shock wave solutions to non-linear systems of hyperbolic conservation laws. In the method of Godunov, the numerical approximation is viewed as a piecewise constant function, with a constant value on each finite volume grid cell at each time step and the time evolution is determined by the exact solution of the Riemann problem (shock tube) at the inter-cell boundaries [86]. Solving the Riemann problem at the interface between grid cells gives a way to estimate the flux at the interface, and differencing these numerical fluxes gives a robust conservative shock-capturing method. This method is only first-order accurate, however, and introduces considerable numerical diffusion that tends to greatly smear out steep gradients. Nevertheless, the Godunov concept determines the basis for many finite volume methods that provide high accuracy numerical solutions to hyperbolic equations which can involve solutions that exhibit shocks, discontinuities or large gradients. Moreover, Godunov [78] proved the famous order barrier theorem stating that no linear convection scheme of second order accuracy or higher can be monotonic. The remedy to achieve higher accuracy has been the use of non-linear discretizations, which adjust themselves according to the local solution so as to maintain a

*bounded* behavior. The basic methodology of van Leer was published in a series of five papers in the journal of computational physics [246]. In this work, the oscillations are regarded as the result of oscillatory interpolation of the discrete initial values. The novel idea of van Leer [243] was to enforce non-oscillatory initial-value reconstruction by use of monotonicity preserving interpolation replacing the piecewise constant approximation of Godunov's scheme by reconstructed states, derived from cell-averaged states obtained from the previous time-step. For each cell, slope limited, reconstructed left and right states are obtained and used to calculate fluxes at the cell boundaries. Then, following Godunov, the van Leer's scheme includes fluxes derived from the solution of Riemann problems. When combined with higher-order reconstruction this leads to upwind-biased differencing. The first method based on the above principles was thus named MUSCL (Monotone Upstream Scheme for Conservative Laws). In a later paper, van Leer [244] introduced a computationally efficient alternative to the original Godunov algorithm by replacing the exact Riemann solver by Roe's approximate Riemann solver [197]. Henceforth, the Godunov-type schemes may be defined as non-oscillatory finite-volume schemes that incorporate the solution (exact or approximate) to Riemann's initial-value problems<sup>10</sup> [245]. These ideas of Godunov and van Leer were later generalized via the concept of total variation diminishing (TVD) schemes, introduced by Harten [83], whereby the variation of the numerical solution is controlled in a non-linear way, such as to forbid the appearance of any new extremum. Such methods give higher order accuracy without dispersive ripples.

Assume that  $\psi_i^n$  is a discrete approximation to  $\psi$  in the  $i$ -th GCV at time step  $n$ . Then, the total variation (TV) at time step  $n$  is defined by:

$$TV^n = \sum_i |\psi_{i+1}^n - \psi_i^n| \quad (12.125)$$

A convection/advection scheme is TVD if it ensures that  $TV^{n+1} \leq TV^n$ .

It is further noticed that in the sense of preserving monotonicity of the solution a difference between the limiting processes of TVD and FCT schemes lies in that the TVD schemes usually are of one step, while the FCT is of two steps. FCT schemes are widely used for simulating time-dependent flows, but are less suited for steady-state calculations and therefore have had little influence in computational fluid dynamics applied to chemical reactor engineering. The TVD schemes, on the other hand, can be easily implemented into standard CFD codes by means of the deferred correction approach using flux limiters without enlarging the stencil.

Some commonly used TVD limiters are:

- MC (Monotonic centered) limiter of van Leer [242]:

$$\phi(r) = (r + |r|)/(1 + r), \quad (12.126)$$

---

<sup>10</sup> The conservation law together with piecewise constant data having a single discontinuity is known as the Riemann problem [134].

- MinMod limiter of Harten [83] (see also Sweby [228]):

$$\phi(r) = \text{MinMod}(r, 1) = \max(0, \min(r, 1)), \quad (12.127)$$

- SUPERBEE limiter of Roe [198, 199]:

$$\phi(r) = \max[0, \min(2r, 1), \min(r, 2)], \quad (12.128)$$

The use of first order down-winding (i.e.,  $\phi(r) = 2r$ ) in regions of high resolution curvature leads to an over-compressive behavior in smooth regions that may be responsible for artificial steepening of what should be weak gradients.

- MUSCL (Monotonic Upwind Scheme for Convective Laws) limiter of van Leer [242, 243]:

$$\phi(r) = \max[0, \min(2, 2r, (1 + r)/2)]. \quad (12.129)$$

- SMART (Sharp and Monotonic Algorithm for Realistic Transport) limiter of Gaskell and Lau [68]:

$$\phi(r) = \max[0, \min(4, \frac{3}{4} + \frac{1}{4}r, 2r)], \quad (12.130)$$

- QUICK (Quadratic Upstream Interpolation for Convective Kinematics) of Leonard [123, 124]:

$$\phi(r) = \frac{3}{4} + \frac{1}{4}r, \quad (12.131)$$

- ISNAS (Interpolation Scheme which is Non-oscillatory for Advected Scalars) of Zijlema [267]:

$$\phi(r) = \frac{1}{2}(r + |r|)\frac{r + 3}{(1 + r)^2}, \quad (12.132)$$

- SHARP (Simple High-Accuracy Resolution Program) scheme of Leonard [124]:

$$\phi(r) = \min[\max(0, 2r(r^{1/2} - 1)/(r - 1)), \max(\frac{3}{4}r + \frac{1}{4}, -\frac{5}{4})] \quad (12.133)$$

The SHARP and SMART schemes are monotone versions of the QUICK scheme.

The TVD limiters are functions of smoothness monitors determining the local gradient of the variable field. Several monitors were outlined by Yang and Przekwas [261]. Three of these monitors are [134, 199, 241]:

$$r_e = \frac{(\psi_{E-\sigma} - \psi_{P-\sigma})}{(\psi_E - \psi_P)} \quad (12.134)$$

$$r_e = \frac{(|v_{e-\sigma}| - \frac{\Delta t}{\Delta z} v_{e-\sigma}^2)(\psi_{E-\sigma} - \psi_{P-\sigma})}{[(|v_e| - \frac{\Delta t}{\Delta z} v_e^2)(\psi_E - \psi_P)]} \quad (12.135)$$

$$r_e = \frac{v_{e-\sigma}(\psi_{E-\sigma} - \psi_{P-\sigma})}{[v_e(\psi_E - \psi_P)]} \quad (12.136)$$

in which  $\sigma = \text{sign}(v_e)$ . The first of these monitors is most frequently used.

The face values of the property  $\psi$  can be constructed in the hybrid form of a non-linear sum of low order  $\psi^L$  and high order  $\psi^H$  approximations. For flow in the positive  $x$ -direction  $(\mathbf{v} \cdot \mathbf{n})_e > 0$ , the TVD value of  $\psi_e$  may be written as [261]:

$$\psi_e^{TVD} = \phi(r_e)\psi_e^H + (1 - \phi(r_e))\psi_e^L = \psi_e^L + \phi(r_e)(\psi_e^H - \psi_e^L) \quad (12.137)$$

The simplest TVD schemes are constructed combining the first-order (and diffusive) upwind scheme and the second order dispersive central difference scheme. These TVD schemes are globally second order accurate, but reduce to first order accuracy at local extrema of the solution.

In terms of the deferred correction method the corresponding coefficients in (12.98) are defined as:

$$a_W = D_w + \max(F_w, 0) \quad (12.138)$$

$$a_E = D_e + \max(0, -F_e) \quad (12.139)$$

$$a_P = a_W + a_E + (F_e - F_w) - S_{\psi,p}\Delta V \quad (12.140)$$

$$S_{\psi,u}^{TVD}\Delta V = (S_{\psi,u} + S_{\psi,u}^{DCS})\Delta V \quad (12.141)$$

The advantage of this approach is that the main coefficients are positive and satisfy the requirement for conservativeness, boundedness and transportiveness.

The deferred correction source (DCS) term obtained for the TVD implementation can be defined by:

$$S_{\psi,u}^{DCS} = \left[ \frac{1}{2}\phi(r_e^-)(\psi_E - \psi_P)\max(-F_e, 0) - \frac{1}{2}\phi(r_e^+)(\psi_E - \psi_P)\max(F_e, 0) \right. \\ \left. - \frac{1}{2}\phi(r_w^-)(\psi_P - \psi_W)\max(-F_w, 0) + \frac{1}{2}\phi(r_w^+)(\psi_P - \psi_W)\max(F_w, 0) \right] \quad (12.142)$$

The corresponding monitors for each face flux term equals the ratio of the upstream to the downstream gradient. For the  $e$  face, these are defined by:

$$r_e^+ = \frac{\psi_P - \psi_W}{\psi_E - \psi_P} \quad (12.143)$$

$$r_e^- = \frac{\psi_{EE} - \psi_E}{\psi_E - \psi_P} \quad (12.144)$$

The superscripts  $+$  and  $-$  are used to indicate the positive and negative flow directions.

Another approach to construct monotonic high-resolution convection schemes employs non-linear slope limiters around discontinuities to constrain the approximation of the grid cell face values, initially estimated on the basis of a higher-order approximation, to lie within specific limits. These non-linear slope limiters are generally designed based on the normalized-variable (NV) approach proposed by Leonard [124, 126] and further developed by Gaskell and Lau [68]. The normalized variable (NV) approach of Leonard [124, 126] uses the locally normalized variable  $\psi^*$  to predict the local behavior of the converted variable  $\psi$ :

$$\psi^* = \frac{\psi - \psi_U}{\psi_D - \psi_U} \quad (12.145)$$

where  $\psi_U$  is the upwind node value and  $\psi_D$  the downstream value.

In terms of normalized variables,  $\psi_U^* = 0$  and  $\psi_D^* = 1$ . Let  $\psi_f^*$  be the normalized face value on the downstream GCV face. For locally monotonic node-values, the interpolative constraints on  $\psi_f^*$  are:

$$\psi_C^* \leq \psi_f^* \leq 1 \quad \text{for} \quad 0 \leq \psi_C^* \leq 1 \quad (12.146)$$

where  $\psi_C^*$  is the normalized central node value.

The basic idea behind the universal limiter is that, for locally monotone node values, the normalized face values must lie between the upstream and downstream normalized node-values. Otherwise, the interpolative monotonicity would be destroyed. In addition, to enforce local monotonicity in initially non-monotonic ranges (i.e.,  $\psi_C^* < 0$  or  $\psi_C^* > 1$ ),  $\psi_C^*$  must be corrected. A simple strategy is to use a first order UDS approximation that satisfies the limiter constraints, hence we can write:

$$\psi_f^* = \psi_C^* \quad \text{if} \quad \psi_C^* > 1 \quad \text{or} \quad \psi_C^* < 0 \quad (12.147)$$

Other higher-order functional relationships are possible [128, 131]. The normalized variable diagram [124, 126] was used as basis for development of the universal limiter. The universal limiter banishes unphysical oscillations without corrupting the accuracy of the underlying method. The monotonic SHARP (Simple High-Accuracy Resolution Program) scheme of Leonard [124] consist in using the universal slope limiter concept for monotonic resolution to modify the standard third-order steady-state QUICK approximations of the face values. The SHARP scheme was the first multi-dimensional monotonic convection schemes designed with high accuracy based on the NV approach. Later, Leonard [126] developed the 1D

ULTIMATE (Universal Limiter for Transient Interpolation Modeling of Advective Transport Equations) scheme based on the NV approach. The ULTIMATE scheme consist of using an extended universal limiter for transient interpolation modeling of the advective transport equations. The ULTIMATE strategy was basically designed for explicit schemes of arbitrary high order. However, with minor modifications, the ULTIMATE strategy can be applied to steady-flow multi-dimensional simulations. The steady-state ULTIMATE scheme thus gives ULTRA-SHARP simulations of steady multi-dimensional flows containing discontinuities [125].

A cost-effective strategy for highly convective flows containing discontinuities, without distorting smooth profiles or clipping narrow local extrema was introduced by Leonard and Niknafs [127]. This scheme represents an extension of the transient ULTIMATE scheme. In smooth regions the unlimited third order QUICK-EST (QUICK with Estimated Streaming Terms) scheme was used. In relatively large-gradient or strong-curvature regions, higher-order upwinding with the universal limiter was employed. The ULTRA (Universal Limiter for Tight Resolution and Accuracy) approach of Leonard and Mokhtari [125, 128] was designed to guarantee monotonicity for high-resolution non-oscillatory multidimensional steady-state high-speed convective modeling. The ULTIMATE 1D universal limiter of Leonard [126], was later extended to multi-dimensional flows by Thuburn [236]. The multi-dimensional method was designed for advected passive scalars in either compressible or incompressible flow and on arbitrary grids. Recently, the flux limiters (FL) and the normalized variables (NV) design principles that are employed to construct non-linear high resolution convection schemes have been shown to lead to the same constraints on the fluxes [124, 237, 255]. However, three different boundedness criteria are frequently employed, these are the total variational diminishing (TVD) [83], positivity [164] and the convection boundedness criterion (CBC) [68]. Thus, although these schemes have slightly different conceptual bases, the two approaches lead to mathematically equivalent schemes [237]. In multidisciplinary research fields, it happens now and then that mathematically equivalent schemes are invented independently more than once, often with different conceptual bases [237]. It follows that the NV variable  $\psi_C^*$  is analogous to the TVD monitor  $r$  and the two quantities are related by the simple expression  $r = \psi_C^*/(1 - \psi_C^*)$  which allows the conversion of NV schemes to FL and visa versa [124, 126]. The two distinct notations did emerge because the same methods were derived independently in different communities of science and engineering.

#### 12.7.4.5 Other Convection/Advection Schemes

High-order convection/advection schemes are widely used in meteorological applications solving hyperbolic equations. For example, in European weather forecast models the explicit non-flux-based modified methods of characteristics have been very popular as they are very fast. Typical examples of this type of schemes are the semi-Lagrangian advection schemes of Bates and McDonald [11], McDonald [149] and McDonald [150]. These methods have an unrestricted time step advantage, but

also an important disadvantage that they are not strictly conservative due to their non-flux-based formulation. Moreover, in the last decades a lot of work has been focused on designing explicit schemes for passive scalars. These schemes have been applied solving the transport equations for the scalar variables in the weather forecast models (e.g., [234]), and especially for the air pollution dispersion models solving the convection-diffusion equation (e.g., [12, 99, 159, 235]). A large number of explicit numerical advection algorithms were described and evaluated for the use in atmospheric transport and chemistry models by Rood [200], and Dabdub and Seinfeld [39]. A requirement in air pollution simulations is to calculate the transport of pollutants in a strictly conservative manner. For this purpose, the flux integral method has been a popular procedure for constructing an explicit single step forward in time conservative control volume update of the unsteady multidimensional convection-diffusion equation. The second order moments (SOM) [181, 203], Bott [19, 20], and UTOPIA (Uniformly Third-Order Polynomial Interpolation Algorithm) [129] schemes are all derived based on the flux integral concept. A limitation for long term dynamic simulations is the restrictions on the size of the time step for explicit schemes. The meteorological models are often solved applying operator splitting methods. The second order explicit two step method derived by MacCormack [139] from a combined space and time splitting discretization is sometimes used. The fractional step, time splitting and Strang splitting [227] techniques are more commonly used. In the ongoing quest for an explicit, single-time-step, conservative, flux-based, highly accurate, non-oscillatory finite volume scheme for multidimensional advection dominated flows, without restrictions on the time-step, Leonard et al. [130] developed the NIRVANA (Non-oscillatory, Integrally Restricted, Volume-Averaged Numerical Advection) Scheme for one-dimensional advection. The explicit operator splitting techniques based on sequential one-dimensional updates may contain large splitting errors. To reduce the splitting errors associated with these splitting techniques, Leonard et al. [133] developed the MACHO (Multidimensional Advective Conservative Hybrid Operator) and COSMIC (Conservative Operator Splitting for Multidimensions with Inherent Consistency) splitting strategies. These multidimensional methods have the unrestricted time step advantages of semi-Lagrangian schemes, but with the important additional attribute of strict conservation due to their flux-based formulation. The fast and conservative versions of the flux-based modified method of characteristics may also be a useful for this purpose [195].

### 12.7.5 Brief Evaluation of Convection/Advection Schemes

The first order upwind scheme and several variations of this scheme are very diffusive and should be avoided. Much better results can be obtained with bounded higher-order schemes. The choice of smoothness monitor is not very important for the performance of the TVD schemes, whereas the choice of limiter can be crucial [96]. For some limiters, inherent oscillations, rather than being suppressed, are converted into a series of small monotonic steps, a phenomena known as *stair-casting*

[126]. In general, the performance of most of the limiter functions has been found to be fairly similar giving solutions that are free from non-physical wiggles. The second- and third order schemes represent a trade-off between accuracy and computational time. Interpolation of order higher than third makes sense only if the integrals are approximated using higher-order quadrature formulas. Furthermore, since such schemes often produce oscillatory solutions when the grid is not sufficiently fine and are difficult to program, they are rarely used. The second- and third-order schemes are thus preferable, as the improved accuracy gained by higher order schemes are much more costly. Implicit time integration schemes are not as efficient as the corresponding explicit schemes due to the computational time required on the iterative process. With larger time steps the accuracy of implicit schemes decrease rapidly. The widespread use of the implicit schemes with Courant numbers ten- or even hundredfold the magnitude of what is used in an explicit method, is not justifiable in the presence of gradients or steps in the convected variable.

## 12.8 Implicit Upwind Discretization of the Scalar Transport Equation

The governing transport equation for a scalar property  $\psi$  in an unsteady flow has the general form:

$$\frac{\partial(\rho\psi)}{\partial t} + \nabla \cdot (\rho\mathbf{v}\psi) = \nabla \cdot (\Gamma_\psi \nabla \psi) + S_\psi \quad (12.148)$$

To illustrate the principles of the finite volume method, as a first approach, the implicit upwind differencing scheme is used for a multi-dimensional problem. Although the upwind differencing scheme is very diffusive, this scheme is frequently recommended on the grounds of its stability as the preferred method for treatment of convection terms in multiphase flow and determines the basis for the implementation of many higher order upwinding schemes.

Introducing the standard finite volume space integrations and integrating over the time interval  $t_n$  to  $t_{n+1}$  using the implicit Euler approximation, the resulting discretized equation becomes:

$$\begin{aligned} & [(\rho\psi)^{n+1} - (\rho\psi)^n] \frac{\Delta V}{\Delta t} + (\rho v_x \psi A)_e^{n+1} - (\rho v_x \psi A)_w^{n+1} \\ & + (\rho v_y \psi A)_n^{n+1} - (\rho v_y \psi A)_s^{n+1} + (\rho v_z \psi A)_t^{n+1} - (\rho v_z \psi A)_b^{n+1} \\ & = (\Gamma_\psi A \frac{\partial \psi}{\partial x})_e^{n+1} - (\Gamma_\psi A \frac{\partial \psi}{\partial x})_w^{n+1} + (\Gamma_\psi A \frac{\partial \psi}{\partial y})_n^{n+1} - (\Gamma_\psi A \frac{\partial \psi}{\partial y})_s^{n+1} \\ & + (\Gamma_\psi A \frac{\partial \psi}{\partial z})_t^{n+1} - (\Gamma_\psi A \frac{\partial \psi}{\partial z})_b^{n+1} + \langle S_\psi \rangle^{n+1} \Delta V \end{aligned} \quad (12.149)$$

The upwind scheme is obtained by substituting the UDS approximation of the convective terms and central difference approximation of the diffusive terms into the equation.

For unsteady problems, the discretized algebraic equation for the upwind scheme example is generally written:

$$a_P^{n+1}\psi_P^{n+1} = a_W^{n+1}\psi_W^{n+1} + a_E^{n+1}\psi_E^{n+1} + a_S^{n+1}\psi_S^{n+1} + a_N^{n+1}\psi_N^{n+1} + a_B^{n+1}\psi_B^{n+1} + a_T^{n+1}\psi_T^{n+1} + S_C^{n+1} \quad (12.150)$$

where

$$a_P^{n+1} = a_W^{n+1} + a_E^{n+1} + a_S^{n+1} + a_N^{n+1} + a_B^{n+1} + a_T^{n+1} - F_w^{n+1} + F_e^{n+1} - F_s^{n+1} + F_n^{n+1} - F_b^{n+1} + F_t^{n+1} - S_P^{n+1} \quad (12.151)$$

and

$$a_W^{n+1} = \max(F_w^{n+1}, 0) + D_w^{n+1} \quad (12.152)$$

$$a_E^{n+1} = \max(-F_e^{n+1}, 0) + D_e^{n+1} \quad (12.153)$$

$$a_S^{n+1} = \max(F_s^{n+1}, 0) + D_s^{n+1} \quad (12.154)$$

$$a_N^{n+1} = \max(-F_n^{n+1}, 0) + D_n^{n+1} \quad (12.155)$$

$$a_B^{n+1} = \max(F_b^{n+1}, 0) + D_b^{n+1} \quad (12.156)$$

$$a_T^{n+1} = \max(-F_t^{n+1}, 0) + D_t^{n+1} \quad (12.157)$$

$$S_C^{n+1} = (S_C^{n+1} + \frac{(\rho^n \phi^n)}{\Delta t})\Delta V \quad (12.158)$$

$$S_P^{n+1} = (S_P^{n+1} - \frac{\rho^{n+1}}{\Delta t})\Delta V \quad (12.159)$$

The quantities  $S_{C,\psi}$  and  $S_{P,\psi}$  arise from the source term linearization of the form:  $S_\psi = S_{C,\psi} + S_{P,\psi}\psi_P$ .

Higher-order integration schemes in time and space can be used to improve on the accuracy of the calculations, for example, using the higher order convection schemes presented above. For reactor simulations, any appropriate second- and third-order approximations are recommended.

## 12.9 Solution of the Momentum Equation

In this section, particular pressure-based methods designed to solve the momentum equation are outlined. The numerical methods for solving the momentum component equations differ considerably from those designed to solve the generic scalar transport

equation, because the velocity is a vector quantity. The special treatment of the terms in the momentum equations that are different from those in the generic transport equation is summarized. The survey of the numerical methods for single phase flow given in this section is, to a considerable extent, based on standard textbooks on CFD [56, 164, 249]. The elementary theory is included in this chapter to form a sound basis for the extended algorithms employed solving multiphase problems. The multiphase methods are presented in Sect. 12.11.

### 12.9.1 Discretization of the Momentum Equations

The unsteady term in the momentum equation has the same form as the transient term in the generic transport equation and is discretized in the same manner. The treatment of the *convective term* in the momentum equation basically follows that of the convective term in the generic equation. However, some extra linearization is required as the convective term in the momentum equation is non-linear in the velocity components. The *viscous shear stress terms* in the momentum equation basically correspond to the diffusive term in the generic equation. However, since the momentum equation is a vector equation, the viscous term is more complicated than the generic diffusive term. The first part of the viscous shear stress term in the momentum equations corresponds formally to the diffusive term in the generic transport equation. This shear stress term can be discretized using the approaches described for the corresponding terms of the generic equation. The second viscous shear stress term has no analog in the generic equation but vanishes when the viscosity is constant due to continuity. On the other hand, when the viscosity is spatially variable, this term is non-zero. When solving the resulting algebraic equations, the latter term is conveniently placed as part of the source term. In reactor modeling the bulk viscosity term is normally set to zero for any single phase flow, as discussed in Chaps. 1 and 2. An additional normal stress contribution may be considered for single phase flows, as explained in Chap. 1. For incompressible flow with constant fluid properties, the viscous normal stress contributions vanish as can be shown by use of the continuity equation (the bulk viscosity term also vanishes for incompressible flow). In the particular cases when these terms are non-zero, the mean value approach is normally used thus these terms are assumed constant over the GCV and approximated by appropriate Taylor series expansions. The momentum equation also contains a contribution from the *pressure*, which has no analog in the generic equation. This term is treated as a surface force. The pressure force term is thus approximated using the same quadrature rule as employed for the surface integrals in the generic transport equation. However, due to the close connection of the pressure and the continuity equation, the treatment of this term and the arrangement of variables on the grid play an important role in order to construct stable and accurate solution methods for the pressure-velocity coupling. The *body forces*, like the gravity term, are integrated over the grid volume. Usually, the mean value approach is used, so that the value at

the grid center is multiplied by the grid volume. The apparent forces that may occur in particular coordinate systems, are often considered as body forces and integrated in the same way as the gravity term.

### 12.9.2 Numerical Conservation Properties

In this section the numerical conservation properties of finite volume schemes for inviscid incompressible flow are examined.<sup>11</sup> Emphasis is placed on the theory of kinetic energy conservation. Numerical issues associated with the use of kinetic energy non-conservative schemes are discussed [54, 56, 196].

The discretization approximations applied to the continuity and momentum equations by the finite volume method automatically ensure that mass and momentum are conserved by the discretized equations, provided that the surface fluxes for adjacent grid volumes are identical. These conservative properties are then valid both for a local grid cell and the overall calculation domain. Kinetic energy conservation is more difficult to deal with. It is mentioned that the kinetic energy is conserved in incompressible isothermal flow, because the only energy form of significance is kinetic energy. In Chap. 1 it was shown that the kinetic energy equation can be derived by taking the scalar product of the momentum equation with the velocity. Furthermore, in contrast to compressible flow, for which there is a separate conservation equation for the total energy, in incompressible isothermal flows the momentum and energy balances are consequences of the same equation. This poses specific problems constructing proper solution methods for these flow situations. Principal interest has thus be given to the kinetic energy balance for a macroscopic volume. The volume of interest may be either the entire calculation domain or a generic grid cell volume.

If the local kinetic energy equation (1.133), derived in Sect. 1.2.4, is integrated over a grid volume, and transforming some of the resulting terms from volume to surface integrals by the Gauss' theorem, the result is:

$$\begin{aligned} \frac{\partial}{\partial t} \int_V (\rho \frac{v^2}{2}) dv = & - \int_A \rho \frac{v^2}{2} \mathbf{v} \cdot \mathbf{n} da - \int_A p \mathbf{v} \cdot \mathbf{n} da - \int_A (\boldsymbol{\sigma} \cdot \mathbf{v}) \cdot \mathbf{n} da \\ & - \int_V (-\boldsymbol{\sigma} : \nabla \mathbf{v} - p \nabla \cdot \mathbf{v} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c) dv \end{aligned} \quad (12.160)$$

The first three terms on the RHS are integrals over the surface of the macroscopic volume. It is noted that the kinetic energy in the macroscopic volume is not changed by the action of convection and pressure. The fourth term on the RHS is an inte-

---

<sup>11</sup> The early meteorological finite difference studies of long-term numerical time integrations of the equations of fluid motion, which involve non-linear convection terms, revealed the presence of non-linear instabilities due to aliasing errors [6, 171–173, 259]. To avoid the occurrence of these non-linear instabilities, Arakawa [6] was the first to recognize the importance of the use of numerical schemes which conserve kinetic energy.

gral over the macroscopic volume. The first term in this volume integral disappears if the flow is inviscid. The second term is zero if the flow is incompressible. The third term is zero in the absence of body forces. In this particular case, the inviscid flow of energy through the grid cell surface and the work done by the pressure force acting at this surface are the only processes that can affect the kinetic energy within the macroscopic volume. The kinetic energy is thus globally preserved in this sense. If we run a simulation under the same extreme conditions, this energy property must be preserved by the numerical method as well. However, under the prevailing conditions, this property cannot be enforced separately because the kinetic energy balance is a consequence of the momentum conservation and not by an independent equation. If a numerical method is energy conservative and the net energy flux through the surface is zero, then the overall kinetic energy in the domain does not grow with time. If such a method is used, the velocity at every point in the domain must remain bounded, hence the method reflect a kind of stability. Otherwise, if we devise a numerical scheme that is not strictly energy conservative, the net energy flux through the surface may not be zero and/or the overall kinetic energy in the domain can grow with time and create numerical instabilities in our simulations. In many of these schemes the leading truncation error in the kinetic energy equation has the form of an extra dissipation term. In low speed incompressible flows the addition to the internal energy is rarely significant but the loss of kinetic energy is often quite important to the flow. For compressible flows, both effects of the truncation error can be significant. The truncation errors in the time and spatial discretization methods can both destroy the energy conservation property. Kinetic energy preservation is thus especially important in computing unsteady flows. Typical examples are long-term time dependent geophysical flow simulations and dynamic turbulent simulations. For this reason, the interaction between dynamic model dissipation and numerical dissipation is a very important topic in these fields of computational dynamics. For steady flows, energy conservation has generally got less attention. However, it is rather obvious that these truncation errors are analogous to the terms in the generic transport equation which we did referred to as *artificial diffusion* or *numerical diffusion*. For obvious reasons, in some fields of science the truncation error terms occurring in the kinetic energy equation are named *numerical dissipation* or *artificial dissipation*. In a broader view, in dynamics it is implied that when the pure convection/advection equation (which is free of physical diffusion) is solved for any property by a numerical approximation method that reduces the amplitude and changes the shape of the initial wave in a way analogous to a diffusional process, the method is said to contain numerical dissipation. From the above discussion it may be inferred that for geophysical flow simulations and simulations of turbulent flow, using either direct numerical simulations (DNS) or large eddy simulations (LES), it is highly desirable to employ schemes that conserve mass, momentum, and kinetic energy [54]. However, many numerical methods approximate the transport of kinetic energy from the large scale vortices to the smaller ones in an erroneous manner. Hence, the kinetic energy stored at the smaller vortex scales may grow and the solution method can become unstable. In such situations some apparent dissipation that have no connection to physics are sometimes added to provide stability of numerical methods.

It is noted that kinetic energy conservation is associated with numerical stability but not to the convergence or accuracy properties of a method. However, the physical dissipation used in the simulation is determined by the sum of the dynamic model dissipation and the apparent dissipation added.

### 12.9.3 Choice of Variable Arrangement on the Grid

In this section, attention is given to the numerical discretization of the finite volume calculation domain and the choice of variable arrangement on the grid. In the coordinate discretization process one selects the node points in the domain at which the values of the unknown dependent variables are to be computed. In the finite volume method one also selects the location of the grid cell surfaces at which the property fluxes are determined. In this way the computational domain is sub-divided into a number of smaller, non-overlapping sub-domains. There are many variants of the distribution of the computational node points and grid cell surfaces within the solution domain. The grid arrangements associated with the finite volume discretization of the momentum equation are generally more complicated than the one employed for a scalar transport equation. As a first approach, it may be natural to employ a *collocated* grid arrangement and store all the variables at the same set of grid points and to use the same grid volumes for all of them. In this case the number of coefficients that must be computed and stored is minimized, because many of the terms in each of the equations are essentially identical. However, it is not required that all the variables share the same grid. A different arrangement has been shown to be advantageous. In the orthogonal curvilinear coordinates, the *staggered* grid arrangement introduced by Harlow and Welsh [81] offers several advantages over the collocated arrangement. The most important advantage of the staggered arrangement is that a stronger coupling between the velocities and the pressure is achieved. This helps to avoid some types of convergence problems and oscillations in the pressure and velocity fields [164]. In addition, several terms that require interpolation with the collocated arrangement, can be calculated to a second-order approximation without interpolation in the staggered arrangement. The numerical approximation on a staggered grid is also preserving the local and overall kinetic energy. Other grid arrangements have not gained wide popularity in engineering studies of single- and multiphase flows. Numerous analysis of the impact of the grid arrangement on the accuracy and stability of numerical simulations have been performed in other branches of physical science. The arrangement of the grids is, for example, particularly important for dynamic flows in meteorology and oceanography. For further studies of the grid arrangements employed in these geophysical flows, the pioneering work of Arakawa and Lamb [7] may be considered.

### 12.9.4 Calculation of Pressure

In this section, several strategies for determining the pressure in the incompressible flow limit is outlined for pressure-based methods. The extension of the pressure-correction approach to arbitrary Mach numbers is examined.

For pressure-based techniques, the lack of an independent equation for the pressure complicates the solution of the momentum equation. Furthermore, the continuity equation does not have a transient term in incompressible flows because the fluid transport properties are constant. The continuity reduces to a kinematic constraint on the velocity field. One possible approach is to construct the pressure field so as to guarantee satisfaction of the continuity equation. In this case, the momentum equation still determines the respective velocity components. A frequently used method to obtain an equation for the pressure is based on combining the two equations. This means that the continuity equation, which does not contain the pressure, is employed to determine the pressure. If we take the divergence of the momentum equation, the continuity equation can be used to simplify the resulting equation.

The Poisson equation for the pressure becomes:

$$\begin{aligned}\nabla \cdot (\nabla p) &= -\nabla \cdot [\nabla \cdot (\rho \mathbf{v}\mathbf{v} + \boldsymbol{\sigma}) - \rho \mathbf{g} + \frac{\partial(\rho \mathbf{v})}{\partial t}] \\ &= -\nabla \cdot [\nabla \cdot (\rho \mathbf{v}\mathbf{v} + \boldsymbol{\sigma})] - \nabla \cdot (\rho \mathbf{g}) + \frac{\partial^2 \rho}{\partial t^2}\end{aligned}\quad (12.161)$$

in which the transient term is rewritten by use of the continuity equation.

For the case of constant fluid properties (e.g., density and viscosity), the equation reduces to:

$$\nabla \cdot (\nabla p) = -\nabla \cdot [\nabla \cdot (\rho \mathbf{v}\mathbf{v})] \quad (12.162)$$

This simplification is obtained by use of the continuity equation.

The Laplacian operator on the LHS of the pressure equation is the product of the divergence operator originating from the continuity equation and the gradient operator that comes from the momentum equations. The RHS of the pressure equation consists of a sum of derivatives of the convective terms in the three components of the momentum equation. In all these terms, the outer derivative stems from the continuity equation while the inner derivative arises from the momentum equation. In a numerical approximation, it is essential that the consistency of these operators is maintained. The approximations of the terms in the Poisson equations must be defined as the product of the divergence and gradient approximations used in the basic equations. Violation of this constraint may lead to convergence problems as the continuity equation is not appropriately satisfied. Even though the original derivation of this method was based on the governing equations for incompressible flows, in which the fluid properties are constant, this concept can be adapted to many flows with variable fluid properties and weak compressibility.

### 12.9.4.1 Explicit Projection Method for Unsteady Flow

In this section, an explicit time advance scheme for unsteady flow problems is outlined [35]. The momentum equation is discretized by an explicit scheme, and a Poisson equation is solved for the pressure to enforce continuity. The continuity is discretized in an implicit manner. In the original formulation, the spatial derivatives were approximated by finite difference schemes.

To illustrate the basic principles of the projection method, the semi-discretized (discrete in space but not in time) momentum equations are written symbolically as:

$$\frac{\partial(\rho v_i)}{\partial t} = -\frac{\delta(\rho v_i v_j)}{\delta x_j} - \frac{\delta p}{\delta x_i} - \frac{\delta \sigma_{ij}}{\delta x_j} = -C_i - D_i - \frac{\delta p}{\delta x_i} \quad (12.163)$$

where  $\delta/\delta x$  represents a discretized spatial derivative, and  $C_i$  and  $D_i$  are shorthand notations for the convective and viscous terms.

For simplicity, the momentum equation (12.163) is solved with the explicit Euler method in time. The result can be written in symbolic notation as:

$$(\rho v_i)^{n+1} - (\rho v_i)^n = -\Delta t(C_i^n + D_i^n + \frac{\delta p^n}{\delta x_i}) \quad (12.164)$$

The velocity at time step  $n$  is used to compute  $C_i^n$  and  $D_i^n$ , whereas the pressure field at time step  $n$  is used to compute the pressure gradient terms  $\delta p^n/\delta x_i$ . This gives an estimate of  $\rho v_i$  at the new time step  $n+1$ . However, in general, this velocity field does not satisfy the continuity equation.

The continuity equation is generally discretized in an implicit manner:

$$\frac{\partial \rho}{\partial t} + \frac{\delta(\rho v_i)^{n+1}}{\delta x_i} = 0 \quad (12.165)$$

The transient term vanishes for incompressible flows, as the fluid properties are constant. The transient term is retained here to emphasize that this method can be applied for compressible flows as well. For compressible flow both velocity and density appear as dependent variables in the continuity equation. Nevertheless, the discrete form of the mass balance can still be interpreted as a constraint equation for pressure.

In the design of an approach to enforced continuity, the numerical divergence of (12.164) is derived. The result is:

$$\frac{\delta(\rho v_i)^{n+1}}{\delta x_i} - \frac{\delta(\rho v_i)^n}{\delta x_i} = -\Delta t[\frac{\delta}{\delta x_i}(C_i^n + D_i^n + \frac{\delta p^n}{\delta x_i})] \quad (12.166)$$

The first term is the divergence of the new mass fluxes, for which continuity must be enforced. The second term is known if continuity was enforced at time step  $n$ .

With minor manipulation, the result is a discrete Poisson equation for the pressure  $p^n$ :

$$\frac{\delta}{\delta x_i} \left( \frac{\delta p^n}{\delta x_i} \right) = -\frac{\delta}{\delta x_i} (C_i^n + D_i^n) + \frac{1}{\Delta t} \left[ \frac{\delta \rho}{\delta t} + \frac{\delta(\rho v_i)^n}{\delta x_i} \right] \quad (12.167)$$

In this relation, the operator  $\delta/\delta x_i$  outside the parentheses on the LHS is the divergence operator inherited from the continuity equation, while  $\delta p^n/\delta x_i$  is the pressure gradient from the momentum equation. The operator  $\delta\rho/\delta t$  is the time advancement of the continuity equation. If the pressure  $p^n$  satisfies the discrete Poisson equation, the velocity field at time step  $n + 1$  will fulfill continuity (and be divergence free for constant density flows).

The algorithm for time-integration of the momentum equation can then be sketched as follows:

1. Start with a divergence free velocity field  $v_i^n$  that satisfy continuity at time  $t_n$ .
2. Compute the convective  $C_i^n$  and viscous  $D_i^n$  terms and their divergences.
3. Solve the Poisson equation for the pressure  $p^n$ .
4. Compute the mass conservative divergence free velocity field at the new time step.
5. Go to the next time step.

Methods similar to this are commonly used to solve the momentum equation when an accurate time history of the flow is required. In these particular cases, more accurate time advancement methods than the first order Euler method must be used. Explicit methods are preferred for (fast) transient flows because they are more accurate and less computationally demanding than implicit methods with the same time step size. To allow longer time steps to be used and for stability reasons, some of the terms may also be treated implicitly.

#### 12.9.4.2 Implicit Pressure-Correction Methods for Incompressible Flow

In this section, an implicit pressure correction method for incompressible flow is outlined [56, 163, 164, 249]. Implicit methods are preferred for slow-transient flows because they have less stringent time step restrictions than explicit schemes. However, the time step must still be chosen small enough so that an accurate history is obtained. It is further noted that implicit methods can also be used to solve steady problems. In this particular approach, an unsteady form of the problem has to be solved until a steady state is reached. For the artificial time integration, large time steps are often used intending to reach the steady state quickly. If an implicit method is used to advance the momentum equation in time, the discretized equations for the velocities at the new time step are non-linear. Implicit methods thus require an iterative solution process. Several restrictions must be placed on the coefficient matrix to ensure a stable and efficient solution procedure, most important all the coefficients must be positive [164].

### Solution of the Momentum Equation Components

The first major task in this pressure-correction method consist in *solving the momentum equation components*. If the pressure field is given, the solution of the momentum equation components can be obtained by employing the formulation described in Sect. 12.8 for the general variable  $\psi$ . In the momentum equation,  $\psi$  stands for the relevant velocity components, and  $\Gamma$  and  $S$  are to be given their appropriate meanings. The adoption of the staggered grid cell volumes for the velocity components does make the discretized momentum equations somewhat different from the discretized equations for the other  $\psi$ 's that are calculated for the scalar variable grid nodes. The velocity components grid cells are staggered in relation to the scalar variable grid cell volume normally centered around the scalar grid node point P. The staggering for the velocity component  $v_x$  is in the  $x$ -direction only, such that the faces normal to that direction pass through the scalar grid nodes P and E. Similarly, the staggering for the velocity component  $v_y$  is in the  $y$ -direction only, such that the faces normal to that direction pass through the scalar grid nodes P and N. Likewise, the staggering for the velocity component  $v_z$  is in the  $z$ -direction only, such that the faces normal to that direction pass through the scalar grid nodes P and T. The major advantage of the staggered grid is thus that the pressure difference  $p_P - p_E$  can be used to compute the pressure force acting on the grid cell volume for the velocity component  $v_{x,e}$ . Similarly, the pressure difference  $p_P - p_N$  can be used to compute the pressure force acting on the grid cell volume for the velocity component  $v_{y,n}$ . Likewise, the pressure difference  $p_P - p_T$  can be used to compute the pressure force acting on the grid cell volume for the velocity component  $v_{z,t}$ . Moreover, the calculation of the diffusion coefficient and the mass flow rate at the faces of the grid cell volume would require an appropriate interpolation similar to the interpolation required in Sect. 12.8.

The discretized momentum equation components at the surface points can be written as:

$$a_e^{n+1} v_{x,e}^{n+1} = \sum_{nb} a_{nb}^{n+1} v_{x,nb}^{n+1} + S_e^{n+1} - \left( \frac{\delta p^{n+1}}{\delta x} \right)_e \quad (12.168)$$

$$a_n^{n+1} v_{y,n}^{n+1} = \sum_{nb} a_{nb}^{n+1} v_{y,nb}^{n+1} + S_n^{n+1} - \left( \frac{\delta p^{n+1}}{\delta y} \right)_n \quad (12.169)$$

$$a_t^{n+1} v_{z,t}^{n+1} = \sum_{nb} a_{nb}^{n+1} v_{z,nb}^{n+1} + S_t^{n+1} - \left( \frac{\delta p^{n+1}}{\delta z} \right)_t \quad (12.170)$$

The source terms  $S_e, S_n, S_t$  are generally defined in the same manner as for the generalized scalar variable examined in Sect. 12.8. However, for convenience, explaining the solution methods for the momentum equations, the pressure gradient terms are written separately and not included in the source terms. Thus, the source terms contain all of the additional terms that may be explicitly computed in terms of  $v_i^n, i = x, y, z$  as well as any body force or other linearized terms that may depend on the  $v_i^{n+1}$

or other variables at the new time level. Furthermore, in these discrete momentum equations the scalar grid notation is employed. Hence, in (12.168), for example, the index  $e$  refers to a surface point in the scalar grid used for the continuity equation. This surface point coincides with the velocity node in a staggered velocity grid. The other two momentum equation components are treated in a similar manner using the scalar grid notation. The index  $nb$  denotes the neighbor nodes that appears in the discretized momentum equation. The neighbor coefficient  $a_{nb}$  account for the combined convection-diffusion influence at the grid cell volume faces. The number of neighbor terms considered depends on the dimensionality of the problem. For one-dimensional problems, two  $v_i$ ,  $i = x$ , neighbors are considered outside the grid volume centered around P. For two-dimensional problems, four  $v_i$ ,  $i = x, y$  neighbors are considered. Likewise, for three-dimensional problems, six  $v_i$ ,  $i = x, y, z$  neighbors are considered.

If the pressure gradient terms are discretized by the second order central difference approximation, the discretized momentum equation components can be written as:

$$a_e^{n+1} v_{x,e}^{n+1} = \sum_{nb} a_{nb}^{n+1} v_{x,nb}^{n+1} + S_e^{n+1} - A_e(p_E^{n+1} - p_P^{n+1}) \quad (12.171)$$

$$a_n^{n+1} v_{y,n}^{n+1} = \sum_{nb} a_{nb}^{n+1} v_{y,nb}^{n+1} + S_n^{n+1} - A_n(p_N^{n+1} - p_P^{n+1}) \quad (12.172)$$

$$a_t^{n+1} v_{z,t}^{n+1} = \sum_{nb} a_{nb}^{n+1} v_{t,nb}^{n+1} + S_t^{n+1} - A_t(p_T^{n+1} - p_P^{n+1}) \quad (12.173)$$

A comparison of the pressure force term acting on the  $v_{x,e}^{n+1}$  grid cell volume in (12.168) and (12.171), for example, it is noted that the discretization notations therein are related as follows:

$$-\left(\frac{\delta p^{n+1}}{\delta x}\right)_e = -\frac{(p_E^{n+1} - p_P^{n+1})}{\delta x_{v_x}} \Delta V_{v_x} = -A_e(p_E^{n+1} - p_P^{n+1}) \quad (12.174)$$

in which  $\delta x_{v_x}$  represents the width of the staggered grid cell for the velocity component  $v_{x,e}$  denoting the distance between the nodes W and P in the scalar grid,  $\delta x_{EP}$ .  $\Delta V_{v_x}$  denotes the volume of the  $v_{x,e}$  cell, and  $A_e$  is the area on which the pressure difference acts. Similar discretisation schemes are used for the pressure terms in the other components of the momentum equations.

The momentum equation component equations can be solved only when the pressure field is given or somehow estimated. Unless the correct pressure field is employed, the resulting velocity field will not satisfy the continuity equation. Such an approximate velocity field based on an estimated or guessed pressure field  $p^*$  will be denoted by  $v_x^*$ ,  $v_y^*$  and  $v_z^*$ . The estimated velocity field that carry an asterisk (\*) will result from the solution of the discrete momentum equations:

$$a_e^{n+1} v_{x,e}^{n+1,*} = \sum_{nb} a_{nb}^{n+1} v_{x,nb}^{n+1,*} + S_e^{n+1} - A_e(p_E^{n+1,*} - p_P^{n+1,*}) \quad (12.175)$$

$$a_n^{n+1} v_{y,n}^{n+1,*} = \sum_{nb} a_{nb}^{n+1} v_{y,nb}^{n+1,*} + S_n^{n+1} - A_n(p_N^{n+1,*} - p_P^{n+1,*}) \quad (12.176)$$

$$a_t^{n+1} v_{z,t}^{n+1,*} = \sum_{nb} a_{nb}^{n+1} v_{z,nb}^{n+1,*} + S_t^{n+1} - A_t(p_T^{n+1,*} - p_P^{n+1,*}) \quad (12.177)$$

The components of the momentum equation are usually solved one by one in a sequential manner, meaning that the set of algebraic equations for each component of the momentum is solved in turn, treating the grid point values of its dominant velocity as the sole set of unknowns. Due to the non-linearity and coupling of the underlying partial differential equations, (12.171)–(12.173) cannot be solved directly as the coefficients,  $a$ , and the source term,  $S$ , depend on the unknown solution  $v_i^{n+1}$ . An iterative solution method is required.

Unsteady flow simulations require accurate time integration. The iteration process must thus be continued within each time step until the entire system of non-linear equations is satisfied in accordance with an appropriate convergence criterion. For steady flows, on the other hand, it is common either to take an infinite time step and iterate until the steady non-linear equations are satisfied, or march in time without requiring full satisfaction of the non-linear equations at each time step. However, both of these approaches may become unstable if the initial guesses are not sufficiently close to the exact solution, hence in some complex cases the time step must be restricted to ensure that the simulation does not diverge/explode. For unsteady flows the system of non-linear equations are linearized in the iteration process within each time step, since all the solvers are limited to linear systems. The iterative process is thus performed on two different levels. The solver iterations are thus performed on provisional linear systems with fixed coefficients and source terms until convergence. Then, the system coefficients and sources are updated based on the last provisional solution and a new linearized system is solved. This process is continued until the non-linear system is converged, meaning that two subsequent linear systems give the same solution within the accuracy of a prescribed criterion.

The iterations within one time step, in which the coefficients and source terms are updated, are called *outer iterations* to distinguish them from the *inner iterations* performed on linearized systems with fixed coefficients,  $a^{\nu-1}$ , and source terms,  $S^{\nu-1}$ . On each such outer iteration, the equations solved are:

$$a_e^{\nu-1} v_{x,e}^{*,\nu} = \sum_{nb} a_{nb}^{\nu-1} v_{x,nb}^{*,\nu} + S_e^{\nu-1} - A_e(p_E^{*,\nu-1} - p_P^{*,\nu-1}) \quad (12.178)$$

$$a_n^{\nu-1} v_{y,n}^{*,\nu} = \sum_{nb} a_{nb}^{\nu-1} v_{y,nb}^{*,\nu} + S_n^{\nu-1} - A_n(p_N^{*,\nu-1} - p_P^{*,\nu-1}) \quad (12.179)$$

$$a_t^{\nu-1} v_{z,t}^{*,\nu} = \sum_{nb} a_{nb}^{\nu-1} v_{z,nb}^{*,\nu} + S_t^{\nu-1} - A_t(p_T^{*,\nu-1} - p_P^{*,\nu-1}) \quad (12.180)$$

For convenience, the time step index  $n + 1$  is dropped. An outer iteration counter  $\nu$  has been introduced instead. The  $v_{x,e}^{*,\nu}$  thus represents the current iteration estimate of the solution  $v_{x,e}^{n+1}$ . At the beginning of each such outer iteration, the coefficients

and the terms on the RHS of (12.178)–(12.180) are evaluated using the variables at the preceeding outer iteration. Since the pressure used in these outer iterations was obtained from the previous outer iteration or time step, the velocities computed from (12.178) to (12.180) do not normally satisfy the discrete continuity equation. To enforce the continuity equation, the velocities need to be corrected. This is achieved by modifying the pressure field. The corrected final values should thus satisfy the continuity equation.

### Pressure and Velocity Corrections

The second major task is to design an algorithm of improving the guessed pressure  $p^{*,\nu-1}$  such that the resulting estimated velocity field will progressively get closer to satisfy the continuity equation. In the most common family of methods constructed for correcting the pressure, a pressure-correction  $p'^{\nu}$  is used instead of the actual pressure  $p^\nu$ . The velocities computed from the linearized momentum equations  $v_x^{*,\nu}$ ,  $v_y^{*,\nu}$ , and  $v_z^{*,\nu}$ , and the pressure  $p^{*,\nu-1}$  are taken as estimated values to which a small correction must be added:

$$v_i^\nu = v_i^{*,\nu} + v_i'^{\nu} \quad \text{and} \quad p^\nu = p^{*,\nu-1} + p'^{\nu} \quad (12.181)$$

### Velocity Correction Formulas

In a third major task, the velocity components respond to changes in the guessed or estimated pressure are approximated. Substitution of the correct pressure field  $p^{n+1}$  into the momentum equation components (12.178)–(12.180) presumably holding the correct coefficients  $a^{\nu-1}$  and source terms  $S^{\nu-1}$ , the outcome will be the correct velocity field components  $v_x^{n+1}$ ,  $v_y^{n+1}$ , and  $v_z^{n+1}$ . The correct velocity field is thus linked with the correct pressure field through the discretized momentum equation components on the form:

$$a_e^{\nu-1} v_{x,e}^\nu = \sum_{nb} a_{nb}^{\nu-1} v_{x,nb}^\nu + S_e^{\nu-1} - A_e(p_E^{\nu-1} - p_P^{\nu-1}) \quad (12.182)$$

$$a_n^{\nu-1} v_{y,n}^\nu = \sum_{nb} a_{nb}^{\nu-1} v_{y,nb}^\nu + S_n^{\nu-1} - A_n(p_N^{\nu-1} - p_P^{\nu-1}) \quad (12.183)$$

$$a_t^{\nu-1} v_{z,t}^\nu = \sum_{nb} a_{nb}^{\nu-1} v_{z,nb}^{\nu-1} + S_t^{\mu-1} - A_t(p_T^{\nu-1} - p_P^{\nu-1}) \quad (12.184)$$

Subtraction of (12.178)–(12.180) from (12.182) to (12.184), gives:

$$a_e^{\nu-1} v_{x,e}'^\nu = \sum_{nb} a_{nb}^{\nu-1} v_{x,nb}'^\nu - A_e(p_E'^{\nu} - p_P'^{\nu}) \quad (12.185)$$

$$a_n^{\nu-1} v'_{y,e} = \sum_{nb} a_{nb}^{\nu-1} v'_{y,nb} - A_n (p'_N - p'_P) \quad (12.186)$$

$$a_t^{\nu-1} v'_{z,t} = \sum_{nb} a_{nb}^{\nu-1} v'_{t,nb} - A_t (p'_T - p'_P) \quad (12.187)$$

At this point a major approximation is introduced, as the neighboring terms like  $\sum_{nb} a_{nb}^{\nu-1} v'_{x,nb}$ ,  $\sum_{nb} a_{nb}^{\nu-1} v'_{y,nb}$  and  $\sum_{nb} a_{nb}^{\nu-1} v'_{t,nb}$  are dropped to simplify the velocity correction relations.

The resulting relations are called the velocity-correction formulas:

$$v'_{x,e} = \frac{A_e}{a_e^{\nu-1}} (p'_P - p'_E) = d_e (p'_P - p'_E) \quad (12.188)$$

$$v'_{y,n} = \frac{A_n}{a_n^{\nu-1}} (p'_P - p'_N) = d_n (p'_P - p'_N) \quad (12.189)$$

$$v'_{z,t} = \frac{A_t}{a_t^{\nu-1}} (p'_P - p'_T) = d_t (p'_P - p'_T) \quad (12.190)$$

in which

$$d_e = \frac{A_e}{a_e^{\nu-1}}, \quad d_n = \frac{A_n}{a_n^{\nu-1}}, \quad d_t = \frac{A_t}{a_t^{\nu-1}} \quad (12.191)$$

The velocity-correction formulas (12.188)–(12.190) can also be written as:

$$v_{x,e}^\nu = v_{x,e}^{*,\nu} + d_e (p'_P - p'_E) \quad (12.192)$$

$$v_{y,n}^\nu = v_{y,n}^{*,\nu} + d_n (p'_P - p'_N) \quad (12.193)$$

$$v_{z,t}^\nu = v_{z,t}^{*,\nu} + d_t (p'_P - p'_T) \quad (12.194)$$

These relations thus reveal how the approximated velocity components  $v_{x,e}^{*,\nu}$ ,  $v_{y,n}^{*,\nu}$ ,  $v_{z,t}^{*,\nu}$  that carry an asterisk (\*) are to be corrected in response to the pressure corrections to produce the corrected velocity components  $v_{x,e}^{n+1}$ ,  $v_{y,n}^{n+1}$ ,  $v_{z,t}^{n+1}$ .

### Pressure Correction Equation

Even though the velocity component fields are computed from the discrete momentum equation components, the predicted velocity field may still not be correct. This is because the velocity field is also subject to the constraint that it should satisfy the continuity equation.

The fourth major task is thus to correct the velocity components so that they satisfy the discrete continuity equation:

$$\frac{\delta \rho^{\nu-1}}{\delta t} + \frac{\delta (\rho^{\nu-1} v_i^\nu)}{\delta x_i} = 0 \quad (12.195)$$

which is achieved by correcting the pressure field. For incompressible flow, it is assumed that the fluid density  $\rho$  does not directly depend on pressure.

In the pressure-based methods, the continuity is transformed to an equation for a pressure correction quantity. The transient term in the continuity vanishes for incompressible flows, as in this case the fluid properties are constant. The transient term is currently retained to emphasize that this method can be applied for compressible flows as well. In the latter case, the discrete form of the mass balance can still be interpreted as a constraint equation for pressure.

To discretize the continuity, the differential equation is first integrated over the scalar grid cell volume. This is the same grid cell volume as was used for the generalized scalar quantity  $\psi$  in Sect. 12.8. By use of the first order implicit Euler time discretization scheme and the basic theorem of integration for the convective fluxes, a discrete form of (12.195) can be expressed as:

$$\begin{aligned} \frac{(\rho_p^{n+1} - \rho_p^n) \Delta x \Delta y \Delta z}{\Delta t} &+ [(\rho v_x)_e^{n+1} - (\rho v_x)_w^{n+1}] \Delta y \Delta z \\ &+ [(\rho v_y)_n^{n+1} - (\rho v_y)_s^{n+1}] \Delta z \Delta x \\ &+ [(\rho v_z)_t^{n+1} - (\rho v_z)_b^{n+1}] \Delta x \Delta y = 0 \end{aligned} \quad (12.196)$$

To achieve a linearized equation system, the Picard method is employed thus the densities are estimated in the previous iteration step (or kept constant for incompressible flows). The discretized form can thus be expressed as:

$$\begin{aligned} \frac{(\rho_p^{\nu-1} - \rho_p^\nu) \Delta x \Delta y \Delta z}{\Delta t} &+ [(\rho^{\nu-1} v_x^\nu)_e - (\rho^{\nu-1} v_x^\nu)_w] \Delta y \Delta z \\ &+ [(\rho^{\nu-1} v_y^\nu)_n - (\rho^{\nu-1} v_y^\nu)_s] \Delta z \Delta x \\ &+ [(\rho^{\nu-1} v_z^\nu)_t - (\rho^{\nu-1} v_z^\nu)_b] \Delta x \Delta y = 0 \end{aligned} \quad (12.197)$$

By substitution of the velocity components therein by the expressions given by the velocity-correction formulas (12.192)–(12.194), a discretized pressure correction equation is obtained:

$$\begin{aligned} a_p^{\nu-1} p_p^{\prime,\nu} &= a_W^{\nu-1} p_W^{\prime,\nu} + a_E^{\nu-1} p_E^{\prime,\nu} + a_N^{\nu-1} p_N^{\prime,\nu} + a_S^{\nu-1} p_S^{\prime,\nu} + a_T^{\nu-1} p_T^{\prime,\nu} + a_B^{\nu-1} p_B^{\prime,\nu} \\ &+ S^{\nu-1} \end{aligned} \quad (12.198)$$

The coefficients and source term in the pressure-correction equation are defined as:

$$a_E^{\nu-1} = \rho_e^{\nu-1} d_e \Delta y \Delta z, \quad (12.199)$$

$$a_W^{\nu-1} = \rho_w^{\nu-1} d_w \Delta y \Delta z, \quad (12.200)$$

$$a_N^{\nu-1} = \rho_n^{\nu-1} d_n \Delta z \Delta x, \quad (12.201)$$

$$a_S^{\nu-1} = \rho_s^{\nu-1} d_s \Delta z \Delta x, \quad (12.202)$$

$$a_T^{\nu-1} = \rho_t^{\nu-1} d_t \Delta x \Delta y, \quad (12.203)$$

$$a_B^{\nu-1} = \rho_b^{\nu-1} d_b \Delta x \Delta y, \quad (12.204)$$

$$a_P^{\nu-1} = a_E^{\nu-1} + a_W^{\nu-1} + a_N^{\nu-1} + a_S^{\nu-1} + a_T^{\nu-1} + a_B^{\nu-1}, \quad (12.205)$$

$$\begin{aligned} S^{\nu-1} = \frac{(\rho_P^n - \rho_P^{\nu-1}) \Delta x \Delta y \Delta z}{\Delta t} &- [(\rho^{\nu-1} v_x^{*,\nu} A)_e - (\rho^{\nu-1} v_x^{*,\nu} A)_w] \\ &- [(\rho^{\nu-1} v_x^{*,\nu} A)_n - (\rho^{\nu-1} v_x^{*,\nu} A)_s] \\ &- [(\rho^{\nu-1} v_x^{*,\nu} A)_b - (\rho^{\nu-1} v_x^{*,\nu} A)_t] \end{aligned} \quad (12.206)$$

The values of the density is available at the scalar grid nodes only, thus the grid cell interface densities must be approximated by an interpolation method. Irrespective of interpolation method chosen, the value on the grid cell volume surface must be consistently used for both the grid cell volumes to which the interface belongs. It is seen that the source term in the pressure correction equation  $S^{\nu-1}$  corresponds to the negative of the LHS of the discretized continuity equation evaluated in terms of the approximated velocities. Hence, if the source term approaches zero, it means that the approximated velocities in conjunction with the available value of the transient term, do satisfy the continuity equation, and no more pressure corrections are needed.

### The SIMPLE Algorithm

This solution algorithm for calculating the flow fields has been given the name SIMPLE. The acronym SIMPLE stands for Semi-Implicit Method for Pressure-Linked Equations. The words ‘semi-implicit’ in the name SIMPLE have been used to acknowledge the omission of the neighboring terms  $\sum_{nb} a_{nb}^{\nu-1} v_{i,nb}^{\nu}$ ,  $i = x, y, z$ .

*The sequence of operations in the SIMPLE algorithm can be summarized as follows for dynamic problems:*

1. Start calculation of the fields at the new time  $t^{n+1}$  using the latest solution  $v_i^n$  and  $p^n$  (i.e., the initial velocity conditions and a guessed pressure field are used when  $n = 1$ ) as starting estimates for  $v_i^{n+1}$  and  $p^{n+1}$ .
2. Assemble (i.e., recompute the coefficient and source term values with the previous outer iteration,  $\nu - 1$ , variable field values) and solve the linearized algebraic equation systems (12.178)–(12.180) for the velocity components (momentum equations) to obtain  $v_i^{*,\nu}$ .
3. Assemble and solve the pressure-correction equation (12.198) to obtain  $p_i^{\prime,\nu}$ .
4. Correct the velocities and pressure (12.181) to obtain the velocity field  $v_i^\nu$ , which satisfies the continuity equation, and the new pressure  $p^\nu$ .
5. Return to step 2 and repeat, using  $v_i^\nu$  and  $p^\nu$  as improved estimates for  $v_i^{*,\nu}$  and  $p^{*,\nu}$ , until all corrections are negligible small.
6. Advance to the next time step.

To obtain the solution at the new time step in the implicit method, several outer iterations are performed. If the time step is small, only a few outer iterations per

time step are necessary. For steady problems, the time step may be infinite and the under-relaxation parameter acts like a pseudo-time step. Methods of this kind are quite efficient for solving single phase steady state problems.

The convergence performance of the SIMPLE algorithm can be improved by under-relaxation. The pressure correction equation is susceptible to divergence unless some under-relaxation is employed during the iterative process. Hence, only a portion of  $p'^{\nu}$  is added to  $p^{\nu-1}$  after the pressure-correction equation is solved:

$$p^{\nu} = p^{*,\nu-1} + \alpha_P p'^{\nu} \quad (12.207)$$

The velocity components are also under-relaxed. The iteratively improved velocity components  $v_x$ ,  $v_y$ ,  $v_z$  are obtained from:

$$v_{x,e}^{\nu} = \alpha_{v_x} v_{x,e}^{*,\nu} + (1 - \alpha_{v_x}) v_{x,e}^{*,\nu-1} \quad (12.208)$$

$$v_{y,n}^{\nu} = \alpha_{v_y} v_{y,n}^{*,\nu} + (1 - \alpha_{v_y}) v_{y,n}^{*,\nu-1} \quad (12.209)$$

$$v_{z,t}^{\nu} = \alpha_{v_z} v_{z,t}^{*,\nu} + (1 - \alpha_{v_z}) v_{z,t}^{*,\nu-1} \quad (12.210)$$

In the under-relaxation procedure, the under-relaxation parameter  $\alpha$  may take values in the rang:  $0 \leq \alpha \leq 1$ .

### The SIMPLEC Algorithm

Another way of treating the neighbor terms in the velocity-correction equations (12.192)–(12.194) is to approximate them rather than neglecting them. One could approximate the velocity correction term  $\sum_{nb} a_{nb}^{\nu-1} v'_{i,nb}{}^{\nu}$ ,  $i = x, y, z$  at the neighbor nodes by use of the center point velocity correction:

$$\sum_{nb} a_{nb}^{\nu-1} v'_{x,nb}{}^{\nu} \approx \sum_{nb} a_{nb}^{\nu-1} v'_{x,e}{}^{\nu} \quad (12.211)$$

$$\sum_{nb} a_{nb}^{\nu-1} v'_{y,nb}{}^{\nu} \approx \sum_{nb} a_{nb}^{\nu-1} v'_{y,n}{}^{\nu} \quad (12.212)$$

$$\sum_{nb} a_{nb}^{\nu-1} v'_{z,nb}{}^{\nu} \approx \sum_{nb} a_{nb}^{\nu-1} v'_{z,t}{}^{\nu} \quad (12.213)$$

By substitution of these approximations into (12.192)–(12.194), the following approximate relations between  $v_i'^{\nu}$ ,  $i = x, y, z$  and  $p'^{\nu}$  are obtained:

$$v'_{x,e} = - \frac{A_e}{a_e^{\nu-1} - \sum_{nb} a_{nb}^{\nu-1}} (p'_P - p'^{\nu}_{E}) \quad (12.214)$$

$$v'_{y,n} = - \frac{A_n}{a_n^{\nu-1} - \sum_{nb} a_{nb}^{\nu-1}} (p'_P - p'^{\nu}_{N}) \quad (12.215)$$

$$v'_{z,t} = - \frac{A_t}{a_t^{\nu-1} - \sum_{nb} a_{nb}^{\nu-1}} (p'_P - p'^{\nu}_{T}) \quad (12.216)$$

With this approximation the  $a$ -coefficient in front of the pressure gradients are replaced by  $a^{\nu-1} - \sum_{nb} a_{nb}^{\nu-1}$ . This approach is known as the SIMPLEC (SIMPLE Consistent) algorithm [239]. The SIMPLEC approach is generally more stable than the SIMPLE algorithm and does might not require any under-relaxation of the pressure correction.

### 12.9.4.3 Pressure-Correction Method for Compressible Flow

In this section the pressure correction method for incompressible flow is extended to arbitrary Mach numbers [40, 56, 93, 101, 240]. The governing conservation equations for compressible flows are the continuity, momentum and energy equations. In addition, the pressure, density, and temperature are linked by an equation of state. It was shown in Chap. 1 that for compressible flows, the interactions between the mechanical and thermal processes are important. In particular, the viscous dissipation term may be a significant heat source and the conversion of internal energy to kinetic energy (and visa versa) by means of flow dilatation may also be significant. Most of the terms in the governing equations presented in Chap. 1 must then be retained. For low Mach number (almost) incompressible flows, however, the total energy or the heat equation can be approximated by a scalar transport equation for the temperature and only the transient, convection and heat conduction terms are important.

The discretization of the compressible flow equations can still be carried out using the same methods as already presented. However, the solution algorithms designed for incompressible (low Mach number) flow must be adapted to the novel (high Mach number) compressible properties of the governing equations. The relevant changes required are associated with the boundary conditions (since different conditions are required for hyperbolic equations compared to parabolic or elliptic equations), and the nature and treatment of the coupling between the density and the pressure. For compressible flows both velocity and density appear as dependent variables in the mass conservation equation. Nevertheless, the algebraic representation of mass conservation can still be interpreted as a constraint equation for pressure and the modified interpretation of the role of pressure for the segregated approach to solve compressible flow becomes that the pressure must influence the velocity through the momentum equation and the density through the equation of state such that together the resulting velocities and the resulting densities conserve mass.

To explain the modifications required to the pressure-correction equation previously presented for incompressible flow to deal with compressible flows, we consider

a segregated solution method, in which the linearized equations for the velocity components, pressure correction, temperature, and other scalar variables are known. The velocities obtained by solving the linearized momentum equations on the form (12.192)–(12.194), by use of the previous outer iteration values for the pressure and the density, do not satisfy the mass conservation equations (12.195). If the mass fluxes computed from these velocities and the previous outer iteration density (denoted by  $F^{*,\nu}$ ) are inserted into the discretized continuity equation, the result can be expressed as:

$$\frac{(\rho^{\nu-1} - \rho^n)\Delta V}{\Delta t} + F_e^{*,\nu} - F_w^{*,\nu} + F_n^{*,\nu} - F_s^{*,\nu} + F_t^{*,\nu} - F_b^{*,\nu} \neq 0 \quad (12.217)$$

Any mass imbalance must thus be eliminated by a correction method.

The corrected mass balance can be written as:

$$\frac{(\rho^\nu - \rho^n)\Delta V}{\Delta t} + F_e^\nu - F_w^\nu + F_n^\nu - F_s^\nu + F_t^\nu - F_b^\nu = 0 \quad (12.218)$$

In compressible flows, the mass flux depends on both the velocity component normal to the cell face and the variable density. To correct the mass flux imbalance, both the density and the velocity must be corrected.

For example, the corrected mass flux on the  $e$  face of a grid volume can be expressed as:

$$\begin{aligned} F_e^\nu &= F^{*,\nu} + F'^{\nu} = (\rho^\nu v^\nu A)_e = (\rho^{\nu-1} + \rho'^{\nu})_e (v_x^{*,\nu} + v_x'^{\nu})_e A_e \\ &= (\rho^{\nu-1} v_x^{*,\nu} A)_e + (\rho^{\nu-1} v_x'^{\nu} A)_e + (\rho'^{\nu} v_x^{*,\nu} A)_e + (\rho'^{\nu} v_x'^{\nu} A)_e \end{aligned} \quad (12.219)$$

where  $\rho'^{\nu}$  and  $v_{x,e}'^{\nu}$  represent the density and velocity corrections, respectively.

The overall mass flux correction is defined as the sum of all the correction terms:

$$\begin{aligned} F_e'^{\nu} &= (\rho^{\nu-1} v_x'^{\nu} A)_e + (\rho'^{\nu} v_x^{*,\nu} A)_e + (\rho'^{\nu} v_x'^{\nu} A)_e \\ &\approx (\rho^{\nu-1} v_x'^{\nu} A)_e + (\rho'^{\nu} v_x^{*,\nu} A)_e \end{aligned} \quad (12.220)$$

The second order correction term is normally neglected as this term becomes zero more rapidly than the two first order correction terms.

The first of the two remaining terms in the mass flux correction (12.220) is identical to the one obtained for incompressible flows (e.g., adopting the SIMPLE assumption in (12.192)):

$$(\rho^{\nu-1} v_x'^{\nu} A)_e = -(\rho^{\nu-1} A)_e \left( \frac{1}{d_e^{\nu-1}} \right) (p_P'^{\nu} - p_E'^{\nu}) \quad (12.221)$$

The second term in the mass flux correction relation (12.220), is due to the compressibility effects. It involves the correction to the density at the grid cell volume face. If the SIMPLE method is to be extended to compressible flows, the density correction

must be expressed in terms of the pressure correction to enable an efficient update of the density corrections in the pressure correction equation.

For one outer iteration, the temperature may be regarded as provisionally fixed, hence by use of a truncated Taylor series expansion of the density around the previous iteration value and the ideal gas law the current iteration density can be approximated as:

$$\rho'^{\nu} = \rho^{\nu} - \rho^{\nu-1} \approx \left( \frac{\partial \rho}{\partial p} \right)_T p'^{\nu} = \frac{M_{\omega}}{RT} p'^{\nu} \quad (12.222)$$

It is important that the link between the density and pressure corrections becomes qualitatively correct, because the intermediate results may strongly influence the stability and convergence rate of the method.

The second correction term in the mass flux correction can then be written as:

$$(\rho'^{\nu} v_x^{*,\nu} A)_e = \left( \frac{(\frac{\partial \rho}{\partial p})_T F^{*,\nu}}{\rho^{\nu-1}} \right)_e p'_e{}^{\nu} \quad (12.223)$$

The overall mass flux correction on the  $e$  face of a grid volume is thus:

$$F_e'^{\nu} = -(\rho^{\nu-1} A)_e \left( \frac{1}{a_e} \right) (p_P'^{\nu} - p_E'^{\nu}) + \left( \frac{(\frac{\partial \rho}{\partial p})_T F^{*,\nu}}{\rho^{\nu-1}} \right)_e p_e'^{\nu} \quad (12.224)$$

In general the coefficients in this equation depend on the approximations used for the gradients and cell face values of the pressure correction. The part which stems from the velocity correction is identical to that for the incompressible case. The second part depends on the approximation used for the term which corresponds to the convective contribution to the conservation equations. The pressure-correction at the cell faces are usually determined by linear interpolation between the neighboring nodes. Applying a uniform grid the linear interpolation approximation can be expressed as:  $p_e'^{\nu} = (p_E'^{\nu} + p_P'^{\nu})/2$ . The iterative solution process is converged when all the pressure corrections are approaching zero. It is noted that the given pressure-correction method can be applied for arbitrary Mach number flows. At low Mach numbers (almost incompressible flow), the Laplacian term dominates and we recover the Poisson equation. On the other hand, at high Mach number (highly compressible flow), the convective term dominates, reflecting the hyperbolic nature of the flow. Solving the pressure-correction equation is then equivalent to solving the continuity equation for density. Thus, the pressure correction method automatically adjusts to the local nature of the flow and the same method can be applied to the entire flow. Using this unified method the standard boundary conditions applied for incompressible flows also hold for compressible flow and are treated in the same way as for incompressible flow simulations. However, in compressible flow additional boundary conditions are required. Most important, the total pressure must be prescribed.

The continuity equation (12.218), that must be satisfied by the corrected mass fluxes and density, can now be written as:

$$\begin{aligned} \frac{\Delta V}{\Delta t} \left( \frac{\partial \rho}{\partial p} \right)_T p_P^{\prime, \nu} + F_e^{\prime, \nu} - F_w^{\prime, \nu} + F_n^{\prime, \nu} - F_s^{\prime, \nu} + F_t^{\prime, \nu} - F_b^{\prime, \nu} \\ = -(F_e^{*, \nu} - F_w^{*, \nu} + F_n^{*, \nu} - F_s^{*, \nu} + F_t^{*, \nu} - F_b^{*, \nu}) + \frac{\rho_P^n \Delta V}{\Delta t} - \frac{\rho_P^{\nu-1} \Delta V}{\Delta t} \end{aligned} \quad (12.225)$$

in which (12.222) has been used to express  $\rho_P^{\nu}$  in terms of  $\rho_P^{\nu-1}$ .

If the approximations of the mass flux corrections on the form (12.224) are substituted into the latter form of continuity equation (12.225), an algebraic system of equations for the pressure-correction is obtained:

$$a_P^{\nu-1} p_P^{\prime, \nu} = a_W^{\nu-1} p_W^{\prime, \nu} + a_E^{\nu-1} p_E^{\prime, \nu} + a_N^{\nu-1} p_N^{\prime, \nu} + a_S^{\nu-1} p_S^{\prime, \nu} + a_T^{\nu-1} p_T^{\prime, \nu} + a_B^{\nu-1} p_B^{\prime, \nu} + S^{\nu-1} \quad (12.226)$$

with

$$a_E^{\nu-1} = \rho_e^{\nu-1} d_e \Delta y \Delta z + \left( \frac{(\frac{\partial \rho}{\partial p})_T F_e^{*, \nu}}{2 \rho^{\nu-1}} \right)_e, \quad (12.227)$$

$$a_W^{\nu-1} = \rho_w^{\nu-1} d_w \Delta y \Delta z + \left( \frac{(\frac{\partial \rho}{\partial p})_T F_w^{*, \nu}}{2 \rho^{\nu-1}} \right)_w, \quad (12.228)$$

$$a_N^{\nu-1} = \rho_n^{\nu-1} d_n \Delta z \Delta x + \left( \frac{(\frac{\partial \rho}{\partial p})_T F_n^{*, \nu}}{2 \rho^{\nu-1}} \right)_n, \quad (12.229)$$

$$a_S^{\nu-1} = \rho_s^{\nu-1} d_s \Delta z \Delta x + \left( \frac{(\frac{\partial \rho}{\partial p})_T F_s^{*, \nu}}{2 \rho^{\nu-1}} \right)_s, \quad (12.230)$$

$$a_T^{\nu-1} = \rho_t^{\nu-1} d_t \Delta x \Delta y + \left( \frac{(\frac{\partial \rho}{\partial p})_T F_t^{*, \nu}}{2 \rho^{\nu-1}} \right)_t, \quad (12.231)$$

$$a_B^{\nu-1} = \rho_b^{\nu-1} d_b \Delta x \Delta y + \left( \frac{(\frac{\partial \rho}{\partial p})_T F_b^{*, \nu}}{2 \rho^{\nu-1}} \right)_b, \quad (12.232)$$

$$a_P^{\nu-1} = a_E^{\nu-1} + a_W^{\nu-1} + a_N^{\nu-1} + a_S^{\nu-1} + a_T^{\nu-1} + a_B^{\nu-1} + \frac{\Delta V}{\Delta t} \left( \frac{\partial \rho}{\partial p} \right)_T, \quad (12.233)$$

$$\begin{aligned} S^{\nu-1} = \frac{(\rho_P^n - \rho_P^{\nu-1}) \Delta x \Delta y \Delta z}{\Delta t} - [(\rho^{\nu-1} v_x^{*, \nu} A)_e - (\rho^{\nu-1} v_x^{*, \nu} A)_w] \\ - [(\rho^{\nu-1} v_x^{*, \nu} A)_n - (\rho^{\nu-1} v_x^{*, \nu} A)_s] \\ - [(\rho^{\nu-1} v_x^{*, \nu} A)_b - (\rho^{\nu-1} v_x^{*, \nu} A)_t] \end{aligned} \quad (12.234)$$

It is noticed that the terms in the coefficients occurring from the density corrections might be negative and change sign as the velocity or convective fluxes direction may change, thus the system coefficients might be negative, change sign or approach zero.

This coefficient behavior might easily cause numerical stability problems and must be avoided.

#### 12.9.4.4 Pressure-Correction Methods for Reactive Flows

Most chemical reactor flows can be characterized as low Mach number flows. The governing equations for low Mach number reactive flows were derived in Sect 1.2.5. Models for low Mach number reactive flows generally consist of the continuity, momentum, species mass and heat balances. The heat balance is generally expressed in terms of temperature. In general, for non-isothermal reactive low Mach number flows, the mixture density may vary due to changes in temperature, pressure and chemical composition. The temperature changes may be created by the chemical process through the chemical reactions, the heats of reaction, non-ideal fluid mixing, and the external heating or cooling devices. The thermodynamic pressure may be changed by external expansion or compression of the fluid mixture. The local pressure variations caused by the flow are generally very small in chemical reactors, except in the initial phase of flow in multiphase reactors and packed (porous) beds in which the axial pressure drop may be significant but not changing much after a short initial start-up period. The gravity force term may be important for tall liquid columns. The chemical composition can be changed by the chemical reactions in the process. In reactive processes, the fluid transport coefficients and the mixture thermodynamic properties vary basically due to changes in the chemical composition, temperature, thermodynamic pressure created by the chemical process, and not because of any particular flow phenomena.

The basic elements of the solution methods presented above for solving incompressible and compressible flows can be adapted for reactive flows as well. However, special attention must be attributed to the novel system characteristics that the multicomponent fluid mixture properties and temperature may change due to chemical reactions, non-ideal fluid mixing and external heat sources, although the low Mach number indicates that the transport properties should be about constant. Most important, an appropriate algorithm for reactive flows must enable accurate solutions of non-isothermal flows with changes in composition due to chemical reactions. For non-isothermal reactive flows, the interactions between the species mass balances, mixture continuity and momentum equations, and the heat or temperature equation must be considered and they are generally distinct from those of high Mach number compressible flow. In particular, the viscous dissipation term and the conversion of internal heat to kinetic energy (and visa versa) by means of flow dilatation can both be neglected in most cases. The heat equation can thus be approximated by a scalar transport equation for the enthalpy or the temperature in which only the transient, convection/advection, heat conduction, heat of reaction and external heat source terms are important. To calculate the pressure for gas mixtures an appropriate EOS is needed to convert the density correction term into a pressure correction. The ideal gas law is often used. In the work of Solsvik et al. [218] the most stable form of the pressure-correction equation for reactive variable density flows was achieved

by neglecting all the contributions of the density corrections in the fluxes, while the corresponding contribution to the center coefficient  $a_p^{\nu-1}$  occurring from the transient term  $\Delta V M_\omega / \Delta t R T$  was retained. Moreover, the remaining parts of the transient term were placed in the source term  $S^{\nu-1}$ . Numerical stability problems might easily occur for chemical processes associated with large density variations within the domain. If the external pressure is changed, expansion or compression of the fluid mixture within the reactor take place. In this case, the conversion of internal heat to kinetic energy (and visa versa) by means of flow dilatation can not be neglected. A complete heat balance must be used. However, the present reactor simulations do not consider any variations of the external pressure during operation, another simulation with different operating conditions are performed instead. For many liquid mixtures the standard incompressible flow solvers can be adopted to solve isothermal reactive flows with negligible changes in the mixture density due to chemical reactions. No energy equation is then required as the flow and the chemical process are independent of temperature. To solve isothermal reactive flows with limited changes in the mixture density due to chemical reactions, a modified incompressible solver with no energy balance may be used. For chemical processes creating small temperature changes (for liquid mixtures in particular), the incompressible methods may be extended with a temperature equation provided that in all conservation laws temperature dependent transport coefficients and thermodynamic properties are considered.

## 12.10 Fractional Step Methods

The fractional step, or time splitting, concept is more a generic operator splitting approach than a particular solution method [35, 56, 106, 144, 260]. It is essentially an approximate factorization of the methods applied to the different operators in an equation or a set of equations. The overall set of operators can be solved explicitly, implicitly or by a combination of both implicit and explicit discretization schemes.

### Scalar Transport Equation

The fractional step concept is frequently used to solve scalar transport equations on the generic form [12, 99, 159]:

$$\frac{\partial(\rho\psi)}{\partial t} + \nabla \cdot (\mathbf{v}\psi) = \nabla(\Gamma_\psi \nabla\psi) + S_\psi \quad (12.235)$$

This balance equation is written on the conservative flux form, the non-conservative form of the equation is easily obtained by use of the continuity equation.

To illustrate the fractional step method, the explicit Euler advancement of the property  $\psi$  can be written in symbolic form:

$$(\rho\psi)^{n+1} = (\rho\psi)^n + (-C_\psi + D_\psi + S_\psi)^n \Delta t \quad (12.236)$$

where  $C_\psi$ ,  $D_\psi$ , and  $S_\psi$  represent the discretized form of the convective, diffusive, and source terms, respectively.

The fractional step, or time splitting, concept can be adapted to the discretized equation by splitting the discrete scalar equation into a three step method:

$$(\rho\psi)^* = (\rho\psi)^n - C_\psi^n \Delta t \quad (12.237)$$

$$(\rho\psi)^{**} = (\rho\psi)^* + D_\psi^n (\psi^*) \Delta t \quad (12.238)$$

$$(\rho\psi)^{n+1} = (\rho\psi)^{***} = (\rho\psi)^{**} + S_\psi^n (\psi^{**}) \Delta t \quad (12.239)$$

In this example the property  $\psi$  is advanced using the explicit Euler scheme for all the operators. However, both implicit and explicit methods can be employed. In order to take a larger time steps, implicit methods are generally preferred. The convective and diffusive terms can be further split into their components in the various coordinate directions, for example, by use of the Strang [227] operator factorization scheme.

#### Incompressible Viscous Flow

The fractional-step concept can be used to solve the governing equations for the fluid motion as well. To illustrate the overall method with emphasis on the pressure-velocity coupling, a FVM variant of the fractional-step method used by Chorin [35], Fortin et al. [65] and Andersson and Kristoffersen [3] for solving the unsteady Navier-Stokes and continuity equations for incompressible viscous flows is outlined. Consider the equations of motion of an incompressible viscous fluid on the form:

$$\frac{\partial v_i}{\partial t} + \frac{\partial v_i v_j}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 v_i}{\partial x_j \partial x_j} \quad (12.240)$$

The corresponding continuity equation yields:

$$\frac{\partial v_i}{\partial x_i} = 0 \quad (12.241)$$

By use of the explicit Euler scheme, the discrete form of the momentum equations can be written as [3]:

$$\frac{v_i^{n+1} - v_i^n}{\Delta t} = -C_i^n - \beta \frac{\delta p^{n+1}}{\delta x_i} + D_i^n \quad (12.242)$$

It is further assumed that the solution at time level  $n$  is known, satisfying the continuity equation. The solution at the next time level  $n + 1$  is then obtained from the discrete form of the above momentum equation, subject to the discrete continuity constraint which can be expressed as:

$$\frac{\delta v_i^{n+1}}{\delta x_i} = 0 \quad (12.243)$$

The time-splitting method can be adapted to the governing equations by splitting the momentum equation into two intermediate steps:

$$\frac{v_i^* - v_i^n}{\Delta t} = -C_i^n + D_i^n - \beta \frac{\delta p^n}{\delta x_i} \quad (12.244)$$

$$\frac{v_i^{n+1} - v_i^*}{\Delta t} = -\frac{\delta}{\delta x_i}(p^{n+1} - \beta p^n) \quad (12.245)$$

where  $\beta$  is a constant and  $v_i^*$  is an intermediate value of the velocity component. If  $\beta = 0$ , the intermediate velocity is advanced by the convective and viscous terms while the pressure term is ignored. By taking,  $\beta = 1$  instead, more information is carried over from  $v_i^n$  to  $v_i^*$  via the first step. Thus, if the solution tends to a steady state, the velocity  $v_i^{n+1}$  at the new time level becomes equal to  $v_i^*$ .

An essential feature of the two-step decomposition of the momentum equation is that the tentative velocity  $v_i^*$  can be calculated explicitly in the first step, while the new velocity  $v_i^{n+1}$  is related to the new pressure field in the second step. By taking the divergence of the equation in the second step, and making subsequent use of the implicit continuity equation, the Poisson equation for the potential function  $\phi^{n+1}$  is obtained:

$$\frac{\delta}{\delta x_j} \left[ \frac{\delta \phi^{n+1}}{\delta x_j} \right] = \frac{1}{\Delta t} \frac{\delta v_i^*}{\delta x_i} \quad (12.246)$$

The potential function  $\phi$  is defined as:

$$\phi^{n+1} = p^{n+1} - \beta p^n \quad (12.247)$$

With  $\phi^{n+1}$  known from the solution of the Poisson equation, the pressure and velocities at the new time level  $n + 1$  are obtained from:

$$p^{n+1} = p^n + \phi^{n+1} \quad (12.248)$$

$$v_i^{n+1} = v_i^* - \Delta t \frac{\delta \phi^{n+1}}{\delta x_i} \quad (12.249)$$

In application of the fractional step method to the incompressible Navier-Stokes equations, the pressure may be interpreted as a projection operator which projects an arbitrary vector field into a divergence-free vector field.

The fractional step methods have become quite popular. To predict an accurate time history of the flow, higher order discretizations must be employed. Kim and Moin [106], for example, used a second order explicit Adams-Bashforth scheme for the convective terms and a second order implicit Crank-Nicholson scheme for the viscous terms. Boundary conditions for the intermediate velocity fields in time-splitting methods are generally a complex issue [3, 106]. There are many variations of the fractional step methods, due to a vast choice of approaches to time and space discretizations, but they are generally based on the principles described above.

## Chemical Reactive Flow

Jakobsen et al. [95] and Lindborg et al. [135] did apply similar fractional step algorithms combined with FVM discretizations in space for variable density flows to simulate the performance of chemical processes in fixed bed reactors. The fractional steps defining the elements of these algorithms are sketched in the following. In a set of introductory steps, the mixture composition and the temperature were calculated. A set of scalar transport equations on the form (12.236) is generally solved for the species mass densities and the mixture enthalpy at the next time level  $n + 1$ . However, in reactor simulations, the enthalpy balance is frequently expressed in terms of temperature. The discrete form of the governing equations is thus written as:

$$\rho_c^{n+1} = \rho_c^n + (-C_c^n + D_c^{n+1} + S_c^{n+1}) \frac{\Delta t}{\Delta V} \quad (12.250)$$

$$T_c^{n+1} = T_c^n + (-A_T^n + D_T^{n+1} + S_T^{n+1}) \frac{\Delta t}{\Delta V} \quad (12.251)$$

where  $A$  is a shorthand notation for the advective terms.

The mixture density  $\rho^{n+1}$  was then obtained by the sum of the species densities  $\rho_c^{n+1}$ :

$$\rho^{n+1} = \sum_c \rho_c^{n+1} \quad (12.252)$$

In a set of intermediate steps, the evolution of the mixture pressure and velocity components were calculated. The variable density form of the Navier-Stokes equations were split into two intermediate steps.

$$\left( \frac{\rho^{n+1} v_i^* - (\rho v_i)^n}{\Delta t} \right) \Delta V = -C_i^n + D_i^n - \frac{\delta p^n}{\delta x_i} + S_i^n \quad (12.253)$$

$$\left( \frac{(\rho v_i)^{n+1} - (\rho^{n+1} v_i^*)}{\Delta t} \right) \Delta V = -\frac{\delta}{\delta x_i} (p^{n+1} - p^n) \quad (12.254)$$

where  $S$  represents the gravity term. In order to allow longer time steps to be used, implicit schemes must be used for the  $C$ ,  $D$  and  $S$  operators in the first step of the momentum equation solution.

By taking the divergence of the momentum equation in the second step, they did obtain a Poisson equation for the potential function  $\phi^{n+1}$ :

$$\frac{\delta}{\delta x_j} \left[ \frac{\delta \phi^{n+1}}{\delta x_j} \right]_P = \frac{\Delta V}{\Delta t} \left[ \frac{\delta(\rho^{n+1} v_i^*)}{\delta x_i} - \frac{\delta(\rho v_i)^{n+1}}{\delta x_i} \right] \quad (12.255)$$

The solution at the next time level  $n + 1$  was then obtained from the discrete form of the momentum equation, subject to the continuity constraint on the form:

$$\frac{\delta \rho}{\delta t} + \frac{\delta(\rho v_i)^{n+1}}{\delta x_i} = 0 \quad (12.256)$$

The continuity equation for the reactive mixture was used to construct a stable approximation of the RHS of the Poisson equation for the potential function  $\phi$ . The transient term in the continuity equation may be approximated by an explicit high order scheme, or an implicit scheme can be used.

With  $\phi^{n+1}$  known from the solution of the Poisson equation, the pressure and velocities at the new time level  $n + 1$  were obtained from:

$$p^{n+1} = p^n + \phi^{n+1} \quad (12.257)$$

$$v_i^{n+1} = v_i^* - \frac{\Delta t}{\rho^{n+1} \Delta V} \frac{\delta \phi^{n+1}}{\delta x_i} \quad (12.258)$$

For reactive variable density flows, the pressure is interpreted as a projection operator which projects an arbitrary vector field into a vector field which fulfill the continuity equation.

For gas mixtures, the solution of the species mass balances, the temperature equation and the Navier-Stokes equations were followed by a density update. For an ideal gas, the density changes were determined by a complete differential of the density. The complete differential of the ideal gas mixture density, which in accordance with the ideal gas law depends on the mixture molecular mass, pressure and the temperature, i.e.,  $\rho = \rho(p, T, M_\omega)$ , can be expressed as:

$$d\rho = \left( \frac{\partial \rho}{\partial M_\omega} \right)_{T,p} dM_\omega + \left( \frac{\partial \rho}{\partial T} \right)_{M_\omega,p} dT + \left( \frac{\partial \rho}{\partial p} \right)_{M_\omega,p} dp \quad (12.259)$$

$$= \frac{p}{RT} dM_\omega - \frac{pM_\omega}{RT^2} dT + \frac{M_\omega}{RT} dp \quad (12.260)$$

The density update due to dynamic changes in  $M_\omega$ ,  $T$  and  $p$  during one time step is thus approximated as:

$$\rho^{n+1,*} = \rho^n + \frac{p^n}{RT^n} (M_\omega^{n+1} - M_\omega^n) - \frac{\rho^n}{T^n} (T^{n+1} - T^n) + \frac{M_\omega^n}{RT^n} (p^{n+1} - p^n). \quad (12.261)$$

## 12.11 Finite Volume Methods for Multi-fluid Models

In this section, the path-breaking implicit interphase slip algorithm (IPSA) framework by Spalding [219–221] is outlined. Different designs of the basic algorithm for the novel multiphase properties are examined. Two stable and efficient semi-implicit fractional step algorithms for the solution of unsteady two-fluid models are presented in the subsequent section. The first semi-implicit numerical procedure was used simulating bubble column flows [97, 137]. The second semi-implicit fractional

step algorithm was employed for the solution of an unsteady two-fluid granular flow model [136]. The latter semi-implicit procedure has also been extended in order to simulate reactive flows in fluidized beds [138].

### ***12.11.1 Solving the Two-Fluid Model Equations***

In this section, a survey of a selection of path-breaking procedures that have been designed for the numerical solution of the two-fluid model equations is provided. It is emphasized that most of the standard procedures for solving multiphase problems represent more or less adequate extensions of the analogous procedures for single phase flow. The important procedure extensions required in order to solve the two-fluid model equations starting out from the standard single phase finite volume method algorithms, are pointed out and examined in further detail.

The basic discretization of the two-fluid model equations is similar to the approximations of the corresponding transport equations for single phase flow. A minor difference is that the two-fluid model equations contain the novel phase fraction variables that have to be approximated in an appropriate manner. More important, to design robust, stable and accurate solution procedures with appropriate convergence properties for the two-fluid model equations, emphasis must be placed on the treatment of the interface transfer terms in the phasic momentum, heat and mass transport equations. Because of these extra terms, the coupling between the different equations is even more severe for multiphase flows than for single phase flows. A property of the finite volume method is that numerous schemes and procedures can be designed in order to solve the two-fluid model equations. In addition, the coupling terms can be approximated and manipulated in different ways. However, it is very difficult to predict the convergence and stability properties of the novel solution methods. These aspects collectively increase the possibility of devising a numerical procedure which, when put to the test, does not converge. In an early attempt to calculate the phase fractions in an approximate implicit volume fraction-velocity-pressure correction procedure, Spalding [219–221, 223] calculated the phase fractions from the respective phase continuity equations. However, experience did show that it was difficult to conserve mass simultaneously for both phases when the algorithm mentioned above was used. For this reason, Spalding [222] suggested that the volume fraction of the dispersed phase may rather be calculated from a discrete equation that is derived from a combination of the two continuity equations. An alternative form of the latter volume fraction equation, particularly designed for fluids with large density differences, was later proposed by Carver [32]. In this method the continuity equations for each phase were normalized by a reference mass density to balance the weight of the error for each phase. Nevertheless, most of the present finite volume procedures that are used to solve the continuity and momentum equations are derived from the approximate implicit interphase slip algorithm (IPSA) framework proposed by Spalding [219–221, 223]. Rather than representing a particular algorithm and discrete equations, the IPSA framework represents various extensions of

the SIMPLE-like algorithms<sup>12</sup> that have been employed to solve the two-fluid model equations. Different procedure manipulations have been proposed to ensure high convergence rates depending on the coupling between the pressure, velocity and volume fractions and on the need of consideration of both fluids. The original IPSA of Spalding [219] was designed to comprise an approximate implicit coupling between the simultaneous changes of volume fraction and velocity with pressure. The pressure correction equation was designed from the two continuity equations in order to minimize the local imbalance in volume fractions as computed separately from the individual continuity equations. To improve the solution procedure mass conservation treatment for the individual phases and thus the convergence rate, Spalding [220, 221, 223] derived a pressure correction equation which contains a somewhat different attempt to approximate the simultaneous change of volume fraction and velocity with pressure for both phases. A similar third alternative IPSA pressure-correction equation was suggested by Carver [31]. For bubbly flows, Grienberger [77] argued that the two-fluid model contains only one pressure and thus designed a pressure-correction equation from the liquid continuity equation and the liquid velocity corrections formulas in the same way as for single phase flows [164]. One of the most important contributions of Spalding [219, 220] is the partial elimination algorithm (PEA). Due to the tight coupling between the velocities caused by the interface friction terms, manipulation of the discrete discretization equations for the velocity components was considered necessary to ensure sufficiently high convergence rates. The working principle of the PEA is thus to weaken the strong coupling between the phases through the partial elimination of the variables of the interacting phase in the interphase coupling term. Linear algebra is basic to the computer solution of any kind of PDE problem. The mathematical impact of the partial elimination algorithm on the solver for the resulting system of algebraic equations is to reduce the effect of the strong coupling between the phasic momentum equations on the algebraic equations matrix condition number and thereby improve the convergence properties of the problem. Without this manipulation of the equations the condition number is very large as the matrix is almost singular. The PEA can also be generalized and applied to any binary set of the two-fluid model equations that are strongly coupled, e.g., the species mass, continuity, momentum and energy equations, as illustrated in the subsection called *solving strongly coupled equations*.

No significant differences in convergence performance are generally observed assessing the alternative SIMPLE/SIMPLEC/SIMPLER, volume fraction and pressure correction discretization schemes for the solution of the two-fluid model equations [94]. A main limitation associated with these volume fraction and pressure correction procedures is that it is impossible to ensure that both the overall mixture continuity and the individual phase continuities are satisfied at the same time. In addition, to solve the two-fluid model problems, an implicit treatment of the interphase coupling terms is required. In the modern solution algorithms for the two-fluid

---

<sup>12</sup> The velocity- and pressure correction equations in IPSA are frequently derived using the SIMPLEC method (i.e., the SIMPLE- Consistent approximation) by van Doormal and Raithby [239].

model equations, the latter problem is generally relaxed by coupled strategies solving the corresponding transport equations of both phases simultaneously [5, 104, 115, 116, 120, 121, 136]. Numerous multiphase codes for dispersed flows have been developed to date, including both commercial multi-purpose codes and special purpose in-house codes. However, as indicated in the above summary, most of these codes have been originated as computational tools for multidimensional single-phase problems. Improved robustness and higher convergence rates are still important tasks for the code developers. A key feature of the next generation multiphase codes is that from the outset the software design has to be focused on the development of a reliable solver for multiphase flows with the capability to model an arbitrary number of fluid components and phases. A trend in numerical algorithm design is to search for improved convergence rates by solving all the model equations simultaneously. A main goal is thus to avoid the major SIMPLE approximation. The conventional PEA can be replaced by fully coupled algorithms that solve the momentum equations in all the three space dimensions simultaneously. A bottleneck in the modern algorithm design is the optimization of the iteration loop for simultaneous solution of the momentum-, phase fraction- and pressure correction equations. The potential advantages of a coupled treatment over a non-coupled or segregated approach are efficiency, generality and simplicity. The principal drawbacks are the lack of robustness and the higher storage needed for all the coefficients which did prevent such an algorithm to be used in the past.

Detailed and illustrative descriptions of the commonly used two-fluid model solution algorithms and discretization schemes employed in order to solve dynamic two-fluid models for reactive systems can be found elsewhere [94, 137, 218].

### 12.11.1.1 Solving Strongly Coupled Equations

In multiphase reactive flows, the interfacial transfer fluxes of momentum, heat and species mass are of great importance. These interfacial transfer fluxes are generally modeled as a product of the interfacial area concentration, the driving force denoting the difference in the phase values of the primitive variables, and the transfer (proportionality) coefficients. Mathematically, a generic flux  $I_k$  can be expressed on the form:

$$I_k = Ka(\psi_l - \psi_k), \quad l \neq k \quad (12.262)$$

In multiphase reactor simulations, the momentum, heat and species mass balances may thus contain several terms that can be placed in this framework. However, in these problem solvers, the generalized proportionality coefficient  $K$  is usually derived from the steady drag force, and the convective heat and mass transfer fluxes, respectively. Several strategies have been proposed to treat these interfacial coupling terms in the design of appropriate numerical solution methods. A simple way to implement these interphase coupling terms is to apply an explicit discretization scheme. Alternatively, an alternating direction implicit (ADI)-like method can be applied in which the current phase variable in the coupling term can be approximated by an implicit

Although the interphase coupling terms are treated in a more implicit manner in this solution procedure, the weight of the intraphase coupling terms are weakened. A strong coupling between the phases diminishes the influence of the convection-diffusion coefficients, in particular for the lightest phase. The resulting solution of the equations for these phases is thus controlled primarily by the local value in the densest phase. An optimal solution procedure design must thus treat both the interphase- and intraphase coupling terms in an appropriate manner. For this aim, Lindborg et al. [136] used a coupled solver in combination with the partial elimination algorithm (PEA) proposed by Spalding [220]. The combined PEA-coupled solver used in their work is outlined in the following. From the discretized form of the generic transport equation (12.236), the interphase coupling terms can be singled out. With an implicit approximation of the interphase coupling terms, the terms in the discretized equation for the continuous phase can be rearranged and written as:

$$(a_{P,c} + K \Delta V) \psi_{P,c} = \sum_{nb} a_{nb,c} \psi_{nb,c} + S_c + K \psi_{P,d} \Delta V \quad (12.265)$$

For the dispersed phase, the corresponding equation can be expressed as:

$$(a_{P,d} + K \Delta V) \psi_{P,d} = \sum_{nb} a_{nb,d} \psi_{nb,d} + S_d + K \psi_{P,c} \Delta V \quad (12.266)$$

By using deferred estimates of the dispersed phase variable in the continuous phase equation and vice versa, the two equations can be solved sequentially using a standard equation solver. This procedure corresponds to the standard PEA implementation. Alternatively, the dispersed phase variable in the continuous phase equation can be eliminated by use of the dispersed phase transport equation. Rearranging the continuous phase equation, the result can be written as:

$$(a_{P,c} + f_d a_{P,d}) \psi_{P,c} = \sum_{nb} a_{nb,c} \psi_{nb,c} + S_c + f_d \left( \sum_{nb} a_{nb,d} \psi_{nb,d} + S_d \right) \quad (12.267)$$

The corresponding equation representing the dispersed phase can be obtained with a corresponding procedure:

$$(a_{P,d} + f_c a_{P,c}) \psi_{P,d} = \sum_{nb} a_{nb,d} \psi_{nb,d} + S_d + f_c \left( \sum_{nb} a_{nb,c} \psi_{nb,c} + S_c \right) \quad (12.268)$$

where

$$f_k = \frac{K \Delta V}{a_{P,k} + K \Delta V} \quad (12.269)$$

By implicit approximations of all the variables in both phases, the solution can now be obtained by solving the two sets of equations simultaneously. Then, a merged

The formulas for interpolation of the diffusivities at all the surfaces can be written similarly, hence to explain the procedure a single interface case is used as an example.

The interpolation factor  $f_w$  is given by:

$$f_w = \frac{\delta z_{W_w}}{\delta z_{W_w} + \delta z_{wP}} \quad (12.273)$$

For a uniform grid the  $w$  is midway between the nodes,  $f_w = 0.5$  and the interpolated value of  $\Gamma_{\psi,w}$  reduces to the arithmetic mean of  $\Gamma_{\psi,W}$  and  $\Gamma_{\psi,P}$ :

$$\Gamma_{\psi,w} = \frac{1}{2}(\Gamma_{\psi,W} + \Gamma_{\psi,P}) \quad (12.274)$$

The linear interpolation approach cannot accurately treat the abrupt changes in the diffusivity that may occur in some locations in multiphase reactors where the phase fractions change rapidly. To improve the interpolation procedure, one seeks an approximation of the diffusivity that gives an accurate approximation of the diffusive flux for cases with large changes in the material properties. Consider that the grid cell volume surrounding the grid node  $P$  is filled with a material mixture of uniform diffusivity  $\Gamma_{\psi,P}$ , and the one around  $W$  with a material mixture of uniform diffusivity  $\Gamma_{\psi,W}$ . For the phase mixture between node  $P$  and  $W$ , a steady one dimensional analysis of the flux leads to [164]:

$$\Gamma_{\psi,w} = \left( \frac{1-f_w}{\Gamma_{\psi,W}} + \frac{f_w}{\Gamma_{\psi,P}} \right)^{-1} \quad (12.275)$$

For uniform grids, the grid cell interface is placed midway between  $P$  and  $W$ , and  $f_w = 0.5$ , hence the interpolation reduced to the harmonic mean of  $\Gamma_{\psi,W}$  and  $\Gamma_{\psi,P}$ :

$$\Gamma_{w,\psi} = \frac{2\Gamma_{\psi,W}\Gamma_{\psi,P}}{\Gamma_{\psi,W} + \Gamma_{\psi,P}}. \quad (12.276)$$

### ***12.11.2 Explicit Fractional Step Algorithm for Solving the Two-Fluid Model Equations Applied to Bubble Column Flow***

In this section the solution method employed by Jakobsen et al. [97] simulating bubble column flows is outlined. The governing two-fluid model equations were discretized by a finite volume algorithm. A staggered grid arrangement was used. A fractional step scheme similar to those used by Tomiyama and Shimada [238] and Lathouwers [121] was employed. In particular, the single phase algorithms developed

by Jakobsen et al. [95] and Lindborg et al. [135] for porous media were extended to two phase bubbly flows.

Based on a semi-discrete formulation (discretized in time only) of the governing equations for incompressible fluids, the fractional steps defining the solution algorithm are sketched in the following:

1. First, intermediate volume fraction values were calculated solving the continuity equation for the dispersed phase by an explicit discretization scheme:

$$\int_V \left( \frac{\alpha_d^* \rho_d^n - \alpha_d^n \rho_d^n}{\Delta t} \right) dv = - \int_V \nabla \cdot (\alpha_d^n \rho_d^n \mathbf{v}_d^n) dv \quad (12.277)$$

The corresponding continuous phase volume fraction estimate is found by use of (8.11),  $\alpha_c^* = 1 - \alpha_d^*$ .

2. Intermediate velocity values were then obtained by solving the momentum balances without the interfacial coupling terms using explicit discretization schemes for all variables except for the volume fractions. The intermediate volume fraction estimates obtained in step 1 were used in all terms except from the convective terms:

$$\begin{aligned} \int_V \left( \frac{\alpha_k^* \rho_k^n \mathbf{v}_k^* - \alpha_k^n \rho_k^n \mathbf{v}_k^n}{\Delta t} \right) dv = & - \int_V \nabla \cdot (\alpha_k^n \rho_k^n \mathbf{v}_k^n \mathbf{v}_k^n) dv + \int_V \nabla \cdot (\alpha_k^* \boldsymbol{\sigma}_k^n) dv \\ & - \int_V \alpha_k^* \nabla p^n dv + \int_V \alpha_k^* \rho_k^n \mathbf{g} dv \end{aligned} \quad (12.278)$$

3. The lift force was approximated with an explicit Euler time discretization scheme:

$$\int_V \left( \frac{\alpha_k^* \rho_k^n \mathbf{v}_k^{**} - \alpha_k^n \rho_k^n \mathbf{v}_k^*}{\Delta t} \right) dv = \int_V \mathbf{F}_{L,k}^* dv \quad (12.279)$$

In this fractional step, the volume fractions were assumed independent of time.

The steady-drag, virtual mass, turbulent dispersion, and wall lift forces were approximated using a semi-implicit time discretization scheme:

$$\int_V \left( \left( \frac{\alpha_k^* \rho_k^n \mathbf{v}_k^{***} - \alpha_k^n \rho_k^n \mathbf{v}_k^{**}}{\Delta t} \right) - \alpha_c^* [\mathbf{F}_{D,k}^{***} + \mathbf{F}_{V,k}^{***} + \mathbf{F}_{TD,k}^{***} + \mathbf{F}_{W,k}^{***}] \right) dv = 0 \quad (12.280)$$

In this fractional step, the volume fractions were assumed independent of time.

4. A Poisson equation for the pressure like variable  $\phi^{n+1}$  was derived from a discrete form of the momentum equation in which the volume fractions and densities were assumed independent of time:

$$\int_V \left( \frac{\alpha_k^* \rho_k^n \mathbf{v}_k^{n+1} - \alpha_k^* \rho_k^n \mathbf{v}_k^{***}}{\Delta t} \right) dv = - \int_V \alpha_k^* \nabla \phi^{n+1} dv \quad (12.281)$$

where  $\phi^{n+1} = p^{n+1} - p^n$ .

Applying the continuity divergence operator on the terms in this relation, and recognizing that the first divergence term in the resulting relation represents an extended estimate of the transient term in the continuity equation, the resulting relation can be written as:

$$\begin{aligned} \int_V \left( \frac{\nabla \cdot (\alpha_k^* \rho_k^n \mathbf{v}_k^{n+1}) - \nabla \cdot (\alpha_k^* \rho_k^n \mathbf{v}_k^{***})}{\Delta t} \right) dv \\ = \int_V \left( \frac{-\frac{\partial}{\partial t} (\alpha_k \rho_k^n) - \nabla \cdot (\alpha_k^* \rho_k^n \mathbf{v}_k^{***})}{\Delta t} \right) dv = - \int_V \nabla \cdot (\alpha_k^* \nabla \phi^{n+1}) dv \end{aligned} \quad (12.282)$$

The volume fraction variables were assumed to be time dependent in the semi-implicit discretization scheme used to solve the continuity equations.

Considering the last two terms in the above relation, the transient term was then approximated by an explicit Euler time discretization scheme followed by volume integration in which the transient term was kept constant. If we thereafter multiply the resulting relation by  $\Delta t / \rho_k^n$ , the relation can be rewritten as:

$$\frac{\alpha_k^n - \alpha_k^{n+1}}{\Delta t} \Delta V - \frac{1}{\rho_k^n} \int_V \nabla \cdot (\alpha_k^* \rho_k^n \mathbf{v}_k^{***}) dv = - \frac{\Delta t}{\rho_k^n} \int_V \nabla \cdot (\alpha_k^* \nabla \phi^{n+1}) dv \quad (12.283)$$

If we take the sum of the corresponding equations for both phases and requiring that (8.11) is fulfilled both at time  $n$  and  $n + 1$ , a Poisson equation for the pressure like variable is obtained:

$$\begin{aligned} - \frac{1}{\rho_d^n} \int_V \nabla \cdot (\alpha_d^* \rho_d^n \mathbf{v}_d^{***}) dv - \frac{1}{\rho_c^n} \int_V \nabla \cdot (\alpha_c^* \rho_c^n \mathbf{v}_c^{***}) dv \\ = - \frac{\Delta t}{\rho_d^n} \int_V \nabla \cdot (\alpha_d^* \nabla \phi^{n+1}) dv - \frac{\Delta t}{\rho_c^n} \int_V \nabla \cdot (\alpha_c^* \nabla \phi^{n+1}) dv \end{aligned} \quad (12.284)$$

5. The volume fraction values at the new time level  $n + 1$  were obtained by solving the continuity equation for the dispersed phase using the latest estimate of the  $\alpha_k$  and  $\mathbf{v}_k$  variables:

$$\int_V \left( \frac{\alpha_d^{n+1} \rho_d^n - \alpha_d^n \rho_d^n}{\Delta t} \right) dv = - \int_V \nabla \cdot (\alpha_d^* \rho_d^n \mathbf{v}_d^{n+1}) dv \quad (12.285)$$

6. The remaining scalar transport equations, like the  $k$ - $\varepsilon$  turbulence model, are solved in the same way as the discrete scalar transport equation (12.236).

The fractional step concept applied to the scalar equations consists of successive applications of the methods for the different operators determining parts of the transport equations. The convective and diffusive terms are further split into their components in the various coordinate directions as explained in Sect. 12.9.4.4.

The convective terms were solved using a second order TVD scheme in space, and a first order explicit Euler scheme in time. The TVD scheme applied was constructed by combining the central difference scheme and the classical upwind scheme by adopting the smoothness monitor of van Leer [241] and the monotonic centered limiter [242]. The diffusive terms were discretized with a second order central difference scheme. The time-splitting scheme employed is of first order.

### 12.11.3 Implicit Fractional Step Method for Solving the Two-Fluid Granular Flow Model Equations Applied to Fluidized Bed Flow

In this section the solution method employed by Lindborg et al. [136] simulating fluidized bubbling bed reactors is outlined. The governing two-fluid equations for granular flows were discretized on a staggered grid arrangement using the finite volume method. A fractional-step scheme similar to those reported in the literature [97, 121, 238] is developed on the basis of the single-phase algorithms reported by Jakobsen et al. [95, 135].

The fractional steps defining the algorithm are sketched in the following:

#### 1. Mixture composition calculation

For reactive mixtures, the species mass fractions at time level  $n + 1$  were calculated implicitly in accordance with the species mass balances on the generic form:

$$\begin{aligned} \int_V \left( \frac{\alpha_c^n \rho_c^n \omega_i^{n+1} - \alpha_c^n \rho_c^n \omega_i^n}{\Delta t} \right) dv &= - \int_V \nabla \cdot (\alpha_c^n \rho_c^n \mathbf{v}_c^n \omega_i^{n+1}) dv \\ &+ \int_V \nabla \cdot (\alpha_c^n \rho_c^n D_{m,i} \nabla \omega_i^{n+1}) dv + \int_V M_{\omega_i} R_i^{n+1} dv \end{aligned} \quad (12.286)$$

The integration of the species transport equations was followed by a density update due to the change in the ideal gas mixture composition:

$$\rho_c^* = \rho_c^n + \frac{p^n}{RT_c} (M_{\omega_c}^{n+1} - M_{\omega_c}^n) \quad (12.287)$$

## 2. Temperature calculation

The chemical process and the external heating or cooling devices may give rise to temperature changes. The evolution of the temperature was thus computed as:

$$\begin{aligned} & \int_V \alpha_k^n \rho_k^* C p_k \left( \frac{T_k^{n+1} - T^n}{\Delta t} \right) dv \\ &= - \int_V \alpha_k^n \rho_k^* C p_k \mathbf{v}_k^n \cdot \nabla T_k^{n+1} dv + \int_V \nabla \cdot (k_k \nabla T_k^{n+1}) dv \\ & \quad + \int_V \sum_r (-\Delta H_{R,r,k}) R_{r,k}^{n+1} dv + \int_V Q_k^{n+1} dv \end{aligned} \quad (12.288)$$

The solution of the heat balance is followed by a density update:

$$\rho_c^{**} = \rho_c^* + \frac{p^n M^{n+1}}{R} \left( \frac{1}{T_c^{n+1}} - \frac{1}{T_c^n} \right) \quad (12.289)$$

## 3. Volume fraction calculation—Iteration loop comprising steps 3–5

Estimates of the volume fraction values at the new time level  $n+1$  were predicted by solving the dispersed phase continuity equation implicitly using the latest values of the dispersed phase velocity field:

$$\int_V \left( \frac{\alpha_d^\nu \rho_d^{n+1} - \alpha_d^n \rho_d^n}{\Delta t} \right) dv = - \int_V \nabla \cdot (\alpha_d^\nu \rho_d^{n+1} \mathbf{v}_d^\nu) dv + \int_V \Gamma_{V,d} dv \quad (12.290)$$

The corresponding continuous phase volume fraction value was calculated from (8.11),  $\alpha_c^\nu = 1 - \alpha_d^\nu$ .

## 4. Granular temperature calculation—Iteration loop comprising steps 3–5

An intermediate granular temperature field was computed by use of the latest estimates of the volume fraction- and velocity fields (i.e., calculated within the iteration loop):

$$\begin{aligned}
\int_V \frac{3}{2} \left[ \frac{\alpha_d^\nu \rho_d^{n+1} \Theta^\nu - \alpha_d^n \rho_d^n \Theta^n}{\Delta t} \right] dv &= - \int_V \frac{3}{2} \nabla \cdot (\alpha_d^\nu \rho_d^{n+1} \mathbf{v}_d^\nu \Theta) dv \\
&+ \int_V \boldsymbol{\sigma}_d^\nu : \nabla \mathbf{v}_d^\nu dv + \int_V \nabla \cdot (\Gamma_d \nabla \Theta^\nu) dv \\
&- \int_V 3\beta^\nu \Theta^\nu dv + \int_V \beta^\nu < \mathbf{C}_c \cdot \mathbf{C}_d >^\nu dv - \int_V \gamma dv
\end{aligned} \quad (12.291)$$

The particle pressure is then calculated based on the preliminary estimates of the volume fractions and the granular temperature:

$$p_d^\nu = \alpha_d^\nu \rho_d^{n+1} \Theta^\nu [1 + 2(1 - e) \alpha_d^\nu g_0^\nu] \quad (12.292)$$

### 5. Particle pressure- and velocity correction—Iteration loop comprising steps 3–5

A preliminary estimate of the dispersed phase velocity was obtained with a simplified form of the momentum equation, assuming that the particle pressure and drag forces are the dominant forces:

$$\begin{aligned}
\int_V \left( \frac{\alpha_d^\nu \rho_d^{n+1} \mathbf{v}_d^{\nu+1} - \alpha_d^n \rho_d^n \mathbf{v}_d^n}{\Delta t} \right) dv \\
= - \int_V \nabla p_d^\nu dv - \int_V K^\nu (\mathbf{v}_d^{\nu+1} - \mathbf{v}_c^{\nu+1}) dv
\end{aligned} \quad (12.293)$$

This simplification reduces the overall computational costs drastically.

It was further assumed that the continuous phase momentum equation is dominated by the drag force only:

$$\int_V \left( \frac{\alpha_c^\nu \rho_c^{n+1} \mathbf{v}_c^{\nu+1} - \alpha_c^n \rho_c^n \mathbf{v}_c^n}{\Delta t} \right) dv = \int_V K^\nu (\mathbf{v}_d^{\nu+1} - \mathbf{v}_c^{\nu+1}) dv \quad (12.294)$$

An estimate of the continuous phase velocity was obtained by reformulating the equation:

$$\mathbf{v}_c^{\nu+1} = \frac{\alpha_c^n \rho_c^n \mathbf{v}_c^n + \Delta t K^\nu \mathbf{v}_d^{\nu+1}}{D} \quad (12.295)$$

where  $D = \alpha_c^\nu \rho_c^{n+1} + \Delta t K^\nu$ .

If (12.293) is solved with respect to the velocity estimate of the dispersed phase, followed by eliminating the unknown velocity of the continuous phase by use of (12.295), the result is:

$$\mathbf{v}_d^{\nu+1} = \frac{\alpha_d^n \rho_d^n \mathbf{v}_d^n - \Delta t \nabla p_d^\nu + \Delta t K^\nu \alpha_c^n \rho_c^n \mathbf{v}_c^n / D}{\alpha_d^n \rho_d^n + \Delta t K^\nu (1 - \Delta t K^\nu / D)} \quad (12.296)$$

The steps 3–5 were performed in an iterating manner until the overall squared change in volume fraction  $\varepsilon = \sum_V (\alpha_d^{\nu+1} - \alpha_d^\nu)^2$  for two consecutive iterations was less than a predefined criterion typically of the order of the machine precision.

### 6. Iterative velocity calculation

After the iteration loop in steps 3–5 is converged with the simplified momentum equation, improved velocity estimates were obtained from the complete momentum equation.

The discrete momentum balance was solved for the velocity using an implicit Euler discretization scheme:

$$\begin{aligned}
 & \int_V \left( \frac{\alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^* - \alpha_k^n \rho_k^n \mathbf{v}_k^n}{\Delta t} \right) dv \\
 &= - \int_V \nabla \cdot (\alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^n \mathbf{v}_k^*) dv \\
 &+ \int_V \nabla \cdot \boldsymbol{\sigma}_k^* dv - \int_V \alpha_k^{n+1} \nabla p^n dv \\
 &+ \int_V \alpha_k^n \rho_k^{new} \mathbf{g} dv + \int_V \mathbf{M}_k^* dv
 \end{aligned} \tag{12.297}$$

The density estimate  $\rho_k^{new}$  denotes the latest obtained density of phase  $k$ . In the dispersed phase  $\rho_d^{new} = \rho_d^{n+1}$ , while in the continuous phase  $\rho_c^{new} = \rho_c^{**}$ .

### 7. Iterative gas pressure- and velocity corrections

A gas pressure update was then performed to correct the pressure- and velocity fields:

$$\begin{aligned}
 & \int_V \left( \frac{\alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^{n+1} - \alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^*}{\Delta t} \right) dv \\
 &= - \int_V \alpha_k^{n+1} \nabla \delta p dv \pm \int_V K (\delta \mathbf{v}_l - \delta \mathbf{v}_k) dv, \quad l \neq k
 \end{aligned} \tag{12.298}$$

The pressure correction therein,  $\delta p = p^{n+1} - p^n$ , was obtained by solving the Poisson equation (the derivation is outlined below in paragraph called *derivation of the Poisson equation for the gas pressure*):

$$\begin{aligned}
& \sum_k \left( \frac{1}{\rho_k^0} \nabla \cdot \left( \alpha_k^{n+1} \rho_k^{new} G_k \nabla \delta p \right) \right) \\
&= \sum_k \left( \frac{1}{\rho_k^0} \nabla \cdot \left( \alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^* \right) \right) + \sum_k \left( \frac{1}{\rho_k^0} \frac{\partial}{\partial t} (\alpha_k \rho_k) \right) - \sum_k \left( \frac{\Gamma_k}{\rho_k^0} \right)
\end{aligned} \tag{12.299}$$

After the pressure correction,  $\delta p$ , is known, the velocities of the dispersed and continuous phases were corrected according to (12.306) and (12.307), respectively.

Finally, the gas density is updated in accordance with the ideal gas law:

$$\rho_c^{n+1} = \rho_c^{**} + \frac{M_\omega^{n+1}}{RT_c^{n+1}} (p^{n+1} - p^n) \tag{12.300}$$

## 8. Update of turbulence fields

The  $k - \varepsilon$  turbulence model equations were discretized by an implicit fractional step scheme similar to (12.236).

### 12.11.3.1 Summary of the Algorithm

- Integration of species mass balance for the mass fractions including a density update due to change in mixture composition.
- Iterative loop solving for the particle volume fraction, granular temperature and velocity estimates.
- Re-calculation of the velocities by solving the full momentum equations.
- Iterative calculation of the gas pressure and velocities.
- Solution of turbulence model equations.

In the work of Lindborg et al. [136], the resulting linear equation systems were solved with preconditioned Krylov subspace projection methods [205]. The Poisson equation was solved by a conjugate gradient (CG)-solver, while the other transport equations were solved using a bi-conjugate gradient (BCG)-solver which can handle also non-symmetric equations systems. The solvers were preconditioned with a Jacobi preconditioner.

### 12.11.3.2 Derivation of the Poisson Equation for the Gas Pressure

First, to balance the residual contributions from both phases, the continuity equations are normalized with respect to a constant representative density of the respective phases  $\rho_k^0$ . Then, we take the sum of the normalized continuity equations for the two phases. The result can be written as:

$$\sum_k \left( \frac{1}{\rho_k^0} \frac{\partial}{\partial t} (\alpha_k \rho_k) \right) + \sum_k \left( \frac{1}{\rho_k^0} \nabla \cdot (\alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^{n+1}) \right) = \left( \frac{\Gamma_k}{\rho_k^0} \right) \quad (12.301)$$

The velocity corrections  $\delta \mathbf{v}_k = \mathbf{v}_k^{n+1} - \mathbf{v}_k^*$  were introduced into (12.301):

$$\begin{aligned} \sum_k \left( \frac{1}{\rho_k^0} \frac{\partial}{\partial t} (\alpha_k \rho_k) \right) + \sum_k \left( \frac{1}{\rho_k^0} \nabla \cdot (\alpha_k^{n+1} \rho_k^{new} \delta \mathbf{v}_k) \right) \\ = - \sum_k \left( \frac{1}{\rho_k^0} \nabla \cdot (\alpha_k^{n+1} \rho_k^{new} \mathbf{v}_k^*) \right) \end{aligned} \quad (12.302)$$

The velocity corrections in (12.302) were then substituted by the pressure corrections employing appropriately defined pressure-velocity correction relationships. The pressure-velocity correction relationships were constructed by subtracting the discrete momentum equations with the pressure at the old time level  $n$  and the preliminary estimates for velocity fields (12.297) from the semi-implicit discretization of the momentum equation with the corrected pressure and the estimates for the velocity fields that satisfy the continuity equations. The desired relationships are the given on the form:

$$\int_V \frac{\alpha_k^{n+1} \rho_k^{n+1}}{\Delta t} \delta \mathbf{v}_k dv = - \int_V \alpha_k^{n+1} \nabla \delta p dv + \int_V K (\delta \mathbf{v}_l - \delta \mathbf{v}_k) dv, \quad l \neq k \quad (12.303)$$

Introducing a new variable  $T_k = \frac{\alpha_k^{n+1} \rho_k^{n+1}}{\Delta t}$  and rearranging these two relations to determine the velocity corrections for the two phases, we obtain:

$$\delta \mathbf{v}_c = \frac{K \delta \mathbf{v}_d - \alpha_c^{n+1} \nabla \delta p}{T_c + K} \quad (12.304)$$

$$\delta \mathbf{v}_d = \frac{K \delta \mathbf{v}_c - \alpha_d^{n+1} \nabla \delta p}{T_d + K} \quad (12.305)$$

Eliminating the continuous phase velocity correction in (12.305) by use of (12.304), the required pressure-velocity correction relation for the dispersed phase is achieved:

$$\delta \mathbf{v}_d = - \left[ \frac{\alpha_d^{n+1} T_c + K}{T_c T_d + K(T_c + T_d)} \right] \nabla \delta p = -G_d \nabla \delta p \quad (12.306)$$

where  $G_d = \frac{\alpha_d^{n+1} T_c + K}{T_c T_d + K(T_c + T_d)}$ .

By use of (12.306) eliminating the dispersed phase velocity in (12.304), the pressure-velocity correction relation for the continuous phase can be written as:

$$\delta \mathbf{v}_c = - \left[ \frac{\alpha_c^{n+1} + KG_d}{T_c + K} \right] \nabla \delta p = -G_c \nabla \delta p \quad (12.307)$$

where  $G_c = \frac{\alpha_c^{n+1} + \beta G_d}{T_c + K}$ .

A Poisson equation (12.299) was then obtained by inserting the pressure-velocity correction relationships into (12.302).

### 12.11.3.3 Convergence Problems and Failure of Well-Posedness of Granular Theory Closures

A common problem encountered when developing algorithms intended for simulation of fluidized beds is that numerical problems may occur in the dense regions of the domain. A high solids volume fraction restricts the fluctuating particle movement and thus reduces the granular temperature, which in turn reduces the solid pressure. As a result, local compactions may get even more compact. If the solids volume fraction approaches maximum packing, even small variations in the packing have extreme impact on the radial distribution function that instantly causes very steep gradients in the particle pressure, which in the worst case results in convergence problems. Thus, some kind of modification is commonly made in order to obtain convergence. In the work by Lindborg et al. [136], for example, the solid pressure is assumed to change its dependency from  $p_d^{kc}(\theta, \alpha_d)$  to  $p_d^{kc}(\alpha_d)$  if the temperature sinks below a certain threshold ( $\theta_{\text{crit}} = \max |\theta_{\text{min}}, \theta|$ ). The lower limit is dependent on the magnitude of the energy dissipation. A threshold value of  $\theta_{\text{min}} = 1 \times 10^{-6} \text{ m}^2/\text{s}^2$  was applied. This model modification was not necessary when including frictional stresses since these mechanisms cause extra resistance to particle motion in the dense areas and thereby reduce the probability of large, rapid fluctuations in the distribution function. In addition, the convergence rate is generally improved.

### 12.11.4 Solution of Multi-fluid Models

The multi-fluid model framework is required to simulate chemical processes containing dispersed phases of multiple sizes. Two different designs of the multi-fluid model have emerged over the years representing very different levels of complexity. For dilute flows the dispersed phases are assumed not to interact, so no population balance model is needed. For denser flows a population balance equation is included to describe the effects of the dispersed phases interaction processes. Further details on the multi-fluid model formulations are given in Chaps. 8 and 9.

To solve the multi-fluid model version without the population balance, a relatively simple generalization of the two-fluid IPSA algorithms to multiple dispersed phases [26] are often used [111, 170]. In the referred three-fluid models only two dispersed phases were included in the simulations. Tomiyama and Shimada [238] made a

similar four-fluid model which was solved by a pressure-based finite difference algorithm similar to the single phase SMAC [2] or SOLA [87] methods. In recent years, coupled solver technology is employed in some codes solving the three-fluid models [5, 26]. No attempts has been made to solve the complete multi-fluid model version with a population balance for a continuous distribution of the dispersed phases together with the continuous phase equations. However, a few attempts have been made to solve the complete multi-fluid model version for a few dispersed phases only. In the Multi-Phase-Multi-Group Model [209, 210] and the  $N \times M$  MUSIG model [66, 110, 212],  $N$  particle size groups are used to describe the size distribution within the  $M$  phases (or velocity groups). The two model versions referred above were both implemented and solved in ANSYS CFX codes. However, the former model was solved using a multi-fluid algorithm that is similar to the IPSA procedures [219, 221–223], while the latter model was solved by a coupled solver for the velocities and pressure avoiding the SIMPLE-like approximation [26]. Bove [21] proposed a different approach to solve the multi-fluid model equations in the in-house code FLOTACS. To solve the unsteady multi-fluid model together with a population balance equation for the dispersed phases size distribution, a time splitting strategy was adopted for the population balance equation. The transport operator (convection) of the equation was solved separately from the source terms in the inner iteration loop. In this way the convection operator which coincides with the continuity equation can be employed constructing the pressure-correction equation. The population balance source terms were solved in a separate step as part of the outer iteration loop. The complete population balance equation solution provides the volume fractions of the dispersed phases. When the outer iteration loop was converged, a consistent solution of the dense multi-fluid model was achieved.

## 12.12 Numerical Solution of the Population Balance Equation

The population balance equation (PBE) was outlined in Chap. 9. A frequently employed form the PBE with diameter as the only inner coordinate (property) can be deduced from (9.62). For clarity, this form of the PBE is listed below:

$$\begin{aligned} \frac{\partial f(\xi, \mathbf{r}, t)}{\partial t} + \nabla_r \cdot (f(\xi, \mathbf{r}, t) \mathbf{v}_r) + \frac{\partial}{\partial \xi} (f(\xi, \mathbf{r}, t) v_\xi(\xi, \mathbf{r}, t)) \\ = B_B(\xi, \mathbf{r}, t) - D_B(\xi, \mathbf{r}, t) + B_C(\xi, \mathbf{r}, t) - D_C(\xi, \mathbf{r}, t). \end{aligned} \quad (12.308)$$

The corresponding source terms for breakage and coalescence are defined by (9.87)–(9.90):

$$B_B(\xi, \mathbf{r}, t) = \int_{\xi}^{\infty} \nu(\xi', \mathbf{r}) b_B(\xi', \mathbf{r}) P_B(\xi, \mathbf{r}; \xi') f(\xi', \mathbf{r}, t) d\xi', \quad (9.87)$$

$$D_B(\xi, \mathbf{r}, t) = b_B(\xi, \mathbf{r}) f(\xi, \mathbf{r}, t), \quad (9.88)$$

$$B_C(\xi, \mathbf{r}, t) = \frac{\xi^2}{2} \int_0^{\xi} \frac{\kappa_C((\xi^3 - \xi'^3)^{\frac{1}{3}}, \mathbf{r}, \xi', \mathbf{r})}{(\xi^3 - \xi'^3)^{\frac{2}{3}}} f((\xi^3 - \xi'^3)^{\frac{1}{3}}, \mathbf{r}, \xi', \mathbf{r}, t) d\xi', \quad (9.89)$$

$$D_C(\xi, \mathbf{r}, t) = f(\xi, \mathbf{r}, t) \int_0^{\infty} \kappa_C(\xi, \mathbf{r}; \xi', \mathbf{r}) f(\xi', \mathbf{r}, t) d\xi' \quad (9.90)$$

In mathematical terms the population balance equation (PBE) is classified as a non-linear partial integro-differential equation (PIDE). In the PBE (12.308) the size property variable  $\xi$  ranges from 0 to  $\infty$ . In order to apply a numerical scheme for the solution of the equation a first modification is to fix a finite computational domain. The conventional approximation is to truncate the equation by substitution of the infinite integral limits by the finite limit value  $\xi_{\max}$ . The function  $f(\xi, \mathbf{r}, t)$  denotes the exact solution of the exact equation. It might be assumed that the solution of the truncated PBE is sufficiently close to the exact equation so that the two solutions are practically equal. Hence, the solutions of both forms of the PBE are denoted by  $f(\xi, \mathbf{r}, t)$ .

Analytical solutions of the PBE are only available for very simple forms of the underlying growth, breakage, and coalescence kernel functions. Therefore, numerical methods are usually employed for the solution of most PBEs [9, 27, 186, 258]. The choice of numerical methods are in general problem dependent and optimized for particular applications.

For simple mono-dispersed systems, fluxes and integral results are often considered sufficient for interpreting growth-, coalescence- and breakage data in practical engineering applications. In such situations, only a few of the first moments of the number density distribution function are required. For studies of more complex poly-disperse systems, on the other hand, the local number density distribution functions might be required in order to elucidate the physical phenomena involved. Such analyzes may thus improve our understanding and thus in turn lead to better model predictability of these systems. It is noted that dispersed flows with strong coupling between the internal coordinates and the dispersed phase variables such as the velocities, being relevant characteristics for several multiphase reactor flows, are representative for this type of problems. Moreover, after the number density distribution function is known from the solution of the PBE, any moments of the distribution function can be computed. The knowledge of the number density distribution function may also be required for fitting the underlying mechanistic kernel function parameters and for proper model validation. However, many of the commercial CFD codes still resort to integral formulations minimizing the computational time and memory requirements. It is thus convenient to divide the numerical solution methods into two

main categories. The class of the methods that solve directly for the number density distribution function (e.g., the family of spectral/spectral element/finite element methods called the methods of weighted residuals most frequently represented by the orthogonal collocation, tau, Galerkin or the least squares methods, the stochastic Monte Carlo Methods, the discrete methods, etc.) and the class of methods that solve for the moments of the number density distribution function.

The current section of the chapter on numerical methods is devoted to an outline of the most frequently used numerical methods for solving the population balance equation either for the particle number distribution function or for a few moments of the number density function. The methods considered are the *standard method of moments*, the *quadrature method of moments* (QMOM), the *direct quadrature method of moments* (DQMOM), the *sectional quadrature method of moments* (SQMOM), the *discrete fixed pivot method*, the *finite volume method*, and the family of spectral weighted residual methods with emphasis on the *least squares method*.

### 12.12.1 Methods for the Moments of the Distribution

The method of moments converts the set of PIDEs into a set of PDEs where each PDE represents a given moment of the population size density function. The moment form of the PBE, can be expressed as:

$$\begin{aligned} \frac{\partial \mu_j(\mathbf{r}, t)}{\partial t} + \nabla_{\mathbf{r}} \cdot \int_0^{\infty} (\mathbf{v}_r(\xi, \mathbf{r}, t) f(\xi, \mathbf{r}, t)) \xi^j d\xi \\ = v_{\xi}(\xi = 0, \mathbf{r}, t) f(\xi = 0, \mathbf{r}, t) 0^j + \int_0^{\infty} v_{\xi}(\xi, \mathbf{r}, t) j \xi^{j-1} f(\xi, \mathbf{r}, t) d\xi \\ + \langle B_C(\mathbf{r}, t) \rangle - \langle D_C(\mathbf{r}, t) \rangle + \langle B_B(\mathbf{r}, t) \rangle - \langle D_B(\mathbf{r}, t) \rangle \end{aligned} \quad (9.145)$$

for  $j = 1, 2, \dots$ . The  $j$ -th moment of the number density function  $\mu_j$  is defined by (9.133).

The moment forms of the birth and death terms are given by (9.141)–(9.144):

$$\begin{aligned} \langle B_{B,j}(\mathbf{r}, t) \rangle &= \int_0^{\infty} B_B(\xi, \mathbf{r}, t) \xi^j d\xi \\ &= \int_0^{\infty} \xi^j \int_0^{\infty} \nu(\xi', \mathbf{r}) b_B(\xi', \mathbf{r}) P_B(\xi, \mathbf{r}; \xi') f'^{(1)}(\xi', \mathbf{r}, t) d\xi' d\xi \end{aligned} \quad (9.141)$$

$$\langle D_{B,j}(\mathbf{r}, t) \rangle_j = \int_0^\infty D_B(\xi, \mathbf{r}, t) \xi^j d\xi = \int_0^\infty \xi^j b_B(\xi, \mathbf{r}) f^{(1)}(\xi, \mathbf{r}, t) d\xi, \quad (9.142)$$

$$\begin{aligned} \langle B_{C,j}(\mathbf{r}, t) \rangle_j &= \int_0^\infty B_C(\xi, \mathbf{r}, t) \xi^j d\xi \\ &= \int_0^\infty \frac{\xi^2 \xi^j}{2} \int_0^\infty \frac{\kappa_C((\xi^3 - \xi'^3)^{\frac{2}{3}}; \xi') \tilde{f}^{(1)}((\xi^3 - \xi'^3)^{\frac{1}{3}}, \mathbf{r}, t) f'^{(1)}(\xi', \mathbf{r}, t) d\xi' d\xi \\ &= \frac{1}{2} \int_0^\infty f'^{(1)}(\xi', \mathbf{r}, t) \int_0^\infty \kappa_C(\tilde{\xi}, \mathbf{r}; \xi') (\tilde{\xi}^3 + \xi'^3)^{j/3} \tilde{f}^{(1)}(\tilde{\xi}, \mathbf{r}, t) d\tilde{\xi} d\xi', \end{aligned} \quad (9.143)$$

$$\begin{aligned} \langle D_{C,j}(\mathbf{r}, t) \rangle_j &= \int_0^\infty D_C(\xi, \mathbf{r}, t) \xi^j d\xi \\ &= \int_0^\infty \xi^j f^{(1)}(\xi, \mathbf{r}, t) \int_0^\infty \kappa_C(\xi, \mathbf{r}; \xi') f'^{(1)}(\xi', \mathbf{r}, t) d\xi' d\xi \end{aligned} \quad (9.144)$$

A typical initial condition can be specified on the general form:

$$\mu_j(\mathbf{r}, t = 0) = \hat{\mu}_j(\mathbf{r}), \quad \text{for } j = 1, 2, \dots \quad (9.133)$$

The boundary conditions are generally problem dependent, normally on the Dirichlet, Neumann or mixed forms.

The mathematical closure model characteristics of the velocities and source terms, i.e.,  $\langle D_C \rangle$ ,  $\langle B_C \rangle$ ,  $\langle D_B \rangle$  and  $\langle B_B \rangle$ , determines whether the system of equations are closed or not.

### 12.12.1.1 The Standard Method of Moments

The standard method of moments (MOM) which was first developed by Randolph and Larson [187] and Hulburt and Katz [90]. The standard MOM solves the PBM problem by tracking the time dependence of the lower-order moments of the distribution [90, 151]. The moment methods thus involve the conversion of the PBE for the number density distribution function itself to equations in terms of the moments of the number density distribution function. The lower-order moments are often considered sufficient for estimating the physical properties of many industrial dispersions, whereas the full particle number density distribution might contain more information than is strictly required for such applications. Conversely, the lower-order moments of a dispersion particle number density distribution may be inferred from measurements and compared with the moments obtained from simulations using the MOM.

The key to the MOM is that the lower-order moments can be tracked directly without requiring further information of the number density distribution. The standard MOM accomplishes this achievement by utilizing equations formulated for the evolution of the moments in closed form. For this reason the closure relations employed can only be functions of the moments themselves. It is thus noted that it is necessary to limit the dependency of the growth velocity to a linear function of the size property as well as the expansion of the source terms to the  $k$ -th order moment ( $k \leq j$ ) in order to close the set of the  $j$ -th moment [90, 187]. It is assumed that the moment integration of the source term functions can be expanded in terms of the first  $k$  moments of the distribution. This inherent closure requirement is a severe restriction of the method.

The major success of the standard MOM is associated to the particular problems of practical importance in which the growth velocity  $v_\xi(\xi)$  is such that a closed set of moment equations is obtained. Hulburt and Katz [90] did show that the necessary and sufficient conditions for an exact closure of the growth problems is that the growth velocity can be expressed on the linear form [90]:

$$v_\xi(\xi) = a + b\xi \quad (12.309)$$

where  $a$  and  $b$  are independent of  $\xi$ .

For physical situations in which such linear growth velocity relations are valid, the growth term in (9.145) can be expressed as:

$$j \int \xi^{j-1} v_\xi(\xi) f(\xi, \mathbf{r}, t) d\xi = j \int \xi^{j-1} (a + b\xi) f(\xi, \mathbf{r}, t) d\xi = aj\mu_{j-1} + bj\mu_j \quad (9.140)$$

It is seen that the resulting MOM equations for the evolution of the moments are given in closed form. However, the required form of (12.309) is a severe restriction on the types of growth laws that can be handled by the method. In a similar manner, the PBEs for coalescence and breakage processes can only be closed analytically for particularly simple kernels functions that have little physical relevance. The closure problem thus limits the application of the exact MOM to the cases in which the kernel functions are constants or varies no more than linearly with the size property. It has been proposed to close the MOM equations for problems containing property dependent closures by assuming that the size distribution  $f$  maintains a specified mathematical form parametrized by its moments [90]. This closure approach is rather complex and problem dependent, thus it has not received widespread application. Since the moment methods generally involve the averaging of the PBE by integrating out the internal coordinate resulting in equations in terms of the moments of the number density distribution function, the MOMs are normally computationally more efficient than the methods for the number density distribution function. This MOM property is especially important for coupling the PBE with fluid flow models. In particular, the main advantage of the standard MOM is that the number of moments

required is quite small (often 4–5). However, the MOM is practically severely limited by the fact that only size-independent growth rate and the size-independent coalescence and breakage kernels can be handled accurately [142].

### 12.12.1.2 The Quadrature Method of Moments

In the quadrature method of moment (QMOM) a few moments of the number distribution function  $f$  are tracked in time directly, just as for the standard MOM, but in this approach the requirement of exact closure is replaced by an approximate closure condition that allows the method to be applied under a much broader range of conditions. This method was first proposed by McGraw [151] for modeling aerosol dynamics and has later been extended to aggregation and breakage processes in crystallization by Marchisio et al. [141, 142].

To circumvent the closure problem McGraw [151] introduced a novel approach based on (i) a presumed number density distribution function,<sup>13</sup> where the underlying distribution is assumed to be made of delta functions and (ii) an  $n$ -point Gaussian quadrature approximation.

In QMOM the number distribution function is approximated by a truncated series expansion [141, 142]:

$$f(\xi, \mathbf{r}, t) \approx \sum_{\alpha=1}^P \omega_{\alpha}(\mathbf{r}, t) \delta(\xi - \xi_{\alpha}) \quad (12.310)$$

The  $n$ -point Gaussian quadrature approximation can generally be written as:

$$\int_0^{\infty} g(\xi) f(\xi, \mathbf{r}, t) d\xi \approx \sum_{i=1}^n g(\xi_i) w_i(\mathbf{r}, t) \quad (12.311)$$

where the weights ( $w_i$ ) and points ( $\xi_i$ ) are determined through the product-difference (PD) algorithm from the lower-order moments [73]. The  $g(\xi)$  is a general function representing the PBE terms to be closed.

By approximating the distribution function by the truncated series expansion (12.310) and using the Gaussian quadrature rule (12.311), the  $j$ -th moments (9.133) can be approximated as:

$$\mu_j(\mathbf{r}, t) = \int_0^{\infty} \xi^j f(\xi, \mathbf{r}, t) d\xi \approx \sum_{\alpha=1}^P w_{\alpha}(\mathbf{r}, t) \xi_{\alpha}^j \quad (12.312)$$

---

<sup>13</sup> It is noted that the method of presumed distribution functions was originally proposed by Hulburt and Katz [90]. The QMOM may thus be considered an extension of the Hulburt and Katz [90] procedure [230].

Inserting the same quadrature approximation to the PBE source term integrals, the QMOM generally overcomes the closure problem by using an ad hoc  $n$ -point Gaussian quadrature approximation of the averaging integrals such that the transport equations of lower-order moments are written in terms of the lower-order moments themselves [151].

It remains to determine the points and weights. The essence of the quadrature based closure lies in the fact that the abscissas  $\xi_i$  and weights  $w_i$  may be completely specified in terms of the lower-order moments of the unknown distribution function. Specifically, the points and weights are independent of  $v_\xi(\xi)$  and  $f(\xi)$ . The procedure which is used to compute  $w_i$  and  $\xi_i$  from the lower-order moments is the so-called product-difference (PD) algorithm [73]. This algorithm is based on the minimization of the error committed by replacing the integrals with the  $n$ -points Gaussian quadrature approximation. Starting from the first  $N_q$  moments it is possible to determine the  $N_q/2$  weights and the  $N_q/2$  abscissas that minimize the error by deriving a tridiagonal matrix of rank  $N_q/2$  and by finding its eigenvalues and eigenvectors. Further details of the PD-algorithm are provided elsewhere [73, 151]. The first step in this procedure is the construction of a matrix  $P$ , with components  $P_{i,j}$  starting out from the lower-order moments [151].

The components in the first column of  $P$  are:

$$P_{i,1} = \delta_{i,1}, \quad i \in 1, \dots, 2N_q + 1 \quad (12.313)$$

where  $\delta_{i,1}$  is the Kronecker delta. The components in the second column of  $P$  are:

$$P_{i,2} = (-1)^{i-1} \mu_{i-1}, \quad i \in 1, \dots, 2N_q + 1 \quad (12.314)$$

Since the final weights can be corrected by multiplying by the true  $\mu_0$ , the calculations can be done assuming a normalized distribution with  $m_0 = 1$ .

The remaining components are found from the PD algorithm:

$$P_{i,j} = P_{1,j-1}P_{i+1,j-2} - P_{1,j-2}P_{i+1,j-1}, \quad (12.315)$$

in which  $i \in 1, \dots, 2N_q + 2 - j$ , and  $j \in 3, \dots, 2N_q + 1$ .

If, for example,  $N_q = 2$ , then  $P$  becomes:

$$P = \begin{bmatrix} 1 & 1 & \mu_1 & \mu_2 - \mu_1^2 & \mu_3\mu_1 - \mu_2^2 \\ 0 & -\mu_1 & -\mu_2 & -\mu_3 + \mu_2\mu_1 & 0 \\ 0 & \mu_2 & \mu_3 & 0 & 0 \\ 0 & -\mu_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (12.316)$$

In order to build a quadrature approximation of order  $N_q$ , it suffices to know the first  $2N_q$  moments.

The coefficients of the continued fraction ( $\alpha_i$ ) are generated by setting the first element equal to zero ( $\alpha_1 = 0$ ), and computing the others according to the following recursive relationship:

$$\alpha_i = \frac{P_{1,i+1}}{P_{1,i}P_{1,i-1}}, \quad i \in 2, \dots, 2N_q \quad (12.317)$$

A symmetric tridiagonal matrix is obtained from certain sums and products of  $\alpha_i$ :

$$a_i = \alpha_{2i} + \alpha_{2i-1}, \quad i \in 1, \dots, 2N_q - 1 \quad (12.318)$$

and

$$b_i = -\sqrt{\alpha_{2i+1}\alpha_{2i-1}}, \quad i \in 1, \dots, 2N_q - 2 \quad (12.319)$$

where  $a_i$  and  $b_i$  are, respectively, the diagonal and the co-diagonal of the Jacobi matrix. Once the tridiagonal matrix is determined, generation of the weights and abscissas is done by finding its eigenvalues and eigenvectors. That is, the eigenvalues are the abscissas, and the weights are computed from:

$$w_j = \mu_0 v_{j1}^2 \quad (12.320)$$

where  $v_{j1}$  is the first component of the  $j$ th eigenvector  $\mathbf{v}_j$ .

If the QMOM is applied to the moment form of the PBE (9.145) with the moment form of the source terms (9.141) to (9.144) by use of (12.310), the following closed transport equation can be established:

$$\begin{aligned} & \frac{\partial \mu_j(\mathbf{r}, t)}{\partial t} + \nabla_r \cdot (\mathbf{v}_r(\mathbf{r}, t) \mu_j(\mathbf{r}, t)) \\ &= v_\xi(\xi = 0, \mathbf{r}, t) f(\xi = 0, \mathbf{r}, t) \theta^j + j \sum_i \xi_i^{j-1} v_\xi(\xi_i) w_i(\mathbf{r}, t) \\ &+ \langle B_{C,j}(\mathbf{r}, t) \rangle - \langle D_{C,j}(\mathbf{r}, t) \rangle + \langle B_{B,j}(\mathbf{r}, t) \rangle - \langle D_{B,j}(\mathbf{r}, t) \rangle \end{aligned} \quad (12.321)$$

for  $j = 1, 2, \dots$ . As the dispersed phase is represented through the moments of the distribution, the phase average velocity of the different dispersed phases must be used to solve the transport equations for the moments [53].

The moment forms of the birth and death terms given by (9.141)–(9.144) are transformed using (12.310):

$$\begin{aligned} \langle B_{B,j}(\mathbf{r}, t) \rangle &= \int_0^\infty \xi^j \sum_i \nu(\xi'_i, \mathbf{r}) b_B(\xi'_i, \mathbf{r}) P_B(\xi, \mathbf{r}; \xi'_i) w_i d\xi \\ &= \sum_i b_B(\xi'_i, \mathbf{r}) \int_0^\infty \xi^j h_B(\xi, \mathbf{r}; \xi'_i) d\xi w_i = \sum_i b_B(\xi'_i, \mathbf{r}) \bar{h}_B^j w_i \end{aligned} \quad (12.322)$$

$$\langle D_{B,j}(\mathbf{r}, t) \rangle_j = \sum_i \xi_i^j b_B(\xi_i, \mathbf{r}) w_i, \quad (12.323)$$

$$\langle B_{C,j}(\mathbf{r}, t) \rangle_j = \frac{1}{2} \sum_i w_i \sum_j \kappa_C(\tilde{\xi}_j, \mathbf{r}; \xi'_i) (\tilde{\xi}_j^3 + \xi_i'^3)^{j/3} w_j, \quad (12.324)$$

$$\langle D_{C,j}(\mathbf{r}, t) \rangle_j = \sum_i \xi_i^j w_i \sum_j \kappa_C(\xi_i, \mathbf{r}; \xi'_j, \mathbf{r}) w_j \quad (12.325)$$

in which  $\bar{h}_B^j = \int_0^\infty \xi^j h_B(\xi, \mathbf{r}; \xi'_i) d\xi$ .

The QMOM computational sequence:

1. Specify the initial moments. The  $j$ -th moments definition approximation (12.312) might be employed to compute the required lower-order moments from a measured or presumed initial size distribution. Alternatively, the necessary moments may be computed in terms of a few abscissas and weights representing a population made up of  $N_q$  classes of particles with dimensions  $\xi_1, \xi_2, \dots, \xi_{N_q}$  and number densities  $w_1, w_2, \dots, w_{N_q}$ . Normally,  $N_q$  is a low number, typically  $N_q = 3$ .
2. Compute the weights and abscissas from the given moments by use of the product-difference (PD)-algorithm.
3. Compute the quadrature approximations in the moment equations at the current time level.
4. Compute the moments at the next time level by solving the PBE moment equations. The resulting PDEs are approximated using an explicit discretization for the operators containing quadrature approximations and an implicit approximations of the operators containing any of the lower-order moments.
5. Repeat steps 2–4 until the specified integration time horizon is reached.

The QMOM presents the main advantage of being amenable for coupling with commercial CFD codes due to computational efficiency. However, the QMOM presents three main disadvantages: (i) If QMOM is applied to multi-variate distributions, the technique loses simplicity and efficiency. (ii) The solution of the transport equations for the lower-order moments of the number density distribution function only instead of the PBE for the number density function itself, makes it difficult to treat systems where there is a strong dependency of the dispersed-phase velocity on the internal coordinates. (iii) It is argued that the accuracy of the solution of the quadrature-based moment methods can be improved by increasing the number of quadrature nodes. However, when a sufficient number of nodes is required to achieve reasonable accuracy, the moment-inversion problem frequently becomes ill-conditioned [46, 182, 262]. Dorao and Jakobsen [45, 46] did show that the QMOM is ill-conditioned and not reliable when the complexity of the problem increases. In particular, it was shown that the high order moments are not well represented by QMOM, and that the higher the order of the moment, the higher the error becomes in the predictions. Besides, the nature of the kernel functions determine the number of moments that must be used by QMOM to reach a certain accuracy. The higher the polynomial order of the kernel functions, the higher the number of moments

required for getting reliable predictions. This can reduce the applicability of QMOM in the simulation of poly-disperse flows where the kernel functions can have quite complex functional dependences. On the other hand, QMOM can still be used in some applications where the kernel functions are given as low order polynomials.

### 12.12.1.3 The Direct Quadrature Method of Moments

The major goal of The direct quadrature method of moments (DQMOM) was to derive transport equations for the weights  $w_i$  and abscissas  $\xi_i$  that can be solved directly and which yield the same moments  $\mu_k$  without resorting to the ill-conditioned PD algorithm. Another novel concept imposed is that each phase can be characterized by a weight  $w_i$  and a property vector  $\langle \xi \rangle_i$ , thus the DQMOM can be employed solving the multi-fluid model describing multi-phase systems. Moreover, since each phase has its own momentum balance in the multi-fluid model, the nodes of the DQMOM quadrature approximation are convected with their own velocities. The DQMOM was proposed by Marchisio and Fox [143] and Fan et al. [53] in order to handle poly-dispersed multi-variate systems.

In the DQMOM approach the number density distribution function appearing in the PBE can be thought of as a summation of multi-dimensional Dirac delta functions:

$$f(\mathbf{r}, \boldsymbol{\xi}, t) \approx \sum_{i=1}^{N_i} w_i(\mathbf{r}, t) \prod_{j=1}^{N_j} \delta(\xi_j - \langle \xi_j \rangle_i) \quad (12.326)$$

where  $N_i$  represents the number of delta functions,  $w_i(\mathbf{r}, t)$  denotes the weight of node  $i$ ,  $\langle \xi_j \rangle_i(\mathbf{r}, t)$  is the property  $j$  of node  $i$ . This presumed functional form is characterizing a set of  $N_i$  distinct dispersed phases, thus each phase is characterized by a weight  $w_i$  and a property vector  $\boldsymbol{\xi}_i$ .

The common element between QMOM and DQMOM is that by use of (12.326) any integral expression involving the density function  $f(\mathbf{r}, \boldsymbol{\xi}, t)$  is transformed into a summation and the closure problem is trivial. However, the QMOM and DQMOM differ by the procedure used to obtain weights  $w_i$  and abscissas  $\langle \xi \rangle_i$ . In QMOM the weights and abscissas were computed by use of the PD-algorithm which might work reasonably well for certain mono-variate problems. However, the PD algorithm is based on the theory of canonical moments of a mono-variate distribution function and cannot be applied for a multi-variate system. The DQMOM was thus based on the new idea of tracking directly the nodes and abscissas of the quadrature approximation, rather than tracking the moments of the number density distribution function as was the concept used in the QMOM. The rigorous derivation of the transport equations for the weights  $w_i$  and weighted abscissas  $\mathcal{L}_i = \xi_i w_i$  is reported elsewhere [143].

The resulting transport equations for the weights and weighted abscissas can be written as:

$$\frac{\partial w_i}{\partial t} + \nabla \cdot (\mathbf{v}_i w_i) = a_i \quad (12.327)$$

$$\frac{\partial \mathcal{L}_i}{\partial t} + \nabla \cdot (\mathbf{v}_i \mathcal{L}_i) = b_i \quad (12.328)$$

in which  $a_i$  and  $b_i$  are defined through a linear system found from the first  $2N_q$  moments of the number density function.

This linear system can be written in matrix form as:

$$A\alpha = \mathbf{d} \quad (12.329)$$

The  $2N_q \times 2N_q$  coefficient matrix  $A = [A_1 A_2]$  is defined by:

$$A_1 = \begin{bmatrix} 1 & \cdots & 1 \\ 0 & \cdots & 0 \\ -\xi_1^2 & \cdots & -\xi_{N_q}^2 \\ \vdots & & \vdots \\ 2(1 - N_q)\xi_1^{2N_q-1} & \cdots & 2(1 - N_q)\xi_{N_q}^{2N_q-1} \end{bmatrix} \quad (12.330)$$

and

$$A_2 = \begin{bmatrix} 0 & \cdots & 0 \\ 1 & \cdots & 1 \\ 2\xi_1 & \cdots & 2\xi_{N_q} \\ \vdots & & \vdots \\ (2N_q - 1)\xi_1^{2N_q-2} & \cdots & (2N_q - 1)\xi_{N_q}^{2N_q-2} \end{bmatrix} \quad (12.331)$$

The  $2N_q$  vector of unknowns  $\alpha$  is defined by:

$$\alpha = [a_1 \cdots a_{N_q} b_1 \cdots b_{N_q}] = \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix} \quad (12.332)$$

The known RHS is:

$$\mathbf{d} = [\langle S_0^{N_q} \rangle \cdots \langle S_{2N_q-1}^{N_q} \rangle]^T \quad (12.333)$$

The source term for the  $j$ -th moment  $\langle S_j^{N_q} \rangle$  is defined by:

$$\langle S_j^{N_q} \rangle(\mathbf{r}, t) = \int_0^\infty \xi^j S(\xi, \mathbf{r}, t) d\xi \quad (12.334)$$

The source terms due to coalescence and breakage are similar as for the QMOM:

$$\langle S_k^{N_q} \rangle(\mathbf{r}, t) = \langle B_{C,j}(\mathbf{r}, t) \rangle - \langle D_{C,j}(\mathbf{r}, t) \rangle + \langle B_{B,j}(\mathbf{r}, t) \rangle - \langle D_{B,j}(\mathbf{r}, t) \rangle. \quad (12.335)$$

DQMOM is thus closed in terms of the  $N_q$  weights and abscissas. If the abscissas  $\xi_i$  are unique, then  $A$  will be of full rank. For this case the source terms of the transport equations of the weights and weighted lengths can be found by inverting  $A$  in (12.329):

$$\alpha = A^{-1} \mathbf{d} \quad (12.336)$$

If at any point in the computational domain two abscissas are equal, then the matrix  $A$  is not of full rank thus the matrix is singular, and therefore, it is impossible to convert the matrix. The matrix can also be singular or nearly singular when two abscissas become close to each other with an increase in the number of nodes. For this reason, DQMOM is not a robust technique and has not received widespread applications.

#### 12.12.1.4 The Sectional Quadrature Method of Moments

The sectional quadrature method of moments (SQMOM) represents a hybrid between the sectional method and the quadrature method of moments (QMOM) and was proposed by Attarakih et al. [10] in order to solve the PBE for poly-dispersed systems. The novel idea is based on the concept of primary and secondary particles, where the former is responsible for distribution reconstruction while the latter is responsible for different particle interactions such as breakage and coalescence.

In the classical sectional methods the particle size  $\xi$  domain is discretized into finite number of sections,  $N_{pp}$ . In the particular fixed pivot method proposed by Kumar and Ramkrishna [112], the population in each section was considered to be mono-dispersed, thus each section is represented by a single node value called a fixed pivot normally placed at the middle of each section. In the SQMOM literature notation, on the other hand, these single particle node values are called the primary particles. These nodes are employed for the reconstruction of the distribution. In this way, the greater the number of sections or primary particles ( $N_{pp}$ ), the more accurate is the reconstruction of the distribution. However, as for the classical sectional methods the computational loads might be infeasible, because a large number of sections (or primary particles) is required, not only to reconstruct the shape of the distribution, but also to estimate the desired integral quantities associated with the distribution with reasonable accuracy. Following the fixed pivot concept the interaction between the primary particles in the different sections, due to breakage or/and coalescence events for example, results in new particles which generally does not correspond exactly with the predefined primary particles or pivots due to the discrete approximation of the distribution. The new particles created could thus conserve only one of their lower-order moments (if it is located at the middle of the section), the rest of the lower-order moments are predicted with low accuracy. To overcome this fundamental problem of the sectional methods, in SQMOM  $N_{sp}$  secondary particles are generated in each section with positions (abscissas) that are given by:  $\xi_j^{(i)}: j = 1, 2, \dots, N_{sp}; i = 1, 2, \dots, N_{pp}$ . Moreover, in this way the number of secondary particles (or nodes) dictates the desired number of lower-order moments to be conserved. It follows that

each primary particle has its own secondary particles identified by their positions (sizes) and total number concentration associated with them (weights:  $w_j^{(i)}$ :  $j = 1, 2, \dots, N_{sp}$ ;  $i = 1, 2, \dots, N_{pp}$ ).

This results from partitioning the population density in each section between these particles, according to the variation of the population density in this section, by assigning weights to each particle. In general the value of the weights and the location of the particles depend on the shape of the number density function, thus the positions of the secondary particles reflect the shape of this function in the  $i$ -th section. A major assumption is that the secondary particles are equivalent to the number of quadrature points in the Gaussian quadratures as used in the QMOM. Accordingly, each secondary particle may conserve or reproduce two lower-order moments and in general  $2N_{sp}$  moments in each section. Like in the conventional sectional methods, the SQMOM procedure started by dividing the particle size domain into  $N_{pp}$  contiguous sections. Each section is then seeded by the desired number of secondary particles which carry detailed information about the distribution. In total  $N_{sp} \times N_{pp}$  particles are contributing in the breakage and coalescence events. Due to the increase of the number of interacting particles by the introduction of the secondary particles, more information is gathered about the number density distribution function. It was suggested that this distribution could be reconstructed from the secondary particles by averaging the total weights of the secondary particles with respect to the section width ( $\Delta\xi_i$ ) and locating it at the mean size of the secondary particles. The averaging operations are carried out for all primary particles as follows:

$$\tilde{w}_i(\mathbf{r}, t) = \frac{1}{\Delta\xi_i} \sum_{j=1}^{N_{sp}} w_j^{(i)}(\mathbf{r}, t), \quad i = 1, 2, \dots, N_{pp} \quad (12.337)$$

$$\tilde{\xi}_i(\mathbf{r}, t) = \frac{\sum_{j=1}^{N_{sp}} w_j^{(i)}(\mathbf{r}, t) \xi_j^{(i)}}{\sum_{j=1}^{N_{sp}} w_j^{(i)}(\mathbf{r}, t)}, \quad i = 1, 2, \dots, N_{pp} \quad (12.338)$$

This procedure is considered equivalent to applying the QMOM to each section of an arbitrary width:  $[\xi_{i-1/2}, \xi_{i+1/2}]$ ;  $i = 1, 2, \dots, N_{pp}$  resulting in a set of sectional moments that can be defined as:

$$\mu_r^{(i)}(\mathbf{r}, t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} \xi^r f(\xi, \mathbf{r}, t) d\xi, \quad r = 0, 2, \dots, 2N_{sp} - 1 \quad (12.339)$$

The novel idea behind the SQMOM is to divide the population density function into sections followed by the application of the QMOM to each section. The weights and positions of the secondary particles in the  $i$ -th section (appearing in (12.337) and

(12.338)) are then related to the sectional moments of the unknown function  $f(\xi, t)$  given by (12.339).

The population density in the  $i$ -th section is represented in terms of local secondary particles weights and positions in the following form:

$$f^{(i)}(\xi, \mathbf{r}, t) = \sum_{j=1}^{N_{sp}} w_j^{(i)}(\mathbf{r}, t) \delta(\xi - \xi_j^{(i)}(\mathbf{r}, t)) \quad (12.340)$$

where  $\delta(\xi - \xi_j^{(i)}(\mathbf{r}, t))$  is the Dirac delta function placed at the secondary particle position:  $\xi_j^{(i)}$  with strength  $w_j^{(i)}$ . The positions and weights of the secondary particles are functions of time in order to follow the temporal evolution of the population density function.

To relate the sectional moments  $\mu_r^{(i)}$  to the positions and weights of the secondary particles, (12.340) is substituted into (12.339) thus the following result is obtained:

$$\mu_r^{(i)}(\mathbf{r}, t) = \sum_{j=1}^{N_{sp}} w_j^{(i)}(\mathbf{r}, t) (\xi_j^{(i)})^r, \quad r = 0, 1, \dots, 2N_{sp} - 1 \quad (12.341)$$

It is further noted that the whole population density distribution function might be reconstructed using a series expansion on the same form as (12.340), but in this case the mean weights and positions are assigned to the primary particles given by (12.337) and (12.338):

$$f(\xi, \mathbf{r}, t) = \sum_{i=1}^{N_{pp}} \tilde{w}_i(\mathbf{r}, t) \delta(\xi - \tilde{\xi}_i(\mathbf{r}, t)) \quad (12.342)$$

The final task in SQMOM is to determine a set of weights and positions of the secondary particles ( $\xi_j^{(i)}, w_j^{(i)}: j = 1, 2, \dots, N_{sp}; i = 1, 2, \dots, N_{pp}$ ) from the given a set of sectional moments ( $\mu_r^{(i)}: r = 0, 1, \dots, 2N_{sp} - 1; i = 1, 2, \dots, N_{pp}$ ).

To overcome the difficulty of computing the weights and abscissas by use of the ill-conditioned PD-algorithm for higher-order moments, the number of secondary particles was fixed to one or two in each section and the accuracy of the integration quadrature was achieved by adaptive control of the width of each section. Moreover, analytical solutions were derived for the weights and positions of secondary particles using particular types of quadratures.

If a two-unequal-weight quadrature is employed, the first four low-order sectional moments are used to find two secondary particle positions and weights. The PD algorithm was simplified resulting in the following set of algebraic equations:

$$\xi_{1,2}^{(i)}(\mathbf{r}, t) = -\frac{1}{2}\psi \mp \frac{1}{2}\sqrt{\psi^2 - 4\chi} \quad (12.343)$$

$$w_{1,2}^{(i)}(\mathbf{r}, t) = \left( \frac{\sigma}{\xi - \xi_{1,2}} \right)_{(i)}^2 \frac{\mu_0^{(i)}}{1 + [\sigma/[\xi - \xi_{1,2}]]_{(i)}^2} \quad (12.344)$$

where

$$\psi = \left( \frac{\hat{\mu}_1 \hat{\mu}_2 - \hat{\mu}_3}{\sigma^2} \right)_{(i)}, \quad \chi = \left( \frac{\hat{\mu}_1 \hat{\mu}_3 - \hat{\mu}_2^2}{\sigma^2} \right)_{(i)},$$

$$\sigma^2 = (\hat{\mu}_2 - \hat{\mu}_1^2)_{(i)}, \quad \hat{\mu}_r = \frac{\mu_r}{\mu_0}, \quad \tilde{\xi} = \hat{\mu}_1$$

If a two equal-weight quadrature is employed, only three low-order sectional moments are used to find two secondary particle positions and weights:

$$\xi_{1,2}^{(i)}(\mathbf{r}, t) = \hat{\mu}_1^{(i)} \mp \frac{1}{\sqrt{3}} \sqrt{\frac{\hat{\mu}_3^{(i)}}{\hat{\mu}_1^{(i)}} - (\hat{\mu}_1^{(i)})^2} \quad (12.345)$$

$$w_{1,2}^{(i)}(\mathbf{r}, t) = \frac{1}{2} \hat{\mu}_0^{(i)} \quad (12.346)$$

Employing SQMOM the transformed PBE can be written as:

$$\frac{\partial \mu_r^{(i)}}{\partial t} + \nabla \cdot (\mathbf{v}_r^{(i)} \mu_r^{(i)}) = \langle B_{B,r} \rangle^{(i)} - \langle D_{B,r} \rangle^{(i)} + \langle B_{C,r} \rangle^{(i)} - \langle D_{C,r} \rangle^{(i)} \quad (12.347)$$

The source terms are approximated as:

$$\langle B_{B,r} \rangle^{(i)} \approx \sum_{q=i}^{N_{pp}} \sum_{j=1}^{N_{sp}} b(\xi_j^{(q)}) \langle h_{B,r} \rangle^{(i)} (\xi_j^{(q)}) w_j^{(q)} \quad (12.348)$$

$$\langle D_{B,r} \rangle^{(i)} \approx \sum_{j=1}^{N_{sp}} \xi_j^r b(\xi_j^{(i)}) w_j^{(i)} \quad (12.349)$$

$$\langle B_{C,r} \rangle^{(i)} \approx \sum_{k=1}^{iN_{sp}} \sum_{j=k}^{iN_{sp}} \psi_{k,j,r}^{(i)} \kappa_{j,k} \omega'_j \omega'_k \quad (12.350)$$

$$\langle D_{C,r} \rangle^{(i)} \approx \sum_{k=1}^{iN_{sp}} \eta_k \sum_{n=1}^{N_{sp} N_{pp}} (\xi'_k)^r \kappa_{k,n} \omega'_k \omega'_n \quad (12.351)$$

where

$$\langle h_{B,r} \rangle^{(i)}(\xi_j^q) = \int_{\xi_{i-1/2}}^{\min(\xi_{i+1/2}, \xi_j^{(q)})} \xi^r P(\xi, \xi_j^{(q)}) d\xi \quad (12.352)$$

$$\omega' = [\omega_1^{(1)} \omega_2^{(1)} \omega_1^{(2)} \omega_2^{(2)} \cdots]_{N_{sp}=2} \quad (12.353)$$

$$\xi' = [\xi_1^{(1)} \xi_2^{(1)} \xi_1^{(2)} \xi_2^{(2)} \cdots]_{N_{sp}=2} \quad (12.354)$$

$$\eta_k = \begin{cases} 1 & \text{if } (i-1)N_{sp} + 1 \leq k \leq iN_{sp} \\ 0 & \text{otherwise} \end{cases} \quad (12.355)$$

$$\psi_{k,j,r}^{(i)} = \begin{cases} (1 - \frac{1}{2}\delta_{kj}) & \text{if } (\xi_{i-1/2})^3 \leq [(\xi'_k)^3 + (\xi'_j)^3]^{r/3} < (\xi_{i+1/2})^3 \\ 0 & \text{otherwise} \end{cases} \quad (12.356)$$

The  $r$ -th moment average velocity is defined as:

$$\mathbf{v}_r^{(i)}(\mathbf{r}, t) = \frac{\sum_{j=1}^{N_{sp}} \omega_j^{(i)}(\mathbf{r}, t) (\xi_j^{(i)})^r \mathbf{v}(\xi_j^{(i)}(\mathbf{r}, t))}{\sum_{j=1}^{N_{sp}} \omega_j^{(i)}(\mathbf{r}, t) (\xi_j^{(i)})^r} \quad (12.357)$$

for  $r = 0, 1, \dots, 2N_{sp} - 1$ ;  $i = 1, 2, \dots, N_{pp}$ .  $\delta_{k,j}$  denotes the Kronecker delta.

The function  $\eta_k$  is used to select the secondary particles disappearing due to coalescence in the  $i$ -th section, while  $\psi_{k,j,r}^{(i)}$  is a sparse coalescence matrix whose nonzero elements represent the successful coalescence events between any pairs of secondary particle with locations and weights that are given by the augmented vectors  $\xi'$  and  $w'$ .

The SQMOM has the advantage that it is not tied to the inversion of large sized moment problems as required by QMOM. Such methods generally become ill-conditioned when a large number of moments are required to increase their accuracy. The accuracy of the SQMOM increases by increasing the number of primary particles while using a fixed number of secondary particles. Since the positions and local distributions for two secondary particles are found to have an analytical solution, no large moment inversion problems are encountered.

## 12.12.2 Methods for the Number Density Distribution

### 12.12.2.1 The Sectional Methods

The group of methods collectively called *sectional methods* are sometimes referred to as *zero order methods*, *group methods*, *discrete methods* or *methods of classes*.

In all the methods in this group, the size spectrum is approximated with a set of size classes, or sections. The methods in this group can be further classified as zero-order and high-order methods. In the zero-order methods, all particles belonging to a section or class are supposed to be mono-dispersed and represented by a single size through a zero-order polynomial and thus the particle size distribution is approximated by a histogram [9, 108, 112, 247]. The zero-order methods may also be further classified into two broad types; the internally consistent and inconsistent discretization schemes with respect to the selected integral properties [112]. Higher order methods, on the other hand, approximate the size distribution within each section with a specific functional form, usually a low order polynomial. The higher order methods are more accurate, but they may suffer from stability problems or dispersion effects when dealing with very narrow initial conditions, a drawback also typical of the methods that try to solve directly the continuous version of the PBE. The zero order sectional methods can be derived through a procedure of lumping of the PBE equations in which the mean value theorem is applied either on the number density or on the aggregation/breakage frequency [186, 247]. The general framework of the lumping approach was proposed by Gelbard et al. [70], while the second lumping approach was proposed by Kumar and Ramkrishna [112]. Vanni [247] made a detailed review of the approximate discrete sectional methods for solving PBEs containing the aggregation and breakage processes. Despite their lack of rigor, these techniques are often accurate and they may constitute a valid alternative to the rigorous methods, as their implementation is simpler. The main advantage of the zero order discrete methods is that they give the size distribution directly while the main disadvantages are the high computational resources required and the classes must be defined a priori [186]. These zero order methods offer a very attractive compromise between the very efficient but of limited accuracy moments methods and the very accurate but computationally demanding higher order methods. The sectional methods are generally more robust than the other techniques.

The sectional methods can be described by the following general mathematical derivation [112, 114]. The sectional methods approximate the total number of particles in a finite number of cells. As a first step, the continuous size domain  $\Omega = [0, \xi_{\max}]$  is divided into a small number of cells:

$$\Delta_i = [\xi_{i-1/2}, \xi_{i+1/2}], \quad i = 1, \dots, N_\xi \quad (12.358)$$

with  $\xi_{1/2} = 0$ ,  $\xi_{N_\xi+1/2} = \xi_{\max}$ ,  $\Delta\xi_i = \xi_{i+1/2} - \xi_{i-1/2} \leq \Delta\xi$ .

The representative of each size, usually the center of each cell  $\xi_i = (\xi_{i-1/2} + \xi_{i+1/2})/2$ , is called *pivot* or *grid* point. Note that these will be the points where the particle distributions are considered to be represented by a point mass. They may also be seen as the quadrature points using the mid point rule, which is of second order. This type of partitioning of the spatial domain is known as a *cell centered* representation of the grid. The integration of the governing PBE (12.308) over each cell yields a *semi-discrete* system which can be written as:

$$\frac{\partial \mathbf{n}}{\partial t} + \nabla \cdot (\mathbf{v}\mathbf{n}) = \mathbf{B}_B - \mathbf{D}_B + \mathbf{B}_C - \mathbf{D}_C \quad (12.359)$$

$$\mathbf{n}(0) = \mathbf{n}^{\text{in}} \quad (12.360)$$

in which

$$n_i(t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} f(\xi, \mathbf{r}, t) d\xi, \quad (12.361)$$

$$n_i^{\text{in}}(t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} f^{\text{in}}(\xi, \mathbf{r}) d\xi, \quad (12.362)$$

$$B_{B,i}(t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} \int_{\xi}^{\xi_{\text{max}}+1/2} h_b(\xi, \zeta) b(\zeta) f(\xi, \mathbf{r}, t) d\zeta d\xi, \quad (12.363)$$

$$D_{B,i}(t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} b(\xi) f(\xi, \mathbf{r}, t) d\xi, \quad (12.364)$$

$$B_{C,i}(t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} \int_{\xi}^{\xi_{\text{max}}+1/2} f(\xi, \mathbf{r}, t) d\zeta d\xi, \quad (12.365)$$

$$D_{C,i}(t) = \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} d\xi \quad (12.366)$$

where the  $i$ -th component  $n_i(\mathbf{r}, t)$  of the vector  $\mathbf{n}$  denotes the total number density of particles in the  $i$ -th cell. The main premise of these methods is thus that in practice the user is not necessarily interested in the fundamental number density distribution function  $f$ , but rather in the number density  $n_i$ .

After discretizing in the property space coordinates, all the sectional methods take the following form:

$$\frac{\partial \hat{\mathbf{n}}}{\partial t} + \nabla \cdot (\hat{\mathbf{v}}(\hat{\mathbf{n}})\hat{\mathbf{n}}) = \hat{\mathbf{B}}_B(\hat{\mathbf{n}}) - \hat{\mathbf{D}}_B(\hat{\mathbf{n}}) + \hat{\mathbf{B}}_C(\hat{\mathbf{n}}) - \hat{\mathbf{D}}_C(\hat{\mathbf{n}}) \quad (12.367)$$

$$\mathbf{n}(0) = \mathbf{n}^{\text{in}} \quad (12.368)$$

where  $\hat{\mathbf{B}}_B$ ,  $\hat{\mathbf{D}}_B$ ,  $\hat{\mathbf{B}}_C$  and  $\hat{\mathbf{D}}_C$  are the source term closures generally expressed in terms of  $\hat{\mathbf{n}}$ .

Different variations of the sectional methods for the solution of the governing PBE (12.308) can be obtained from different choices of numerical approximations of  $B_{B,i}$ ,  $D_{B,i}$ ,  $B_{C,i}$  and  $D_{C,i}$  in terms of  $n_i(\mathbf{r}, t)$ . It is noted that the breakage problem is generally easier to solve than the coalescence problem because the breakage model is linear whereas the coalescence problem is non-linear.

Another important point regarding the derivation of sectional methods for the PBE with breakage, coalescence and growth is the particular handling of the particles of the first and last sections in the domain  $\Omega_\xi \in [\xi_{\text{min}}, \xi_{\text{max}}]$ . Considering breakage, there are several alternatives [108]; as a first alternative one may use a non-zero

particle size for the lower limit of the first section. In this case the total particle mass is not by definition constant and the mass decreases as time passes and more particles become smaller than the lower limit of the discretization domain (finite domain error). Elaborate techniques to move the discretization grid in order to minimize the finite domain error might be one option [8]. Another option is to use a first section (or more than one section) containing no-breakage particles which collects the fragments of the larger particles ensuring total mass conservation at all times. A second alternative is to use a first section with zero lower size containing no-breaking particles which collects the fragments of the larger particles ensuring total conservation of mass at all times. This approach (with the possible use of more than one collector sections) is ideally suited for the case of the so-called limited breakage, i.e., non-zero breakage frequency only for particles larger than a cut-off size which might be a acceptable approximation for fluids in fluid dispersions. The third alternative combines finite breakage frequency for all particle sizes and total mass conservation. The lower size of the first section is then zero and the breakage of particles of the first section is taken into account. As time passes the mass of the particles will then accumulate in the first section. Similar considerations must be made for the coalescence source term for the last section. Implementation of the source terms are thus generally not trivial and requires special care. The growth term may also create mass conservation problems due to finite domain errors.

The discrete fixed pivot method proposed by Kumar and Ramkrishna [112] is one of the most widely used sectional method due to its generality and robustness [52, 114]. Kumar and Warnecke [114] did analyzed the performance of several sectional methods and concluded that the fixed pivot technique predicts the first two moments of the distribution very accurately. However, the method consistently over-predicts the number density as well as its higher moments.

### 12.12.2.2 Discrete Fixed Pivot Method

Following the notation of Ramkrishna [186] the method is called the discrete fixed pivot method in which derivatives and integrals are represented by some finite difference approximations. Such discretizations were considered of coarse nature thus the population balance under consideration was essentially macroscopic in particle state space. The wide use of the finite difference schemes to solve PBEs is mainly due to the simple construction of these schemes.

In the discrete fixed pivot method, the dispersed phase size domain is divided into size intervals or sections. If the inner coordinate is the particle diameter  $\xi_i$ , the continuous size domain  $\Omega \in [\xi_{\min}, \xi_{\max}]$  is divided into a number of sections;  $\Delta_i = [\xi_{i-1/2}, \xi_{i+1/2}]$ ,  $i = 1, \dots, N_\xi$ :

$$n_i(\xi_i, \mathbf{r}, t) \equiv \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} f(\xi, \mathbf{r}, t) d\xi \quad (12.369)$$

The population balance is integrated in particle size over all the sub-intervals:

$$\begin{aligned} & \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} \frac{\partial f(\xi, \mathbf{r}, t)}{\partial t} d\xi + \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} \nabla \cdot (f(\xi, \mathbf{r}, t) \mathbf{v}(\xi, \mathbf{r}, t)) d\xi \\ &= \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} (B_B(\xi, \mathbf{r}, t) - D_B(\xi, \mathbf{r}, t) + B_C(\xi, \mathbf{r}, t) - D_C(\xi, \mathbf{r}, t)) d\xi. \end{aligned} \quad (12.370)$$

The section boundaries are independent of time and spatial position so the time derivation and the divergence operator can be moved outside the integral:

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} f(\xi, \mathbf{r}, t) d\xi + \nabla \cdot \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} (f(\xi, \mathbf{r}, t) \mathbf{v}(\xi, \mathbf{r}, t)) d\xi \\ &= \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} (B_B(\xi, \mathbf{r}, t) - D_B(\xi, \mathbf{r}, t) + B_C(\xi, \mathbf{r}, t) - D_C(\xi, \mathbf{r}, t)) d\xi. \end{aligned} \quad (12.371)$$

The result of the integration is a balance equation for the number densities  $n_i(\mathbf{r}, t)$ , in terms of the unknown number density distribution function,  $f(\xi, \mathbf{r}, t)$ , and is, hence, still unresolvable.

A sectional specific number average particle velocity may be introduced to handle the convective terms:

$$\langle \mathbf{v} \rangle_{n_i}(\xi_i, \mathbf{r}, t) = \frac{1}{n_i(\xi_i, \mathbf{r}, t)} \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} f(\xi, \mathbf{r}, t) \mathbf{v}(\xi, \mathbf{r}, t) d\xi \quad (12.372)$$

The sectional methods can thus be employed to solve the PBE in combination with the multi-fluid model having different dispersed phase velocity fields for each section.

Inserting (12.369) and (12.372) into (12.371), yields:

$$\begin{aligned} & \frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \langle \mathbf{v} \rangle_{n_i}) \\ &= \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} (B_B(\xi, \mathbf{r}, t) - D_B(\xi, \mathbf{r}, t) + B_C(\xi, \mathbf{r}, t) - D_C(\xi, \mathbf{r}, t)) d\xi. \end{aligned} \quad (12.373)$$

The integrals (with respect to  $\xi'$ ) in the source term definitions (see (9.87)–(9.90)) can be expressed in terms of a quadrature as a sum of integrals over the sub-intervals. Replacing the corresponding integrals in all the source terms with such a quadrature sum, the macroscopic equation can be formulated as:

$$B_B(\xi, \mathbf{r}, t) = \sum_{j=i}^M \int_{\xi_{j-1/2}}^{\xi_{j+1/2}} \nu(\xi') b_B(\xi') P_B(\xi|\xi') f(\xi', \mathbf{r}, t) d\xi' \quad (12.374)$$

$$D_B(\xi, \mathbf{r}, t) = b_B(\xi) f(\xi, \mathbf{r}, t) \quad (12.375)$$

$$B_C(\xi, \mathbf{r}, t) = \frac{1}{2} \sum_{j=0}^{i-1} \int_{\xi_{j+1/2}}^{\xi_{j-1/2}} \kappa_C((\xi^3 - \xi'^3)^{1/3}, \xi') f((\xi^3 - \xi'^3)^{1/3}, \mathbf{r}, t) f(\xi', \mathbf{r}, t) d\xi' \quad (12.376)$$

$$D_C(\xi, \mathbf{r}, t) = f(\xi, \mathbf{r}, t) \sum_{j=0}^M \int_{\xi_{j-1/2}}^{\xi_{j+1/2}} \kappa_C(\xi, \xi') f(\xi', \mathbf{r}, t) d\xi' \quad (12.377)$$

These source term expressions contain the continuous particle number density function,  $f(\xi, \mathbf{r}, t)$ . However, in order to close the equation the source terms must be expressed entirely in terms of the dependent variable  $n_i(\mathbf{r}, t)$ . The fixed pivot technique is based on the idea of birth modification. The pivot concentrates the particles in the interval at a single representative point. The number density distribution function  $f_1(\xi, \mathbf{r}, t)$  can be approximated as:

$$f(\xi, \mathbf{r}, t) = \sum_{i=0}^M n_i(\mathbf{r}, t) \delta(\xi - \xi_i). \quad (12.378)$$

This density function truncated series expansion gives rise to a source term approximation being equivalent to the use of the *mean value theorem* [112, 186]. The *mean value theorem* can thus be used to cast (12.374)–(12.377) into a closed form in terms of  $n_i$  and  $n_j$ . In each section the kernel function variables are replaced by a mean value.

By substitution of the density function in the source terms (12.374)–(12.377) employing the truncated series expansion (12.378) results in the following source term closure functions:

$$\int_{\xi_{i-1/2}}^{\xi_{i+1/2}} B_B(\xi, \mathbf{r}, t) d\xi = \sum_{j=i}^M n_j \nu(\xi_j) b_B(\xi_j) \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} P_B(d|x_j) d\xi \quad (12.379)$$

$$\int_{\xi_{i-1/2}}^{\xi_{i+1/2}} D_B(\xi, \mathbf{r}, t) d\xi = b_B(\xi_i) n_i \quad (12.380)$$

$$\int_{\xi_{i-1/2}}^{\xi_{i+1/2}} B_C(\xi, \mathbf{r}, t) d\xi = \frac{1}{2} \sum_{j=0}^{i-1} n_j \sum_{(\xi_j + \xi_k) \in A_i} n_k \kappa_C(\xi_k, \xi_j) \quad (12.381)$$

$$\int_{\xi_{i-1/2}}^{\xi_{i+1/2}} D_C(\xi, \mathbf{r}, t) d\xi = n_i \sum_{j=0}^M n_j \kappa_C(\xi_i, \xi_j) \quad (12.382)$$

where it is understood that the coalescence birth term for  $i = 0$  should be set to zero.

Inserting these approximate source term closures into (12.373) gives the following intermediate result:

$$\begin{aligned}
\frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \langle \mathbf{v} \rangle_{n_i}) &= \sum_{j=i}^M n_j \nu(\xi_j) b_B(\xi_j) \int_{\xi_{i-1/2}}^{\xi_{i+1/2}} P_B(\xi | \xi_j) d\xi - b_B(\xi_i) n_i \\
&+ \frac{1}{2} \sum_{j=0}^{i-1} n_j \sum_{(\xi_j + \xi_k) \in A_i} n_k \kappa_C(\xi_k, \xi_j) \\
&- n_i \sum_{j=0}^M n_j \kappa_C(\xi_i, \xi_j), \quad i = 0, 1, \dots, M \quad (12.383)
\end{aligned}$$

The closed equation (12.383) does not necessary conserve the moments of the distribution due to the macroscopic or finite grid resolution employed in the size domain, thus some sort of ad hoc numerical correction must be induced to enforce the conservative moment properties. It is noted that it is mainly at this point in the formulation of the numerical algorithms that the class method of Hounslow et al. [88], the discrete fixed pivot method of Kumar and Ramkrishna [112] and the multi-group approach used by Carrica et al. [30], among others, differs to some extent. The problem in question is related to the birth terms only. Following the discrete fixed pivot method of Kumar and Ramkrishna [112], the formation of a particle of size  $\xi'$  in size range  $(\xi_{i-1/2}, \xi_{i+1/2})$  due to breakage or coalescence is represented by assigning fractions  $\gamma_1(\xi, \xi_i)$  and  $\gamma_2(\xi, \xi_{i+1})$  to the particle populations at the pivots  $\xi_i$  and  $\xi_{i+1}$ , respectively. This is necessary because not all coalescence and breakage result in a particle which has a legitimate size that corresponds exactly to one of the predefined fixed pivots. For the non-valid daughter particle sizes, the new particle is distributed in the two fractions  $\gamma_1(\xi, \xi_i)$  and  $\gamma_2(\xi, \xi_{i+1})$  between the two neighboring size pivots. To determine these two fractions, two moment balance equations are required. The first moment balance equation generally relates to the total volume or mass of the particles, to ensure moment mass conservation. The second moment balance equation can be the number balance for the particles involved in the breakage and coalescence processes. In this case the moment constraint balances can be written as:

$$\gamma_i(\xi, \xi_i) V_p(\xi_i) + \gamma_i(\xi, \xi_{i+1}) V_p(\xi_{i+1}) = V_p(\xi) \quad (12.384)$$

$$\gamma_i(\xi, \xi_i) + \gamma_i(\xi, \xi_{i+1}) = 1 \quad (12.385)$$

The two moment constraint equations (12.384) and (12.385) selected can be expressed in the following explicit form:

$$\gamma_i(\xi, \xi_i) = \frac{V_p(\xi_{i+1}) - V_p(\xi)}{V_p(\xi_{i+1}) - V_p(\xi_i)}, \quad \gamma_i(\xi, \xi_{i+1}) = \frac{V_p(\xi_i) - V_p(\xi)}{V_p(\xi_i) - V_p(\xi_{i+1})}, \quad (12.386)$$

where  $\xi_i \leq \xi < \xi_{i+1}$ .

The fractions  $\gamma_i(\xi, \xi_i)$  and  $\gamma_i(\xi, \xi_{i+1})$  need to be embedded in the source terms as part of the discretization procedure. Following the approach of Kumar and Ramkrishna [112] and Ramkrishna [186] the source terms are modified as:

$$\begin{aligned}
\frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \langle \mathbf{v} \rangle_{n_i}) = & \sum_{j=i}^M \gamma_i(\xi, \xi_{i-1}) n_j \nu(\xi_j) b_B(\xi_j) \int_{\xi_{i-1}}^{\xi_i} P_B(\xi | \xi_j) d\xi \\
& + \sum_{j=i}^M \gamma_i(\xi, \xi_i) n_j \nu(\xi_j) b_B(\xi_j) \int_{\xi_i}^{\xi_{i+1}} P_B(\xi | \xi_j) d\xi \\
& - b_B(\xi_i) n_i \\
& + \frac{1}{2} \sum_{j=0}^{i-1} n_j \sum_{(\xi_j + \xi_k) \in \Lambda_i} n_k \gamma_i(\xi, \xi_i) \kappa_C(\xi_k, \xi_j) \\
& + \frac{1}{2} \sum_{j=0}^{i-1} n_j \sum_{(\xi_j + \xi_k) \in \Lambda_{i-1}} n_k \gamma_i(\xi, \xi_i) \kappa_C(\xi_k, \xi_j) \\
& - n_i \sum_{j=0}^M n_j \kappa_C(\xi_i, \xi_j)
\end{aligned} \tag{12.387}$$

The weighted breakage function can be expressed in a more compact form as:

$$\pi_{i,j} = \int_{x_{i-1}}^{x_i} \gamma_{i-1}(\xi, \xi_i) P_B(\xi | x_j) d\xi + \int_{x_i}^{x_{i+1}} \gamma_i(\xi, \xi_i) P_B(\xi | x_j) d\xi \tag{12.388}$$

Further manipulations of the coalescence terms lead to further reduction of the model complexity as some of the coefficients can be eliminated. Ramkrishna [186] proposed the following compact form of the discretized PBE:

$$\begin{aligned}
\frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \langle \mathbf{v} \rangle_{n_i}) = & \sum_{j=i}^M \gamma_i(\xi, \xi_{i-1}) n_j \nu(\xi_j) b_B(\xi_j) \pi_{i,j} - b_B(\xi_i) n_i \\
& + \sum_{\substack{j \geq k \\ \xi_{i-1} \leq (\xi_j + \xi_k) < \xi_i}} \left( 1 - \frac{1}{2} \delta_{jk} \right) \gamma_i(\xi_j + \xi_k, \xi_{i-1}) \kappa_C(\xi_k, \xi_j) n_j n_k \\
& + \sum_{\substack{j \geq k \\ \xi_i \leq (\xi_j + \xi_k) < \xi_{i+1}}} \left( 1 - \frac{1}{2} \delta_{jk} \right) \gamma_i(\xi_j + \xi_k, \xi_i) \kappa_C(\xi_k, \xi_j) n_j n_k \\
& - n_i \sum_{j=0}^M n_j \kappa_C(\xi_i, \xi_j)
\end{aligned} \tag{12.389}$$

Kumar and Ramkrishna [112] did define the fractions  $\gamma_i(\xi, \xi_i)$  and  $\gamma_i(\xi, \xi_{i+1})$  slightly differently thus the final discretized equations for simultaneous breakage and coalescence were written on a little different form.

Since the above treatment of sectional methods did not deal with growth processes, it is noted that the growth term can be approximated in a similar manner as for the convective terms. In the work of Carrica et al. [30], for example, the growth term was discretized using a sectional method. Considering both positive and negative mass change rates of the particle due to condensation, dissolution or evaporation, the distribution function was discretized using an upwinding approach.

The discrete pivot method provides information on the particle size distribution that is needed in the multi-fluid framework and can also be used for proper validation of the source term closures. However, in order to cover a broad range in the particle size distribution, a large number of sections are often needed making these algorithms rather time consuming. To ensure mass conservation, the smallest particles are generally not allowed to break and the largest particles are normally not involved in the coalescence process.

### 12.12.2.3 The Finite Volume Method

Filbet and Laurençot [58] developed a particular finite volume method (FVM) scheme for discretizing the Smoluchowski equation for purely coalescing systems. For the application of the FVM they established a continuous flux form of the PBE coalescence source terms. The FVM thus ensures that the poly-disperse particle fluxes between the individual sections are conserved in the system. This approach deviates from the conventional sectional methods which are applied to the standard discrete form of the PBE source terms. Kumar et al. [113] adapted the FVM scheme for solving the transformed coalescence source terms to pure breakage and simultaneous breakage and coalescence systems.

Filbet and Laurençot [58] transformed the Smoluchowski equation holding one inner coordinate and containing discrete source terms into an equivalent one-dimensional flux form expressed as:

$$\frac{\partial \xi f}{\partial t} = - \frac{\partial}{\partial \xi} \left( \int_0^\xi \int_{\xi-u}^{\xi_{\max}} u \kappa_C(u, v) f(t, u) f(t, v) dv du \right) \quad (12.390)$$

Denoting by  $g_i^m$  an approximation of the mean value of  $g(t^n, \xi) = \xi f(t^n, \xi)$  on  $\Lambda_i$ , they proposed the FVM scheme:

$$g_i^{n+1} = g_i^n - \frac{\Delta t}{\Delta \xi} \left( J_{i+1/2, C}^n - J_{i-1/2, C}^n \right) \quad (12.391)$$

where

$$J_{i+1/2, C}^n = \sum_{k=1}^i \Delta \xi_k g_k^n \left( \sum_{j=\alpha_{i,k}}^i \int_{\Lambda_j} \frac{\kappa_C(u, \xi_k)}{u} du g_j^n + \int_{\xi_{i+1/2}-\xi_k}^{\xi_{\alpha_{i,k}-1/2}} \frac{\kappa_C(u, \xi_k)}{u} du g_{\alpha_{i,k}-1}^n \right) \quad (12.392)$$

The integer  $\alpha_{i,k}$  corresponds to the index of the cell such that  $\xi_{i+1/2} - \xi_k \in \Lambda_{\alpha_{i,k}-1}$ .

Kumar et al. [113] transformed the conventional pure breakage PBE with discrete source terms into a flux form by adapting the same modeling framework as proposed by Filbet and Laurençot [58] for purely coalescing systems. The breakage equation was thus expressed as:

$$\frac{\partial \xi f}{\partial t} = - \frac{\partial}{\partial \xi} \left( \int_{\xi}^{\infty} \int_0^{\xi} u h_B(u, \epsilon) b(\epsilon) f(t, \epsilon) d\epsilon du \right) \quad (12.393)$$

The breakage flux discretization scheme was expressed as:

$$g_i^{n+1} = g_i^n - \frac{\Delta t}{\Delta \xi} \left( J_{i+1/2,B}^n - J_{i-1/2,B}^m \right) \quad (12.394)$$

where

$$J_{\xi_{i+1/2},B} = - \sum_{k=i+1}^I g_k^n \int_{\Lambda_k} \frac{b(\epsilon)}{\epsilon} d\epsilon \int_0^{\xi_{i+1/2}} u h_B(u, \xi_k) du \quad (12.395)$$

The FVM scheme for simultaneous coalescence and breakage was achieved simply by adding linearly the corresponding numerical fluxes of the two processes. Analogous to the pure breakage and coalescence cases, the scheme was defined as:

$$g_i^{n+1} = g_i^n - \frac{\Delta t}{\Delta \xi} \left( J_{i+1/2}^n - J_{i-1/2}^m \right) \quad (12.396)$$

where

$$J_{i+1/2}^n = J_{i+1/2,C}^n + J_{i+1/2,B}^n \quad (12.397)$$

The particle number density was computed from the average particle number density using the formula:

$$n_i^n = \frac{g_i^n}{\xi_i} \quad (12.398)$$

Kumar et al. [113] performed some FVM performance evaluations and concluded that the calculational time requirements of the FVM is comparable to the other sectional methods. The number density distribution is accurately computed but the zeroth moment results were poor.

#### 12.12.2.4 Weighted Residual Methods: Spectral Solution

To illustrate the application of the WRMs to the PBE, it is convenient to reduce the dimensionality of the fundamental PBE (9.118) to one dimension in physical space and one dimension in the property space without loss of generality. The current PBE problem is thus defined by:

$$v_z \frac{\partial f_{d,m}(\xi, z)}{\partial z} - \frac{\xi v_z}{3\rho_d(z)} \frac{\partial \rho_d(z)}{\partial z} \frac{\partial f_{d,m}(\xi, z)}{\partial \xi} - f_{d,m}(\xi, z) \frac{v_z}{3\rho_d(z)} \frac{\partial \rho_d(z)}{\partial z} = \mathcal{S}(\xi, z) \quad (12.399)$$

The birth and death terms due to breakage and coalescence are generally given as:

$$\begin{aligned} \mathcal{S}(\xi, z) = & -b(\xi)f_{d,m}(\xi, z) + V(\xi) \int_{\xi}^{\xi_{\max}} h(\xi, \zeta) b(\zeta) \frac{f_{d,m}(\zeta, z)}{V(\zeta)} d\zeta \\ & - f_{d,m}(\xi, z) \int_{\xi_{\min}}^{(\xi_{\max}^3 - \xi^3)^{1/3}} \kappa_C(\xi, \zeta) \frac{f_{d,m}(\zeta, z)}{\rho_d(z)V(\zeta)} d\zeta \\ & + \frac{\xi^2 V(\xi)}{2} \int_{\xi_{\min}}^{(\xi^3 - \xi_{\min}^3)^{1/3}} \frac{\kappa_C([\xi^3 - \zeta^3]^{1/3}, \zeta)}{[\xi^3 - \zeta^3]^{2/3}} \frac{f_{d,m}(\zeta, z)}{\rho_d(z)V(\zeta)} \frac{f_{d,m}([\xi^3 - \zeta^3]^{1/3}, z)}{V(\xi) - V(\zeta)} d\zeta \end{aligned} \quad (12.400)$$

To reduce the fundamental PBE (9.118) into the reduced PBE form (12.399), the following simplifying assumptions are applied: (i) steady state, (ii) cross-sectional averaging giving one independent spatial coordinate  $z$ , and (iii) prescribed velocity field of the dispersed phase, i.e.,  $\mathbf{v}_z(\xi, z) = v_z = \text{constant}$ .

The goal is thus to present the PBE (12.399) on the algebraic system form:

$$\mathbf{A}\mathbf{f} = \mathbf{F} \quad (12.401)$$

with  $\mathbf{A}$  and  $\mathbf{F}$  defined according to the least-squares, Galerkin, tau, and orthogonal collocation techniques. For this task, a generalized boundary value problem is formulated:

$$\mathcal{L}f(\xi, z) = g(\xi, z) \quad \text{in } \Omega \quad (12.402a)$$

$$\mathcal{B}f(\xi, z) = f_{\Gamma}(\xi, z) \quad \text{on } \Gamma \quad (12.402b)$$

where  $f(\xi, z)$  is the unknown solution function and  $g(\xi, z)$  is a given source function. Moreover,  $\mathcal{L}\bullet$  is a linear problem operator and  $\mathcal{B}\bullet$  is the boundary condition operator. The problem is defined in the domain  $\Omega = [z_{\min}, z_{\max}] \times [\xi_{\min}, \xi_{\max}]$  with the boundary condition applied on  $\Gamma$ , i.e. the boundary part of the domain  $\Omega$ . It should be noticed that, in a similar manner as for one-dimensional problems, a multi-dimensional problem can be derived and presented on the conventional form (12.401) using a global index numbering procedure.

The generalized problem formulation (12.402) is applied to outline the algebra of the least-squares, Galerkin, tau and orthogonal collocation methods. For the least-squares method, the algebra is outlined based on both the variational principles and the weighted residual framework. Moreover, both the weak and strong formulations of the boundary conditions in the least-squares technique are illustrated. The algebra of the Galerkin, tau and orthogonal collocation methods are outlined based on the weighted residual framework. To formulate these numerical methods elementary knowledge on abstract algebra is required. An outline of the basic mathematical tools is given in the sequel.

## Mathematical Prerequisite Tools

### Lagrange Polynomials

The interpolating polynomial in the Lagrange form is a linear combination of Lagrange basis polynomials:

$$\ell^{P_z}(z) = \sum_{j_z=0}^{P_z} f_{j_z} \ell_{j_z}^{P_z}(z) \quad (12.403)$$

in which  $\ell^{P_z}(z)$  is the interpolating polynomial of degree  $P_z$  and  $\ell_{j_z}^{P_z}(z)$  is the Lagrange basis polynomials of degree  $P_z$ . The Lagrange basis polynomials may be written in product form as:

$$\ell_{j_z}^{P_z}(z) = \prod_{i_z=0, i_z \neq j_z}^{P_z} \frac{z - z_{i_z}}{z_{j_z} - z_{i_z}} \quad (12.404)$$

### Collocation Points

In connection with the solution approximations, the term *collocation points* is normally associated with the act of assigning the error or residual at given points. If nodal basis functions are chosen for the implementation of a spectral method, the solution function is approximated at the collocation points. The location of the collocation points in the  $\Omega$ -domain is generally selected as the roots of one of the orthogonal polynomials in the Jacobi family [229].

### Polynomial Solution Function Expansion

The spectral methods are based on using a representation of the solution  $f$  throughout the domain  $\Omega$  via a polynomial solution function expansion. For a one-dimensional case, the approximate solution can be given as:

$$f(z) \approx f^{P_z}(z) = \sum_{j_z=0}^{P_z} \alpha_{j_z} \Phi_{j_z}^{P_z}(z) \quad (12.405)$$

where  $\Phi_{j_z}^{P_z}(z)$  are the basis or trial functions and  $\alpha_{j_z}$  the basis coefficients.

When the polynomial solution function expansion is substituted into the problem equation and upon the minimization of the residual function, the unknown coefficients  $\alpha_{j_z}$  are determined. The multi-dimensional basis functions can be defined as a product of one-dimensional basis functions. For example, the approximate solution of a two-dimensional problem can be expressed as:

$$f(\xi, z) \approx f^P(\xi, z) = \sum_{j_\xi=0}^{P_\xi} \sum_{j_z=0}^{P_z} \alpha_{j_\xi j_z} \Phi_{j_\xi}^{P_\xi}(\xi) \Phi_{j_z}^{P_z}(z) \quad (12.406)$$

In general, there are two types of basis functions called the modal and nodal bases. Nodal basis functions are commonly used for the implementation of spectral methods because of the resulting simplicity of the method. The nodal basis functions are generally defined in terms of a set of Lagrange basis polynomials (12.404) through a particular set of node values. With this particular type of basis function, i.e.  $\Phi_{j_z}^{P_z}(z) = \ell_{j_z}^{P_z}(z)$  and  $\Phi_{j_\xi}^{P_\xi}(\xi) = \ell_{j_\xi}^{P_\xi}(\xi)$ , the polynomial solution function expansions (12.405) and (12.406) are given as:

$$f(z) \approx f^{P_z}(z) = \sum_{j_z=0}^{P_z} f_{j_z} \ell_{j_z}^{P_z}(z) \quad (12.407)$$

and

$$f(\xi, z) \approx f^P(\xi, z) = \sum_{j_\xi=0}^{P_\xi} \sum_{j_z=0}^{P_z} f_{j_\xi j_z} \ell_{j_\xi}^{P_\xi}(\xi) \ell_{j_z}^{P_z}(z), \quad (12.408)$$

respectively. Because of the Lagrangian polynomial  $\ell_{j_z}^{P_z}(z)$  takes the value one at a particular node  $z_{j_z}$  and are zero at all other nodes the coefficients  $\alpha_{j_z}$  in (12.405) are identified as exactly the solution function values  $f_{j_z}$  at the node point  $z_{j_z}$  (12.407). Hence the problem of finding  $f^P(\xi, z)$  is transformed into the problem of finding unknown basis coefficients. Similarly, for the two-dimensional case the coefficients  $\alpha_{j_\xi j_z}$  take the function values  $f_{j_\xi j_z}$  at the node points  $\xi_{j_\xi}$  and  $z_{j_z}$  (12.408).

### Differentiation

For ordinary or partial differential problems, the discrete approximation to the derivatives is obtained by differentiation of the approximated solution presented by a polynomial trial function expansion. For a nodal basis in terms of the Lagrange basis polynomials, the differentiation of the one-dimensional solution approximation (12.407) is given as:

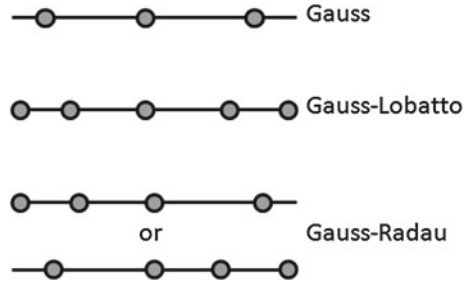

$$\frac{df^{P_z}(z)}{dz} = \sum_{j_z=0}^{P_z} f_{j_z} \frac{d\ell_{j_z}^{P_z}(z)}{dz} \quad (12.409)$$

Similarly, for the two-dimensional solution approximation (12.408) the differentiations are presented as:

$$\frac{\partial f^P(\xi, z)}{\partial z} = \sum_{j_\xi=0}^{P_\xi} \sum_{j_z=0}^{P_z} f_{j_\xi j_z} \ell_{j_\xi}^{P_\xi}(\xi) \frac{d\ell_{j_z}^{P_z}(z)}{dz} \quad (12.410)$$

$$\frac{\partial f^P(\xi, z)}{\partial \xi} = \sum_{j_\xi=0}^{P_\xi} \sum_{j_z=0}^{P_z} f_{j_\xi j_z} \frac{d\ell_{j_\xi}^{P_\xi}(\xi)}{d\xi} \ell_{j_z}^{P_z}(z). \quad (12.411)$$

**Fig. 12.4** Gauss (interior nodes only), Gauss-Lobatto (boundary points + interior points) and Gauss-Radau (one boundary + interior points)

### *Gaussian Quadrature and Orthogonal Polynomials*

An important application of orthogonal polynomials is to high order quadrature rules. Foremost among these are (i) the Gaussian quadrature rule and its close relatives, (ii) the Gauss-Radau and (iii) Gauss-Lobatto rules (see Fig. 12.4). In the sequel, the procedure for computing weights and abscissas for Gaussian quadrature rules are outlined for the Golub–Welsch algorithm using polynomials in the Jacobi family [69, 71, 72, 182, 229].

#### (i) Gauss quadrature

Given the integral:

$$\int_a^b g(\xi) d\xi \quad (12.412)$$

and it's numerical approximation. In the high order Gaussian quadrature formulas, the abscissas are exactly the roots of the orthogonal polynomial as applied for the weighting function  $W(\xi)$  and within the same interval limits  $[a, b]$ . However, high order is not the same as high accuracy. High order translates to high accuracy only when the integrand is very smooth, in the sense of being well-approximated by a polynomial. Let the integrand  $g(\xi)$  be factorable into two functions  $f(\xi)$  and  $W(\xi)$ , where  $f$  is well approximated by a polynomial, with the known non-negative weight function  $W$ . Then there exist weights  $w_j$  such that:

$$\int_a^b g(\xi) d\xi = \int_a^b W(\xi)f(\xi) d\xi \approx \sum_{j=0}^P w_j f(\xi_j) \quad (12.413)$$

It is possible to define a sequence of polynomials  $p_0, p_1, \dots$  such that:

$$\begin{aligned} \int_a^b W(\xi)p_m(\xi)p_n(\xi) d\xi &= 1 & \text{when } m &= n & \text{(orthonormal)} \\ &= 0 & \text{when } m &\neq n & \text{(orthogonal)} \end{aligned} \quad (12.414)$$

Many sets of such polynomials are known, their name and form depend on the choice of the weight function  $W(\xi)$ . In particular, the polynomials in the Jacobi family corresponds to the weight function:

$$W(\xi) = (1 - \xi)^\alpha (1 + \xi)^\beta \quad \text{for} \quad \alpha, \beta > -1 \quad \text{and} \quad -1 < \xi < 1 \quad (12.415)$$

Any set of orthogonal polynomials,  $\{p_j(\xi)\}_{j=0}^P$ , satisfies a three term recurrence relationship:

$$\begin{aligned} p_{-1}(\xi) &= 0 \\ p_0(\xi) &= 1 \\ p_{j+1}(\xi) &= (a_j \xi + b_j) p_j(\xi) - c_j p_{j-1}(\xi) \quad \text{for } j = 0, 1, 2, \dots \end{aligned} \quad (12.416)$$

The recurrence coefficients  $a_j$ ,  $b_j$  and  $c_j$  for the family of Jacobi polynomials are given by:

$$a_j = \frac{(2j + \alpha + \beta + 1)(2j + \alpha + \beta + 2)}{2(j + 1)(j + \alpha + \beta + 1)} \quad (12.417)$$

$$b_j = \frac{(2j + \alpha + \beta + 1)(\alpha^2 - \beta^2)}{2(j + 1)(j + \alpha + \beta + 1)(2j + \alpha + \beta)} \quad (12.418)$$

$$c_j = \frac{(j + \alpha)(j + \beta)(2j + \alpha + \beta + 2)}{(j + 1)(j + \alpha + \beta + 1)(2j + \alpha + \beta)} \quad (12.419)$$

with  $a_j > 0$ , and  $c_j > 0$ . The recurrence coefficient formula given by Eqs. (12.417)–(12.419) are not valid for  $\alpha = \beta$ . When  $\alpha = \beta$  the Jacobi polynomials are called Gegenbauer polynomials, or ultraspherical polynomials. Well known are the Chebyshev polynomial and the Legendre polynomial for which  $\alpha = \beta$  are  $-1/2$  and  $0$ , respectively. Thus, both the Chebyshev and Legendre polynomials are special cases of the Jacobi polynomials.

For the Gauss–Legendre polynomial, the weight function is given as:

$$W(\xi) = 1 \quad -1 < \xi < 1 \quad (12.420)$$

with the three term recurrence relationship:

$$\begin{aligned} p_{-1}(\xi) &= 0 \\ p_0(\xi) &= 1 \\ (j + 1)p_{j+1} &= (2j + 1)\xi p_j - j p_{j-1} \end{aligned} \quad (12.421)$$

Thus the recurrence coefficients of Eq. (12.416) for the Gauss–Legendre polynomial are given as:

$$a_j = \frac{2j + 1}{j + 1} \quad b_j = 0 \quad c_j = \frac{j}{j + 1} \quad (12.422)$$

It is generally faster to use the Golub–Welsch algorithm to find the abscissas rather than using a root-finding method like the Newton’s method on  $p_P(\xi)$ . Adopting the Golub–Welsch algorithm, the recurrence relationship (12.416) is presented on the matrix form as:

$$\xi \begin{bmatrix} p_0 \\ p_1 \\ \vdots \\ p_{P-2} \\ p_{P-1} \end{bmatrix} = \begin{bmatrix} -\frac{b_1}{a_1} & \frac{1}{a_1} & & & \\ \frac{c_2}{a_2} & -\frac{b_2}{a_2} & \frac{1}{a_2} & & \\ & \ddots & \ddots & \ddots & \\ & & \frac{c_{P-1}}{a_{P-1}} & -\frac{b_{P-1}}{a_{P-1}} & \frac{1}{a_{P-1}} \\ & & & \frac{c_P}{a_P} & -\frac{b_P}{a_P} \end{bmatrix} \begin{bmatrix} p_0 \\ p_1 \\ \vdots \\ p_{P-2} \\ p_{P-1} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ \frac{p_P}{a_P} \end{bmatrix} \quad (12.423)$$

or, equivalently in matrix notation:

$$\xi \mathbf{p}(\xi) = T \mathbf{p}(\xi) + \frac{p_P(\xi)}{a_P} \mathbf{e}_P \quad (12.424)$$

where  $T$  is the tridiagonal matrix and  $\mathbf{e}_P = [0, 0, \dots, 0, 1]^T$ . If the polynomials are evaluated in a root of the polynomial  $p_P(\xi)$ , i.e.  $p_P(\xi_j) = 0$ , then Eq. (12.424) simplifies to:

$$\xi \mathbf{p}(\xi) = T \mathbf{p}(\xi) \quad (12.425)$$

Moreover,  $p_P(\lambda_j) = 0$  if and only if  $\lambda_j \mathbf{p}(\lambda_j) = T \mathbf{p}(\lambda_j)$  where  $\lambda_j$  is an eigenvalue of the tridiagonal matrix  $T$ . Hence, the roots of  $p_P(\xi)$ , which are the abscissas of the quadrature rule, are also the eigenvalues of the matrix  $T$ , i.e.  $\xi_j = \lambda_j$ . The matrix  $T$  is symmetric if the polynomials are orthonormal.

Otherwise, for numerical efficiency, we may perform a diagonal similarity transformation  $D$  which yields a symmetric tridiagonal matrix  $J$ :

$$D T D^{-1} = J = \begin{bmatrix} -\frac{b_1}{a_1} & \left(\frac{c_2}{a_1 a_2}\right)^{1/2} & & & \\ \left(\frac{c_2}{a_1 a_2}\right)^{1/2} & -\frac{b_2}{a_2} & \left(\frac{c_3}{a_2 a_3}\right)^{1/2} & & \\ & \left(\frac{c_3}{a_2 a_3}\right)^{1/2} & -\frac{b_3}{a_3} & \left(\frac{c_4}{a_3 a_4}\right)^{1/2} & \\ & & \ddots & \ddots & \ddots \\ & & & \left(\frac{c_P}{a_{P-1} a_P}\right)^{1/2} & -\frac{b_P}{a_P} \end{bmatrix} \quad (12.426)$$

$$= \begin{bmatrix} \tau_1 & \gamma_1 & & & \\ \gamma_1 & \tau_2 & \gamma_2 & & \\ & \gamma_2 & \tau_3 & \gamma_3 & \\ & & \ddots & \ddots & \ddots \\ & & & \gamma_{P-1} & \tau_P \end{bmatrix}$$

where

$$\tau_i = -\frac{b_i}{a_i} \quad \text{and} \quad \gamma_i = \left( \frac{c_{i+1}}{a_i a_{i+1}} \right)^{1/2} \quad (12.427)$$

The similarity transformation preserves the eigenvalues, thus matrix  $J$  has the same eigenvalues as  $T$ . If  $\mathbf{v}_j$  is the eigenvector corresponding to the eigenvalue  $\lambda_j$  normalized so that  $\mathbf{v} \cdot \mathbf{v} = 1$ , then:

$$w_j = \mu_0 v_{j,1}^2 \quad (12.428)$$

where

$$\mu_0 = \int_a^b W(\xi) d\xi = \int_{-1}^1 W(\hat{\xi}) d\hat{\xi} \quad (12.429)$$

and where  $v_{j,1}$  is the first component of  $\mathbf{v}$ . Hence, both the abscissas and the weight coefficients of the quadrature rule (12.413) can be calculated from the eigensystem of the matrix  $J$ .

(ii) Gauss–Radau quadrature

Generally not applied to PBEs and thus not presented in this context.

(iii) Gauss–Lobatto quadrature

In many applications it is desirable to generate Gauss-type quadrature rules with preassigned abscissas, e.g. for solving boundary value problems. For the Gauss–Lobatto–Jacobi quadratures, we prescribe  $\xi_0 = -1$  and  $\xi_P = 1$ . A matrix  $\tilde{J}$  must thus be constructed such that  $\lambda_{\min}(\tilde{J}) = -1$  and  $\lambda_{\max}(\tilde{J}) = 1$ . This implies that a polynomial  $p_{P+1}(\xi)$  must be determined so that:

$$p_{P+1}(\xi = -1) = p_{P+1}(\xi = 1) = 0 \quad (12.430)$$

In accordance with the notation in (12.426), the recurrence relationship (12.416) is rewritten as:

$$\gamma_{P+1} p_{P+1}(\xi) = (\xi - \tau_{P+1}) p_P(\xi) - \gamma_P p_{P-1}(\xi) \quad (12.431)$$

Applying the constraints (12.430) on (12.431) implies:

$$\begin{aligned} \tau_{P+1} p_P(\xi = -1) + \gamma_P p_{P-1}(\xi = -1) &= (-1) p_P(\xi = -1) \\ \tau_{P+1} p_P(\xi = +1) + \gamma_P p_{P-1}(\xi = +1) &= (+1) p_P(\xi = +1) \end{aligned} \quad (12.432)$$

We may identify (12.431) with the matrix equation (12.424):

$$\xi \mathbf{p}(\xi) = J \mathbf{p}(\xi) + \gamma_P p_P(\xi) \mathbf{e}_P \quad (12.433)$$

Thus, if

$$[J - (-1)I] \boldsymbol{\eta} = \mathbf{e}_P \quad (12.434)$$

$$[J - (+1)I]\mu = \mathbf{e}_P \quad (12.435)$$

then

$$\eta_j = -\frac{1}{\gamma_P} \frac{p_{j-1}(\xi = -1)}{p_P(\xi = -1)} \quad (12.436)$$

$$\mu_j = -\frac{1}{\gamma_P} \frac{p_{j-1}(\xi = +1)}{p_P(\xi = +1)} \quad (12.437)$$

The constraints (12.430) are thus equivalent to the following system of equations:

$$\begin{aligned} \tau_{P+1} - \eta_P \gamma_P^2 &= -1 \\ \tau_{P+1} - \mu_P \gamma_P^2 &= 1 \end{aligned} \quad (12.438)$$

Finally, the matrix  $\tilde{J}$  is constructed:

$$\tilde{J} = \begin{bmatrix} J & \gamma_P \mathbf{e}_P \\ \gamma_P \mathbf{e}_P^T & \tau_{P+1} \end{bmatrix} \quad (12.439)$$

The quadrature points and weights are obtained based on the eigensystem of the matrix  $\tilde{J}$ , as described for the Gauss quadratures.

### Geometry Mapping

Geometry mapping is of particular relevance for implementing a general spectral solver [51]. Whereas the physical problem is defined in the  $\Omega$  domain, the Jacobi roots and quadrature weights are conveniently computed in a reference domain. The mapping technique enables all the operations to either be performed in the reference domain or in the physical domain. The reference domain for computing Jacobi roots and quadrature weights is  $\Omega_{\text{ref}} = [-1, 1]^d$ .

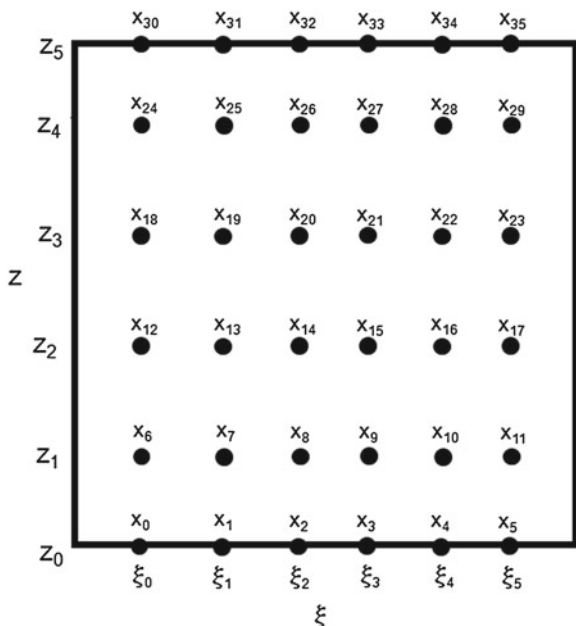

### Global Index Procedure

The system of algebraic equations of a multi-dimensional problem can be assembled on the conventional form (12.401), which simplifies the numerical manipulation. In this approach, the numerical solution approximation is expressed by a global index numbering procedure.

Given a two-dimensional problem with coordinates  $\xi$  and  $z$ , the global index  $J$  is defined in term of the local indices  $j_z$  and  $j_\xi$ . By following the global grid labeling as sketched in Fig. 12.5, the global index is given as

$$J = j_\xi + j_z(P_\xi + 1) \quad (12.440)$$

where  $J \in [0, \mathcal{P} = (P_\xi + 1)(P_z + 1) - 1]$ ,  $0 \leq j_\xi \leq P_\xi$  and  $0 \leq j_z \leq P_z$ .

**Fig. 12.5** Global grid labeling procedure considering a two-dimensional case. A GL-GLL- grid where  $x_I$  is the global numbering, and  $\xi_i$  and  $z_i$  denote the two local one-dimensional numberings

Using the global index procedure, the solution approximation (12.408) can be rewritten in the following way:

$$\begin{aligned}
 f(\xi, z) &\approx f^{\mathcal{P}}(\xi, z) = \sum_{j_{\xi}=0}^{P_{\xi}} \sum_{j_z=0}^{P_z} f_{j_{\xi}j_z}^{\mathcal{P}} \ell_{j_{\xi}}^{P_{\xi}}(\xi) \ell_{j_z}^{P_z}(z) \\
 &= \sum_{j_{\xi}=0}^{P_{\xi}} \sum_{j_z=0}^{P_z} f_{j_{\xi}j_z}^{\mathcal{P}} \ell_{j_zj_{\xi}}^{\mathcal{P}}(\xi, z) = \sum_{J=0}^{\mathcal{P}} f_J^{\mathcal{P}} \ell_J^{\mathcal{P}}(\xi, z)
 \end{aligned} \tag{12.441}$$

in which

$$\ell_{j_{\xi}}^{P_{\xi}}(\xi) \ell_{j_z}^{P_z}(z) = \ell_{j_zj_{\xi}}^{\mathcal{P}}(\xi, z) = \ell_J^{\mathcal{P}}(\xi, z) \tag{12.442}$$

and

$$f_{j_{\xi}j_z}^{\mathcal{P}} = f_J^{\mathcal{P}} \tag{12.443}$$

In the global numbering procedure sketched in Fig. 12.5 the  $\xi$  points in the grid can be given in vector form as:

$$\xi = \begin{bmatrix} \xi_0 \\ \xi_1 \\ \vdots \\ \xi_{P_\xi} \end{bmatrix}_{\text{local}} \quad \text{and} \quad \xi = \begin{bmatrix} \xi_0 \\ \vdots \\ \xi_{P_\xi} \\ \xi_0 \\ \vdots \\ \xi_{P_\xi} \\ \xi_0 \\ \vdots \\ \xi_{P_\xi} \end{bmatrix} = \begin{bmatrix} \xi_0 \\ \vdots \\ \xi_{P_\xi} \\ \xi_{P_\xi+1} \\ \vdots \\ \xi_{2P_\xi+1} \\ \vdots \\ \xi_{P-P_\xi} \\ \vdots \\ \xi_{\mathcal{P}} \end{bmatrix}_{\text{global}} \quad (12.444)$$

The corresponding  $z$ -points in the grid is given as:

$$z = \begin{bmatrix} z_0 \\ z_1 \\ \vdots \\ z_{P_z} \end{bmatrix}_{\text{local}} \quad \text{and} \quad z = \begin{bmatrix} z_0 \\ \vdots \\ z_0 \\ z_1 \\ \vdots \\ z_1 \\ z_2 \\ \vdots \\ z_2 \\ \vdots \\ z_{P_z} \\ \vdots \\ z_{P_z} \end{bmatrix} = \begin{bmatrix} z_0 \\ \vdots \\ z_{P_\xi} \\ z_{P_\xi+1} \\ \vdots \\ z_{2P_\xi+1} \\ z_{2(P_\xi+1)} \\ \vdots \\ z_{3P_\xi+1} \\ \vdots \\ z_{\mathcal{P}-P_\xi} \\ \vdots \\ z_{\mathcal{P}} \end{bmatrix}_{\text{global}} \quad (12.445)$$

Hence, it follows that the solution vector is expressed as:

$$f^{\mathcal{P}} = \begin{bmatrix} f_{j_z=0, j_\xi=0} \\ f_{j_z=0, j_\xi=1} \\ \vdots \\ f_{j_z=0, j_\xi=P_\xi} \\ f_{j_z=1, j_\xi=0} \\ \vdots \\ f_{j_z=1, j_\xi=P_\xi} \\ \vdots \\ f_{j_z=P_z, j_\xi=0} \\ \vdots \\ f_{j_z=P_z, j_\xi=P_\xi} \end{bmatrix}_{\text{local}} = \begin{bmatrix} f_{J=0} \\ f_{J=1} \\ \vdots \\ f_{J=P_\xi} \\ f_{J=P_\xi+1} \\ \vdots \\ f_{J=2P_\xi} \\ \vdots \\ f_{J=\mathcal{P}-P_\xi} \\ \vdots \\ f_{J=\mathcal{P}} \end{bmatrix}_{\text{global}} \quad (12.446)$$

In integral approximations the two-dimensional quadrature weights are defined as:

$$W_{I_Q} = W_{i_{q\xi}}^\xi W_{i_{qz}}^z \quad (12.447)$$

where  $W_{i_{q\xi}}^\xi$  and  $W_{i_{qz}}^z$  are the local one-dimensional quadrature weights for the coordinates  $\xi$  and  $z$ , respectively. Further, the global quadrature points are denoted by  $I_Q$ .

### Least-Squares Method

There are two conceptually different options available for the formulation of the spectral solution methods: (i) the variational method and (ii) the weighted residual method. Moreover, there are two ways to implement the boundary conditions: (i) the weak formulation and (ii) the strong formulation [98, 184]. In the weak form, it is required that the residual of both the model equation and the boundary conditions are satisfied at the boundary domain. On the other hand, in the strong form, some linear combinations of the polynomials to satisfy the boundary conditions are performed, or alternatively, the boundary conditions are enforced as additional constraints. In the latter case of the strong form implementation, the algebraic equation system of the model equations is relaxed by the number of boundary condition constraints to give equal number of unknowns as there are algebraic equations. However, the rigorous way to derive the least-squares method is by following the variational principles. In the weighted residual framework, an analogy to the variational principle is adopted for the implementation of the boundary conditions. Details on the least-squares method are given by, e.g., [13–17, 98, 174–179, 183–185]. Outlines of the least-squares

theory provided by the chemical engineering community may be found in, e.g., [43, 217, 218, 225, 265].

The two formulations discussed are outlined in the sequel based on the generalized problem formulation (12.402).

*The Least-Squares Method Based on Variational Principles (Weak Formulation)*

The basic idea of the least-squares method is to minimize the integral of the square of the residual over the computational domain. In order to find the approximation in the sense of the least squares error, the following norm-equivalent least-squares function is defined for the generalized problem formulation (12.402):

$$\mathcal{J}(f; g, f_\Gamma) = \frac{1}{2} \|\mathcal{L}f(\xi, z) - g(\xi, z)\|_{Y(\Omega)}^2 + \frac{1}{2} \|\mathcal{B}f(\xi, z) - f_\Gamma(\xi, z)\|_{\hat{Y}(\Gamma)}^2 \quad (12.448)$$

with the norms defined as:

$$\|\bullet\|_{Y(\Omega)}^2 = \langle \bullet, \bullet \rangle_{Y(\Omega)} = \int_{\Omega} \bullet \bullet \, d\Omega \quad (12.449)$$

$$\|\bullet\|_{\hat{Y}(\Gamma)}^2 = \langle \bullet, \bullet \rangle_{\hat{Y}(\Gamma)} = \int_{\Gamma} \bullet \bullet \, d\Gamma \quad (12.450)$$

where the spaces  $Y(\Omega)$  and  $\hat{Y}(\Gamma)$  provide the norms for measuring the residuals.

Based on variational analysis, the minimization statement is equivalent to:

Find  $f(\xi, z) \in X(\Omega)$  such that

$$\lim_{\epsilon \rightarrow 0} \frac{d\mathcal{J}(f(\xi, z) + \epsilon v(\xi, z); g(\xi, z), f_\Gamma(\xi, z))}{d\epsilon} = 0 \quad \forall v(\xi, z) \in X(\Omega) \quad (12.451)$$

where the  $X(\Omega)$  is the solution space. The space  $X(\Omega)$  serves as a trial space for the candidate minimizers of the functional. Thus, the solution procedure consists in seeking the solution  $f$  in the function space  $X(\Omega)$ . The space  $X(\Omega)$  is determined by the problem and the mathematical formulation used. The interpretation of the minimization statement (12.451) is the search for a minimum limit of the least-squares functional  $\mathcal{J}(f + \epsilon v; g, f_\Gamma)$  that is expressed as a function of a perturbed solution function  $f(\xi, z)$  defined by a generalized perturbation function  $v(\xi, z)$  multiplied by a small amplitude variable  $\epsilon$ . Thus, in terms of the functional (12.448) the variational minimization statement (12.451) is presented by:

$$\lim_{\epsilon \rightarrow 0} \frac{d}{d\epsilon} \left[ \frac{1}{2} \|\mathcal{L}[f(\xi, z) + \epsilon v(\xi, z)] - g(\xi, z)\|_{Y(\Omega)}^2 + \frac{1}{2} \|\mathcal{B}[f(\xi, z) + \epsilon v(\xi, z)] - f_\Gamma(\xi, z)\|_{\hat{Y}(\Gamma)}^2 \right] = 0 \quad (12.452)$$

Provided that  $\mathcal{L}\bullet$  and  $\mathcal{B}\bullet$  are linear operators, the variational minimization statement (12.452) can be rewritten as

$$\lim_{\epsilon \rightarrow 0} \frac{d}{d\epsilon} \left[ \frac{1}{2} \|\mathcal{L}f(\xi, z) + \epsilon \mathcal{L}v(\xi, z) - g(\xi, z)\|_{Y(\Omega)}^2 + \frac{1}{2} \|\mathcal{B}f(\xi, z) + \epsilon \mathcal{B}v(\xi, z) - f_\Gamma(\xi, z)\|_{\hat{Y}(\Gamma)}^2 \right] = 0 \quad (12.453)$$

Using the definitions of the norms (12.449) and (12.450) and further noting that the order of the differentiation and integration operations may be interchanged as the integral limit  $\Omega$  is not a function of  $\epsilon$ , the latter expression can be given as:

$$\begin{aligned} & \frac{1}{2} \lim_{\epsilon \rightarrow 0} \frac{d}{d\epsilon} \int_{\Omega} \left( \mathcal{L}f(\xi, z) + \epsilon \mathcal{L}v(\xi, z) - g(\xi, z) \right)^2 d\Omega \\ & + \frac{1}{2} \lim_{\epsilon \rightarrow 0} \frac{d}{d\epsilon} \int_{\Gamma} \left( \mathcal{B}f(\xi, z) + \epsilon \mathcal{B}v(\xi, z) - f_\Gamma(\xi, z) \right)^2 d\Gamma \\ & = \int_{\Omega} \left( [\mathcal{L}f(\xi, z) - g(\xi, z)] \mathcal{L}v(\xi, z) \right) d\Omega \\ & + \int_{\Gamma} \left( [\mathcal{B}f(\xi, z) - f_\Gamma(\xi, z)] \mathcal{B}v(\xi, z) \right) d\Gamma \\ & = 0 \end{aligned} \quad (12.454)$$

In the bracket form of the norms (12.449) and (12.450), the minimization statement (12.454) is given as

$$\begin{aligned} & \left\langle \mathcal{L}f(\xi, z), \mathcal{L}v(\xi, z) \right\rangle_{Y(\Omega)} + \left\langle \mathcal{B}f(\xi, z), \mathcal{B}v(\xi, z) \right\rangle_{\hat{Y}(\Gamma)} \\ & = \left\langle g(\xi, z), \mathcal{L}v(\xi, z) \right\rangle_{Y(\Omega)} + \left\langle f_\Gamma(\xi, z), \mathcal{B}v(\xi, z) \right\rangle_{\hat{Y}(\Gamma)} \end{aligned} \quad (12.455)$$

The latter statement is normally rearranged in the matrix form:

$$\mathcal{A}(f(\xi, z), v(\xi, z)) = \mathcal{F}(g(\xi, z), f_\Gamma(\xi, z), v(\xi, z)) \quad (12.456)$$

with

$$\mathcal{A}(f(\xi, z), v(\xi, z)) = \left\langle \mathcal{L}f(\xi, z), \mathcal{L}v(\xi, z) \right\rangle_{Y(\Omega)} + \left\langle \mathcal{B}f(\xi, z), \mathcal{B}v(\xi, z) \right\rangle_{\hat{Y}(\Gamma)} \quad (12.457)$$

$$\mathcal{F}(g(\xi, z), f_\Gamma(\xi, z), v(\xi, z)) = \left\langle g(\xi, z), \mathcal{L}v(\xi, z) \right\rangle_{Y(\Omega)} + \left\langle f_\Gamma(\xi, z), \mathcal{B}v(\xi, z) \right\rangle_{\hat{Y}(\Gamma)} \quad (12.458)$$

For spectral methods, the solution  $f(\xi, z)$  throughout the domain  $\Omega$  is represented via a polynomial trial function expansion. The discretization procedure thus consists in finding the approximate solution in a reduced subspace, i.e.  $f^{\mathcal{P}}(\xi, z) \in X^{\mathcal{P}}(\Omega) \subset X(\Omega)$ . Up to this point, in the variational analysis, no explicit definition of  $X(\Omega)$ , the space used for expressing  $f(\xi, z)$ , have been made. One possible representation of  $X^{\mathcal{P}}(\Omega)$  can be obtained in terms of the two-dimensional Lagrange basis functions (12.442), i.e.  $X^{\mathcal{P}}(\Omega) = \text{span}\{\ell_0^{\mathcal{P}}(\xi, z), \dots, \ell_{\mathcal{P}}^{\mathcal{P}}(\xi, z)\}$ . Thus, in this particular subspace, any function  $f^{\mathcal{P}}(\xi, z) \in X^{\mathcal{P}}(\Omega)$  can be expressed by Eq. (12.441).

Inserting the polynomial trial function expansion in terms of Lagrangian polynomials,  $\ell_j$ , i.e. approximation (12.441), into Eq. (12.456), and choosing systematically  $v(\xi, z) = \ell_0^{\mathcal{P}}(\xi, z), \dots, \ell_{\mathcal{P}}^{\mathcal{P}}(\xi, z)$ , a solvable system of algebraic equations is achieved. The first algebraic equation is achieved by choosing the first element  $v(\xi, z) = \ell_0^{\mathcal{P}}(\xi, z)$  in the subspace  $X^{\mathcal{P}}(\Omega) = \text{span}\{\ell_0^{\mathcal{P}}(\xi, z), \dots, \ell_{\mathcal{P}}^{\mathcal{P}}(\xi, z)\}$ :

$$\mathcal{A} \left( \sum_{J=0}^{\mathcal{P}} f_J \ell_J^{\mathcal{P}}(\xi, z), v(\xi, z) = \ell_0^{\mathcal{P}}(\xi, z) \right) = \mathcal{F} \left( g(\xi, z), f_{\Gamma}(\xi, z), v(\xi, z) = \ell_0^{\mathcal{P}}(\xi, z) \right) \quad (12.459)$$

which is equivalent to

$$\begin{aligned} & \left\langle \mathcal{L} \left[ \sum_{J=0}^{\mathcal{P}} f_J \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{L} [\ell_0^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} + \left\langle \mathcal{B} \left[ \sum_{J=0}^{\mathcal{P}} f_J \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{B} [\ell_0^{\mathcal{P}}(\xi, z)] \right\rangle_{\hat{Y}(\Gamma)} \\ &= \left\langle g(\xi, z), \mathcal{L} [\ell_0^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} + \left\langle f_{\Gamma}(\xi, z), \mathcal{B} [\ell_0^{\mathcal{P}}(\xi, z)] \right\rangle_{\hat{Y}(\Gamma)} \end{aligned} \quad (12.460)$$

Moreover, we continue to chose elements  $v(\xi, z) = \ell_I^{\mathcal{P}}$  in the space  $v(\xi, z) = \{\ell_0^{\mathcal{P}}(\xi, z), \dots, \ell_{\mathcal{P}}^{\mathcal{P}}(\xi, z)\}$ , and further utilized the linearity of the operators  $\mathcal{L}_{\bullet}$  and  $\mathcal{B}_{\bullet}$ . Thus, the latter equation can be rewritten and presented in the general form:

$$\begin{aligned} & \sum_{J=0}^{\mathcal{P}} f_J \left\langle \mathcal{L} [\ell_J^{\mathcal{P}}(\xi, z)], \mathcal{L} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} + \sum_{J=0}^{\mathcal{P}} f_J \left\langle \mathcal{B} [\ell_J^{\mathcal{P}}(\xi, z)], \mathcal{B} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{\hat{Y}(\Gamma)} \\ &= \left\langle g(\xi, z), \mathcal{L} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} + \left\langle f_{\Gamma}(\xi, z), \mathcal{B} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{\hat{Y}(\Gamma)} \end{aligned} \quad (12.461)$$

Hence, more compactly, the algebraic equation system is allocated on the form (12.401) in which the matrix  $A$  and the vectors  $\mathbf{f}$  and  $\mathbf{F}$  are defined as:

$$[A]_{IJ} = \left\langle \mathcal{L} [\ell_J^{\mathcal{P}}(\xi, z)], \mathcal{L} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} + \left\langle \mathcal{B} [\ell_J^{\mathcal{P}}(\xi, z)], \mathcal{B} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{\hat{Y}(\Gamma)} \quad (12.462)$$

$$[\mathbf{F}]_I = \left\langle g(\xi, z), \mathcal{L} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} + \left\langle f_{\Gamma}(\xi, z), \mathcal{B} [\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{\hat{Y}(\Gamma)} \quad (12.463)$$

$$[\mathbf{f}]_J = f_J^{\mathcal{P}}(\xi, z) \quad \text{or alternatively} \quad [\mathbf{f}]_I = f_I^{\mathcal{P}}(\xi, z) \quad (12.464)$$

for all  $I, J = 0, \dots, \mathcal{P}$ . The indices  $I$  and  $J$  refer to the particular basis functions in the expansion of the perturbation function  $v(\xi, z)$  and the solution function  $f^{\mathcal{P}}(\xi, z)$ , respectively. In an alternative interpretation, the index  $I$  refers to the collocation point, whereas the index  $J$  refers to the polynomial order of the polynomial trial function expansion (12.441).

*The Least-Squares Method as Derived Through the Weighted Residual Framework (Weak Formulation)*

The term *method of weighted residuals* was original coined by Crandall [38] to describe a variety of methods (e.g., Galerkin, methods of moments, orthogonal collocation and least-squares) having in common the fact that minimizing the residual  $\mathcal{R}$  is interpreted as equating to zero weighted integrals or inner products [250]. Thus, an equivalent method for the continuous functional  $\mathcal{J}(f; g, f_{\Gamma})$  (Eq. 12.448) minimization procedure consists in finding the minimum of the inner product of the weight function  $w$  and residual function  $\mathcal{R}$ , i.e.  $\langle w, \mathcal{R} \rangle$ . Considering the generalized problem formulation (12.402), the minimization statement of the inner products can be given as:

$$\langle w_{\Omega, I}, \mathcal{R}_{\Omega} \rangle + \langle w_{\Gamma, I}, \mathcal{R}_{\Gamma} \rangle = \int_{\Omega} w_{\Omega, I} \mathcal{R}_{\Omega} \, d\Omega + \int_{\Gamma} w_{\Gamma, I} \mathcal{R}_{\Gamma} \, d\Gamma = 0 \quad (12.465)$$

$\forall I = 0, 1, \dots, \mathcal{P}$ . The weight functions  $w_I$  are known also as test functions.

The residuals  $\mathcal{R}_{\Omega}$  and  $\mathcal{R}_{\Gamma}$  are given as:

$$\mathcal{R}_{\Omega} = \mathcal{L}f(\xi, z) - g(\xi, z) \quad \text{in } \Omega \quad (12.466)$$

$$\mathcal{R}_{\Gamma} = \mathcal{B}f(\xi, z) - f_{\Gamma}(\xi, z) \quad \text{on } \Gamma \quad (12.467)$$

The spectral methods are based on using a representation of the solution  $f(\xi, z)$  throughout the domain  $\Omega$  via a polynomial trial function expansion (Eq. 12.406). A nodal basis expansion in terms of the Lagrange basis polynomials is obtained by letting  $\Phi_{j_z}^{P_z}(z) = \ell_{j_z}^{P_z}(z)$  and  $\Phi_{j_{\xi}}^{P_{\xi}}(\xi) = \ell_{j_{\xi}}^{P_{\xi}}(\xi)$ . Thus, the series expansion is given by Eq. (12.408), or alternatively by Eq. (12.441) in terms of global indices. The resulting residual functions are thus in terms of the solution function values  $f_{j_z j_{\xi}} = f_J$  at the node points  $z_{j_z}$  and  $\xi_{j_{\xi}}$ :  $\mathcal{R}_{\Omega} = \mathcal{R}_{\Omega}(f_0, f_1, \dots, f_{\mathcal{P}})$  and  $\mathcal{R}_{\Gamma} = \mathcal{R}_{\Gamma}(f_0, f_1, \dots, f_{\mathcal{P}})$ . It follows that in the least-squares method the weight functions in Eq. (12.465) are chosen as:

$$w_{\Omega, I} = \frac{\partial}{\partial f_I} \mathcal{R}_{\Omega}(f_0, f_1, \dots, f_{\mathcal{P}}) \quad \forall I = 0, 1, \dots, \mathcal{P} \quad (12.468)$$

$$w_{\Gamma,I} = \frac{\partial}{\partial f_I} \mathcal{R}_\Gamma(f_0, f_1, \dots, f_{\mathcal{P}}) \quad \forall I = 0, 1, \dots, \mathcal{P} \quad (12.469)$$

With this definition of the weight functions, the weighted residual integral statement becomes:

$$\begin{aligned} \int_{\Omega} w_{\Omega,I} \mathcal{R}_{\Omega} d\Omega + \int_{\Gamma} w_{\Gamma,I} \mathcal{R}_{\Gamma} d\Gamma &= \int_{\Omega} \frac{\partial \mathcal{R}_{\Omega}}{\partial f_I} \mathcal{R}_{\Omega} d\Omega + \int_{\Gamma} \frac{\partial \mathcal{R}_{\Gamma}}{\partial f_I} \mathcal{R}_{\Gamma} d\Gamma \\ &= \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Omega} \mathcal{R}_{\Omega}^2 d\Omega + \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Gamma} \mathcal{R}_{\Gamma}^2 d\Gamma = 0 \end{aligned} \quad (12.470)$$

The latter equation may be manipulated by using the definitions of the residuals (12.466) and (12.467) and inserting the approximate solution (12.441).

Provided that the  $\mathcal{L}_{\bullet}$  and  $\mathcal{B}_{\bullet}$  are linear operators, the order of operation may be interchanged:

$$\begin{aligned} &\frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Omega} \mathcal{R}_{\Omega}^2 d\Omega + \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Gamma} \mathcal{R}_{\Gamma}^2 d\Gamma \\ &= \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Omega} \left( \mathcal{L}f(\xi, z) - g(\xi, z) \right)^2 d\Omega + \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Gamma} \left( \mathcal{B}f(\xi, z) - f_{\Gamma}(\xi, z) \right)^2 d\Gamma \\ &= \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Omega} \left( \mathcal{L} \left[ \sum_{J=0}^{\mathcal{P}} f_J \ell_J^{\mathcal{P}}(\xi, z) \right] - g(\xi, z) \right)^2 d\Omega \\ &\quad + \frac{1}{2} \frac{\partial}{\partial f_I} \int_{\Gamma} \left( \mathcal{B} \left[ \sum_{J=0}^{\mathcal{P}} f_J \ell_J^{\mathcal{P}}(\xi, z) \right] - f_{\Gamma}(\xi, z) \right)^2 d\Gamma \\ &= \int_{\Omega} \left( \sum_{J=0}^{\mathcal{P}} f_J \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] - g(\xi, z) \right) \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega \\ &\quad + \int_{\Gamma} \left( \sum_{J=0}^{\mathcal{P}} f_J \mathcal{B} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] - f_{\Gamma}(\xi, z) \right) \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Gamma = 0 \end{aligned} \quad (12.471)$$

Hence,

$$\begin{aligned} &\sum_{J=0}^{\mathcal{P}} f_J \int_{\Omega} \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega + \sum_{J=0}^{\mathcal{P}} f_J \int_{\Gamma} \mathcal{B} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Gamma \\ &= \int_{\Omega} g(\xi, z) \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega + \int_{\Gamma} f_{\Gamma}(\xi, z) \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Gamma \end{aligned} \quad (12.472)$$

The latter expression may alternatively be expressed by use of the bracket inner product operator:

$$\begin{aligned} \sum_{J=0}^{\mathcal{P}} f_J \left\langle \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{Y(\Omega)} + \sum_{J=0}^{\mathcal{P}} f_J \left\langle \mathcal{B} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{\hat{Y}(\Gamma)} \\ = \left\langle g(\xi, z), \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{Y(\Omega)} + \left\langle f_{\Gamma}(\xi, z), \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{\hat{Y}(\Gamma)} \end{aligned} \quad (12.473)$$

The algebraic equation system (12.473) can be written on the form:

$$\sum_{J=0}^{\mathcal{P}} f_J [A]_{IJ} = [\mathbf{F}]_I \quad (12.474)$$

where

$$[A]_{IJ} = \left\langle \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{Y(\Omega)} + \left\langle \mathcal{B} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{\hat{Y}(\Gamma)} \quad (12.475)$$

$$[\mathbf{F}]_I = \left\langle g(\xi, z), \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{Y(\Omega)} + \left\langle f_{\Gamma}(\xi, z), \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{\hat{Y}(\Gamma)} \quad (12.476)$$

Furthermore, if  $\mathbf{f}^T = [f_0, f_1, \dots, f_{\mathcal{P}}]$ , the algebraic equation system can be expressed on the standard form (12.401). This is the same results as obtained by the variational method.

### Implementation (Weak Formulation)

In the following, the general implementation issues of the generalized problem formulation (12.402) are presented. Based on variational or weighted residual principles (weak formulation), the algebraic equation system (12.401) where  $A$  and  $\mathbf{F}$  are defined by (12.462) and (12.463) or alternatively (12.475) and (12.476) as obtained by the weak formulation of the least-squares technique can be presented as:

$$\begin{aligned} [A]_{IJ} &= \int_{\Omega} \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega + \int_{\Gamma} \mathcal{B} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Gamma \\ &= \sum_{I_Q=0}^{\mathcal{P}} \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] w_{I_Q} \\ &\quad + \sum_{I_Q=0}^{\mathcal{P}} \mathcal{B} \left[ \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] w_{I_Q} \end{aligned}$$

$$= \sum_{I_Q=0}^{\mathcal{P}} [L]_{I_Q J} [\Lambda]_{I_Q I_Q} [L]_{I_Q I} + \sum_{I_Q=0}^{\mathcal{P}} [B]_{I_Q J} [\Lambda]_{I_Q I_Q} [B]_{I_Q I} \quad (12.477)$$

$$\begin{aligned} [\mathbf{F}]_I &= \int_{\Omega} g(\xi, z) \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega + \int_{\Gamma} f_{\Gamma}(\xi, z) \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Gamma \\ &= \sum_{I_Q=0}^{\mathcal{P}} g(\xi_{I_Q}, z_{I_Q}) \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] W_{I_Q} \\ &\quad + \sum_{I_Q=0}^{\mathcal{P}} f_{\Gamma}(\xi_{I_Q}, z_{I_Q}) \mathcal{B} \left[ \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] W_{I_Q} \end{aligned} \quad (12.478)$$

$$\begin{aligned} &= \sum_{I_Q=0}^{\mathcal{P}} [\mathbf{g}]_{I_Q} [\Lambda]_{I_Q I_Q} [L]_{I_Q I} + \sum_{I_Q=0}^{\mathcal{P}} [\mathbf{f}_{\Gamma}]_{I_Q} [\Lambda]_{I_Q I_Q} [B]_{I_Q I} \\ [\mathbf{f}]_J &= f_J = f(\xi_J, z_J) \end{aligned} \quad (12.479)$$

where

$$[L]_{I_Q J} = \mathcal{L} \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \quad \text{and} \quad [L]_{I_Q I} = \mathcal{L} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \quad (12.480)$$

$$[B]_{I_Q J} = \mathcal{B} \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \quad \text{and} \quad [B]_{I_Q I} = \mathcal{B} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \quad (12.481)$$

$$\Lambda = \begin{bmatrix} W_0 & 0 & \dots & 0 \\ 0 & W_1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & W_{\mathcal{P}} \end{bmatrix} \quad (12.482)$$

The global quadrature weights in the diagonal matrix,  $\Lambda$ , is computed by relationship (12.447). Alternatively, the matrix  $A$  and vector  $\mathbf{F}$  can be written in the compact form:

$$A = \mathcal{L}^T \Lambda \mathcal{L} + \mathcal{B}^T \Lambda \mathcal{B} \quad (12.483)$$

$$\mathbf{F} = \mathcal{L}^T \Lambda \mathbf{g} + \mathcal{B}^T \Lambda \mathbf{f}_{\Gamma} \quad (12.484)$$

It is noticed that a quadrature rule is applied in (12.477) and (12.478). In order to reduce time consuming operations, the quadrature points are normally chosen the same as the collocation points in the approximation of the norm integrals of the least-squares method. The quadrature points and the collocation points are defined at the same locations when both type of points are determined as the roots of the same type of orthogonal polynomial of the same order. In this case  $[\mathbf{f}]_J = f_J$  coincides with  $[\mathbf{f}]_{I_Q} = f_{I_Q}$ .

Given the boundary condition that  $f(\xi, z)$  is specified for  $z = 0, \forall \xi$ , the boundary matrix  $B$  is given as

$$B = \begin{bmatrix} \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix} & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \\ \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \\ \vdots & \vdots & \ddots & \vdots \\ \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \end{bmatrix} \quad (12.485)$$

where the sub-matrices are of dimension  $(P_\xi + 1) \times (P_\xi + 1)$ .

The vector  $\mathbf{f}_\Gamma$  is given as:

$$\mathbf{f}_\Gamma = \begin{bmatrix} f(\xi_0, z_0) \\ f(\xi_1, z_0) \\ \vdots \\ f(\xi_{P_\xi}, z_0) \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (12.486)$$

#### *The least-Squares Method Based on Variational Principles (Strong Formulation)*

Considering the strong formulation of the boundary conditions, the following norm-equivalent least-squares function is defined for the generalized problem formulation (12.402):

$$\mathcal{J}(f; g, f_\Gamma) = \frac{1}{2} \|\mathcal{L}f(\xi, z) - g(\xi, z)\|_{Y(\Omega)}^2 \quad (12.487)$$

with the norm defined by (12.449). The minimization statement is expressed as:

Find  $f(\xi, z) \in X(\Omega)$  such that

$$\lim_{\epsilon \rightarrow 0} \frac{d\mathcal{J}(f(\xi, z) + \epsilon v(\xi, z); g(\xi, z))}{d\epsilon} = 0 \quad \forall v(\xi, z) \in X(\Omega) \quad (12.488)$$

We notice the similarity to (12.451) and follow the procedure of (12.452)–(12.455). The given minimization statement can be presented on matrix form as:

$$\mathcal{A}(f(\xi, z), v(\xi, z)) = \mathcal{F}(g(\xi, z), v(\xi, z)) \quad (12.489)$$

with

$$\mathcal{A}(f(\xi, z), v(\xi, z)) = \left\langle \mathcal{L}f(\xi, z), \mathcal{L}v(\xi, z) \right\rangle_{Y(\Omega)} \quad (12.490)$$

$$\mathcal{F}(g(\xi, z), f_I(\xi, z), v(\xi, z)) = \left\langle g(\xi, z), \mathcal{L}v(\xi, z) \right\rangle_{Y(\Omega)} \quad (12.491)$$

With these approximations, (12.441), (12.456), and by choosing systematically  $v(\xi, z) = \ell_0^{\mathcal{P}}(\xi, z), \dots, \ell_{\mathcal{P}}^{\mathcal{P}}(\xi, z)$ , a solvable system of algebraic equations is obtained.

Following the steps of (12.459)–(12.461), the algebraic equation system is allocated on the conventional form (12.401), in which  $A$  and  $\mathbf{F}$  are defined as:

$$[A]_{IJ} = \left\langle \mathcal{L}[\ell_J^{\mathcal{P}}(\xi, z)], \mathcal{L}[\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} \quad (12.492)$$

$$[\mathbf{F}]_I = \left\langle g(\xi, z), \mathcal{L}[\ell_I^{\mathcal{P}}(\xi, z)] \right\rangle_{Y(\Omega)} \quad (12.493)$$

for all  $I, J = 0, \dots, \mathcal{P}$ .

*The Least-Squares Method as Derived Through the Weighted Residual Framework (Strong Formulation)*

Considering the generalized problem formulation (12.402), the inner product minimization statement is presented by (12.494), with manipulations of the resulting equation system to enforce the strong form of the boundary conditions:

$$\langle w_{\Omega, I}, \mathcal{R}_{\Omega} \rangle_{\Omega} = \int_{\Omega} w_{\Omega, I} \mathcal{R}_{\Omega} \, d\Omega = 0 \quad \forall I = 0, 1, \dots, \mathcal{P} \quad (12.494)$$

In the minimization statement (12.494), the residual  $\mathcal{R}_{\Omega}$  and weighing function  $w_{\Omega, I}$  are given by (12.466) and (12.468), respectively. With these definitions the weighted residual integral (12.494) is given as:

$$\int_{\Omega} w_{\Omega, I} \mathcal{R}_{\Omega} \, d\Omega = \int_{\Omega} \frac{\partial \mathcal{R}_{\Omega}}{\partial f_I^{\mathcal{P}}} \mathcal{R}_{\Omega} \, d\Omega = \frac{1}{2} \frac{\partial}{\partial f_I^{\mathcal{P}}} \int_{\Omega} \mathcal{R}_{\Omega}^2 \, d\Omega = 0 \quad \forall I = 0, 1, \dots, \mathcal{P} \quad (12.495)$$

We notice the similarity to (12.470) and proceed in the same manner as performed in (12.471)–(12.473). The obtained expressions for matrix  $A$  and vector  $\mathbf{F}$ , equation (12.474), can thus be presented as, respectively:

$$[A]_{IJ} = \left\langle \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right], \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{\Omega} \quad (12.496)$$

$$[\mathbf{F}]_I = \left\langle g(\xi, z), \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] \right\rangle_{\Omega} \quad (12.497)$$

### Implementation (Strong Formulation)

In the following, the general implementation issues of the generalized problem formulation (12.402) are presented. Based on variational or weighted residual principles (strong formulation), the algebraic equation system (12.401) in which  $A$  and  $\mathbf{F}$  are defined by (12.492)–(12.493) or alternatively (12.496)–(12.497) as obtained by the strong formulation of the least-squares technique:

$$\begin{aligned} [A]_{IJ} &= \int_{\Omega} \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi, z) \right] \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega \\ &= \sum_{I_Q=0}^{\mathcal{P}} \mathcal{L} \left[ \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] w_{I_Q} \\ &= \sum_{I_Q=0}^{\mathcal{P}} [L]_{I_Q J} [\Lambda]_{I_Q I_Q} [L]_{I_Q I} \end{aligned} \quad (12.498)$$

$$\begin{aligned} [\mathbf{F}]_I &= \int_{\Omega} g(\xi, z) \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi, z) \right] d\Omega \\ &= \sum_{I_Q=0}^{\mathcal{P}} g(\xi_{I_Q}, z_{I_Q}) \mathcal{L} \left[ \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \right] w_{I_Q} \\ &= \sum_{I_Q=0}^{\mathcal{P}} [\mathbf{g}]_{I_Q} [\Lambda]_{I_Q I_Q} [L]_{I_Q I} \end{aligned} \quad (12.499)$$

in which the matrices  $L$  and  $\Lambda$  are given by (12.480) and (12.482). The boundary conditions can be included by manipulation of the matrix  $\mathcal{A}$  (12.498) and vector  $\mathbf{F}$  (12.499). Given the boundary condition that  $f(\xi, z)$  is specified for  $z = 0, \forall \xi$ , the manipulated matrix (12.498) and vector (12.499) are given as:

$$A' = \begin{bmatrix} \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix} & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \\ [A]_{I=P_\xi+1, J=0} & \dots & \dots & [A]_{I=P_\xi+1, J=\mathcal{P}} \\ \vdots & & & \\ \vdots & & \ddots & \vdots \\ [A]_{I=\mathcal{P}, J=0} & \dots & & [A]_{I=\mathcal{P}, J=\mathcal{P}} \end{bmatrix} \quad (12.500)$$

$$\mathbf{F}' = \begin{bmatrix} f(\xi_0, z_0) \\ f(\xi_1, z_0) \\ \vdots \\ f(\xi_{P_\xi}, z_0) \\ [\mathbf{F}]_{I=P_\xi+1} \\ \vdots \\ [\mathbf{F}]_{I=\mathcal{P}} \end{bmatrix} = \begin{bmatrix} [\mathbf{f}_\Gamma]_{I=0} \\ [\mathbf{f}_\Gamma]_{I=1} \\ \vdots \\ [\mathbf{f}_\Gamma]_{I=P_\xi} \\ [\mathbf{F}]_{I=P_\xi+1} \\ \vdots \\ [\mathbf{F}]_{I=\mathcal{P}} \end{bmatrix} \quad (12.501)$$

It should be noticed that the global numbering procedure as sketched in Fig. 12.5 is adopted.

### Galerkin, Tau and Orthogonal Collocation Methods

For particular problems, it is possible to formulate spectral methods starting out from variational principles. The variational methods provide a means to obtain approximate solutions to differential equations based on minimizing the functional of the equation. For example, the Rayleigh–Ritz method [190, 194] is applied to approximate the solution of variational problems and problems that reduce to variational problems. In particular, the Rayleigh–Ritz method applies calculus of variation for some energy minimization problems due to the fact that the nature organizes itself to a state of minimum energy. The Galerkin method [67] can be considered a broad generalization of the Ritz method because it can be used not only as an approximate solution of variational problems, but also for problems that do not reduce to variational problems. The Galerkin method represents a sub-class of the method of weighted residuals and is always applicable because it does not depend on the existence of a variational principle. There is always a Galerkin method that corresponds to the variational method, but the reverse is not true. Thus, in one view, the Galerkin method may be interpreted as either variational principle or regular method of weighted residual. To distinguish the two methods, a system of equations is said to

be self-adjoint when we can formulate a variational principle for the corresponding problem. Because of the Ritz method is applicable only for equations that are self-adjoint, the Galerkin method is commonly considered a more universal approach for the construction of a spectral approximation. The variational and Galerkin methods give, however, identical results for a system of self-adjoint equations.

The general framework of the weighted residual methods can be presented as:

$$\langle w_I, \mathcal{R} \rangle = 0 \quad \forall I = 0, 1, \dots, \mathcal{P} \quad (12.502)$$

where  $w_I$  represents a weight function and  $\mathcal{R}$  denotes the residual of the generalized problem (12.402). The choice of weight function distinguishes between the spectral solution schemes.

The weight function is identical in the Galerkin and tau methods (i.e. weight function is set equal to the basis function in the polynomial trial function expansion, see (12.405)–(12.408)). The essential difference between the Galerkin and the tau methods is the treatment of the boundary conditions (strong form). In the tau method, the boundary conditions are enforced as additional equations and in order to get a system of equations where the number of unknowns is identical to the number of equations, the equation system has to be relaxed such that  $n$  residual equations are replaced by the  $n$  boundary conditions. In the Galerkin method, some linear combinations of the polynomials that fulfill the boundary conditions must be performed.

The simplicity of the the orthogonal collocation method [59, 153, 192, 251–253] results from employing the Dirac delta function as the weight function.

### *Galerkin and Tau Methods*

Consider the generalize problem formulation defined by (12.402a) and (12.402b). The inner product minimization statement is given by (12.494). In both the Galerkin and tau methods, the weighting functions are chosen identical to the basis function, i.e.  $w_{\Omega, I} = \ell_I^{\mathcal{P}}(\xi, z)$ . Hence,

$$\begin{aligned} & \left\langle \ell_I^{\mathcal{P}}(\xi, z), \mathcal{R}_{\Omega}^{\mathcal{P}}(\xi, z, f_0^{\mathcal{P}}, \dots, f_J^{\mathcal{P}}, \dots, f_{\mathcal{P}}^{\mathcal{P}}) \right\rangle \\ &= \int_{\Omega} \mathcal{R}_{\Omega}^{\mathcal{P}}(\xi, z, f_0^{\mathcal{P}}, \dots, f_J^{\mathcal{P}}, \dots, f_{\mathcal{P}}^{\mathcal{P}}) \ell_I^{\mathcal{P}}(\xi, z) \, d\Omega \\ &= \int_{\Omega} \left[ \sum_{J=0}^{\mathcal{P}} f_J^{\mathcal{P}} \mathcal{L} \ell_J^{\mathcal{P}}(\xi, z) - g(\xi, z) \right] \ell_I^{\mathcal{P}}(\xi, z) \, d\Omega \\ &= \sum_{I_Q=0}^{\mathcal{P}} \left[ \sum_{J=0}^{\mathcal{P}} f_J^{\mathcal{P}} \mathcal{L} \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) - g(\xi_{I_Q}, z_{I_Q}) \right] \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) W_{I_Q} \\ &= \sum_{J=0}^{\mathcal{P}} f_J^{\mathcal{P}} \sum_{I_Q=0}^{\mathcal{P}} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \mathcal{L} \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) W_{I_Q} \end{aligned}$$

$$-\sum_{I_Q=0}^{\mathcal{P}} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) g(\xi_{I_Q}, z_{I_Q}) W_{I_Q} = 0 \quad \forall I = 0, 1, \dots, \mathcal{P} \quad (12.503)$$

in which  $\mathcal{R}_{\Omega}$  is defined by (12.466). Moreover, the polynomial trial function expansion (12.406) has been adopted to approximate the solution function.

The latter equation can be presented on the conventional matrix form (12.401):

$$[A]_{IJ} = \sum_{I_Q=0}^{\mathcal{P}} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) \mathcal{L} \ell_J^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) W_{I_Q} = \sum_{I_Q=0}^{\mathcal{P}} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) [L]_{I_Q J} W_{I_Q} \quad (12.504)$$

$$[\mathbf{F}]_I = \sum_{I_Q=0}^{\mathcal{P}} \ell_I^{\mathcal{P}}(\xi_{I_Q}, z_{I_Q}) g(\xi_{I_Q}, z_{I_Q}) W_{I_Q} \quad (12.505)$$

and with  $\mathbf{f}^T = [f_0^{\mathcal{P}}, f_1^{\mathcal{P}}, \dots, f_{\mathcal{P}}^{\mathcal{P}}]^T$ .

Moreover,  $L$  is defined in accordance to (12.480). The equation system must be manipulated in order to enforce the boundary conditions. Given the boundary condition that  $f(\xi, z)$  is specified for  $z = 0, \forall \xi$ . For the tau method, the strong form implementation of the boundary conditions are handled in the same manner as in (12.500) and (12.501). On the other hand, the Galerkin method requires relative more comprehensive manipulations. Thus, the  $P_{\xi} + 1$  first column and rows are removed from matrix  $A$  (12.500), and the  $P_{\xi} + 1$  first rows are removed from the vector  $\mathbf{F}$  (12.501). The vector  $\mathbf{F}$  is further manipulated with the  $A$  matrix coefficients to enforce the boundary conditions:

$$A'' = \begin{bmatrix} [A]_{I=P_{\xi}+1, J=0} & \cdots & [A]_{I=P_{\xi}+1, J=\mathcal{P}} \\ \vdots & & \\ \vdots & & \ddots & \vdots \\ [A]_{I=\mathcal{P}, J=0} & \cdots & [A]_{I=\mathcal{P}, J=\mathcal{P}} \end{bmatrix} \quad (12.506)$$

$$\mathbf{F}'' = \begin{bmatrix} [\mathbf{F}]_{I=P_{\xi}+1} - f(\xi_0, z_0) [A]_{I=P_{\xi}+1, J=0} \cdots - f(\xi_{P_{\xi}}, z_0) [A]_{I=P_{\xi}+1, J=P_{\xi}+1} \\ \vdots \\ [\mathbf{F}]_{I=\mathcal{P}} - f(\xi_0, z_0) [A]_{I=\mathcal{P}, J=0} \cdots - f(\xi_{P_{\xi}}, z_0) [A]_{I=\mathcal{P}, J=P_{\xi}+1} \end{bmatrix} \quad (12.507)$$

### Orthogonal Collocation Method

Consider the generalize problem formulation defined by (12.402a) and (12.402b). The inner product minimization statement is given by (12.494). In the orthogonal collocation method, the weighting function is the Dirac delta function, i.e.,

$\omega_{\Omega,I}(\mathbf{x}) = \delta(\mathbf{x} - \mathbf{x}_I)$ . Accordingly, at the location  $\mathbf{x} = \mathbf{x}_I$  the residual is forced to zero such that the generalized problem (12.402) is satisfied at these points. Thus the inner products are given as:

$$\begin{aligned} \left\langle \delta(\mathbf{x} - \mathbf{x}_I), \mathcal{R}_{\Omega}^{\mathcal{P}}(\xi, z, f_0^{\mathcal{P}}, \dots, f_J^{\mathcal{P}}, \dots, f_P^{\mathcal{P}}) \right\rangle &= \int_{\Omega} \mathcal{R}_{\Omega}^{\mathcal{P}}(\xi, z, f_0^{\mathcal{P}}, \dots, f_J^{\mathcal{P}}, \dots, f_P^{\mathcal{P}}) \delta_I \, d\Omega \\ &= \mathcal{R}_{\Omega}^{\mathcal{P}}(\xi, z, f_0^{\mathcal{P}}, \dots, f_J^{\mathcal{P}}, \dots, f_P^{\mathcal{P}})|_{\mathbf{x}=\mathbf{x}_I} \\ &= \sum_{J=0}^{\mathcal{P}} f_J^{\mathcal{P}} \mathcal{L}\ell_J^{\mathcal{P}}(\xi_I, z_I) - g(\xi_I, z_I) \\ &= 0 \quad \forall I = 0, 1, \dots, \mathcal{P} \end{aligned} \quad (12.508)$$

where the polynomial trial function expansion (12.406) has been applied to approximate the solution function. The approximated solution  $f^{\mathcal{P}}(\xi_I, z_I)$  for  $I = 0, 1, \dots, \mathcal{P}$  obtained by the collocation method is thus represented by finding a particular set of unknown coefficients  $\{f_J^{\mathcal{P}}, J = 0, 1, \dots, P\}$  which satisfy (12.508).

Equation (12.508) can be presented on the form (12.401):

$$[A]_{IJ} = \mathcal{L}\ell_J^{\mathcal{P}}(\xi_I, z_I) = [L]_{IJ} \quad (12.509)$$

$$[\mathbf{F}]_I = g(\xi_I, z_I) \quad (12.510)$$

$$\mathbf{f} = [f_0^{\mathcal{P}}, f_1^{\mathcal{P}}, \dots, f_P^{\mathcal{P}}]^T \quad (12.511)$$

in which  $L$  is defined in accordance to (12.480). Further, the treatment of the strong form implementation of the boundary conditions can follow the approach of (12.506) and (12.507). However, due to the simplicity, the approach in (12.500) and (12.501) is employed in the present study for the orthogonal collocation method.

### *Implementation Issues for Spectral Solution of the PBE*

Further details on the implementation issues using the least-squares method for the solution of the PBE (12.399) is given by Solsvik and Jakobsen [218]. The implementation framework discussed by Solsvik and Jakobsen [218] can be adopted for the Galerkin, tau and orthogonal collocation methods notifying the differences in the algebra of the solution techniques. The problem operator matrix  $L$  and source vector  $\mathbf{g}$  that are applied to obtain the equation system  $A\mathbf{f} = \mathbf{F}$  of the orthogonal collocation (12.509)–(12.510), Galerkin (12.504)–(12.505), tau (12.504)–(12.505), and least-squares (strong form) (12.498)–(12.499) methods are given in the sequent. Manipulation of the resulting equation system to enforce the boundary conditions follows the technique as presented by (12.500)–(12.501) (orthogonal collocation, tau, strong form least-squares) and (12.506)–(12.507) (Galerkin). In addition to the problem operator matrix  $L$  and source vector  $\mathbf{g}$ , the boundary operator matrix  $B$  and boundary values  $\mathbf{f}_\Gamma$  constitute the weak formulation of the least-squares method (12.477) and (12.478).

### Boundary Conditions

Considering the PBE problem (12.399), a set of boundary conditions are required. In the present study, the following set of boundary conditions are employed: (i)  $f(\xi, z) = 0$  for  $\xi = \xi_{\min}$ ,  $\forall z$ , and (ii)  $f(\xi, z) = \text{specified}$  for  $z = 0$ ,  $\forall \xi$ . Figure 12.6 holds the specified distribution function at  $z = 0$ .

### The Linear System of Algebraic Equations

In order to obtain a system of algebraic equations, the PBE (12.399) and the boundary conditions must be transformed into a discrete form. In spectral methods, the solution function is approximated in terms of a polynomial solution function expansion (12.408). The differentiation of the discrete solution approximation were presented as (12.410) and (12.411). The PBE (12.399) is an integro-differential equation. Thus, appropriate quadrature rules are required for the numerical solution. Integral approximations can be presented on the form:

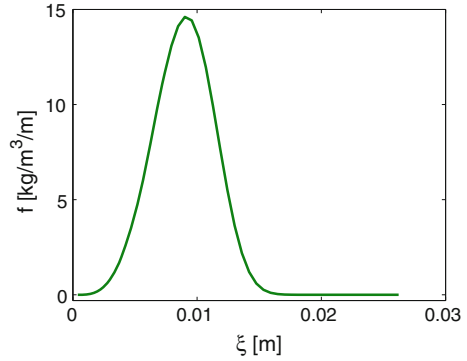

$$\int_{\xi_1}^{\xi_2} f(\zeta, z) d\zeta \approx \sum_{i_{q\zeta}=0}^{P_{i_{q\zeta}}} \left\{ \sum_{j_{\zeta}=0}^{P_{\zeta}} \sum_{j_z=0}^{P_z} f_{j_{\zeta}j_z} \ell_{j_{\zeta}}^{P_{\zeta}}(\zeta_{i_{q\zeta}}) \ell_{j_z}^{P_z}(z) \right\} W_{i_{q\zeta}}^{P_{\zeta}}(\xi_1, \xi_2) \quad (12.512)$$

A problem arises as the solution vector  $f$  is only available in the collocation points,  $f_{j_{\zeta}j_z}$ , and not necessarily in the  $\zeta$ -points,  $f_{j_{\zeta}j_z}$ . Thus the integral approximation (12.512) is modified as follows:

$$\int_{\xi_1}^{\xi_2} f(\zeta, z) d\zeta \approx \sum_{i_{q\zeta}=0}^{P_{i_{q\zeta}}} \sum_{j_{\xi}=0}^{P_{\xi}} \sum_{j_z=0}^{P_z} f_{j_{\xi}j_z} \ell_{j_{\xi}}^{P_{\xi}}(\zeta_{i_{q\zeta}}) \ell_{j_z}^{P_z}(z) W_{i_{q\zeta}}^{P_{\zeta}}(\xi_1, \xi_2) \quad (12.513)$$

The two-dimensional population balance problem defined by Eq. (12.399) is formulated on the conventional form (12.401) by use of a global index numbering procedure. The matrixes  $L$  and  $A$ , and the vectors  $\mathbf{F}$  and  $\mathbf{f}$  are defined terms of the global index numbering. However, in the implementation the problem operator computations are generally performed in the standard coordinate index-loops whereas the resulting values are assigned to the  $L$ -operators which are expressed in global indexes thus the coordinate system indices must be transform into the global numbering and visa versa. Thus, a transformation formula defining the relationship between the coordinate index and global indices are required. The relationship between the coordinate index notation and global indices is based on the grid labeling as illustrated in Fig. 12.5 and the transformation formula required is given by (12.440). This information may be computed once and made available through a global index matrix. For the global index labeling procedure illustrated in Fig. 12.5, the corresponding global matrix is defined as:

**Fig. 12.6** Particle size distribution at the entrance of the vessel, i.e.  $f_{d,m}(\xi, z = 0)$

$$[\text{GM}]_{jzj\xi} = \begin{bmatrix} 0 & 1 & \dots & 5 \\ 6 & 7 & \dots & 11 \\ \vdots & \vdots & \ddots & \vdots \\ 30 & 31 & \dots & 35 \end{bmatrix} \quad (12.514)$$

The pseudo code 1 illustrates how the information of the global index  $I_Q$  can be obtained from the local indices  $i_z$  and  $i_\xi$  through the global index matrix, GM (12.514). Further, the pseudo code 1 defines the global weight matrix  $\Lambda$  (12.482) based on the local weights  $W_{i_{qz}}$  and  $W_{i_{q\xi}}$ . The computation of the boundary matrix (12.526) is also illustrated.

10:       $[B]_{I_Q I_Q} = 1$ 
11:    end if
12:     $[\Lambda]_{I_Q I_Q} = W_{i_{q\xi}} W_{i_{qz}}$ 
13:   end for
14: end for

```

---

Considering the PBE (12.399), the problem matrix  $[L]$ , as defined by (12.480), is given by (12.515)–(12.522):

- Convection in the physical space  $z$ :

$$[L_1]_{IQJ} = v_z \ell_{j_\xi}^{P_\xi}(\xi_{iq_\xi}) \frac{\partial \ell_{j_z}^{P_z}(z)}{\partial z} \Big|_{iq_z} \quad (12.515)$$

- Convection in the property coordinate  $\xi$ , i.e., particle growth:

$$[L_2]_{IQJ} = - \frac{\xi_{iq_\xi} v_z}{3\rho_d(z_{iq_z})} \frac{\partial \rho_d(z)}{\partial z} \Big|_{iq_z} \frac{\partial}{\partial \xi} \ell_{j_\xi}^{P_\xi}(\xi) \Big|_{iq_\xi} \ell_{j_z}^{P_z}(z_{iq_z}) \quad (12.516)$$

$$[L_3]_{IQJ} = - \ell_{j_\xi}^{P_\xi}(\xi_{iq_\xi}) \ell_{j_z}^{P_z}(z_{iq_z}) \frac{v_z}{3\rho_d(z_{iq_z})} \frac{\partial \rho_d(z)}{\partial z} \Big|_{iq_z} \quad (12.517)$$

- Breakage death:

$$[L_4]_{IQJ} = H \left( \xi_{iq_\xi} - \sqrt[3]{2\xi_{\min}^3} \right) \times b(\xi_{iq_\xi}) \ell_{j_\xi}^{P_\xi}(\xi_{iq_\xi}) \ell_{j_z}^{P_z}(z_{iq_z}) \quad (12.518)$$

- Breakage birth:

$$[L_5]_{IQJ} = - H \left( \sqrt[3]{\xi_{\max}^3 - \xi_{\min}^3} - \xi_{iq_\xi} \right) \times V(\xi_{iq_\xi}) \ell_{j_z}^{P_z}(z_{iq_z}) \\ \times \sum_{iq_\zeta=0}^{P_\zeta} \left[ h(\xi_{iq_\xi}, \zeta_{iq_\zeta}) b(\zeta_{iq_\zeta}) \frac{\ell_{j_\xi}^{P_\xi}(\zeta_{iq_\zeta})}{V(\zeta_{iq_\zeta})} W_{iq_\zeta}^{P_\zeta}(\xi_{iq_\xi}, \xi_{\max}) \right] \quad (12.519)$$

- Coalescence death:

$$[L_6]_{IQJ} = H \left( \sqrt[3]{\xi_{\max}^3 - \xi_{\min}^3} - \xi_{iq_\xi} \right) f_{j_\xi j_z}^{\nu-1} \\ \times \frac{\ell_{j_z}^{P_z}(z_{iq_z})}{\rho_d(z_{iq_z})} \times \sum_{iq_\zeta=0}^{P_\zeta} \left[ \kappa_C(\xi_{iq_\xi}, \zeta_{iq_\zeta}) \frac{\ell_{j_\xi}^{P_\xi}(\zeta_{iq_\zeta})}{V(\zeta_{iq_\zeta})} \right. \\ \left. \times W_{iq_\zeta}^{P_\zeta}(\xi_{\min}, [(\xi_{\max})^3 - (\xi_{iq_\xi})^3]^{1/3}) \right] \quad (12.520)$$

- Coalescence birth:

$$[L_7]_{IQJ} = - H \left( \xi_{iq_\xi} - \sqrt[3]{2\xi_{\min}^3} \right) \times \frac{\xi_{iq_\xi}^2 V(\xi_{iq_\xi})}{2} \frac{\ell_{j_z}^{P_z}(z_{iq_z})}{\rho_d(z_{iq_z})}$$

$$\begin{aligned}
& \times \sum_{i_{q\zeta}} \left[ \frac{\kappa_C ([\xi_{i_{q\xi}}]^3 - [\zeta_{i_{q\zeta}}]^3)^{1/3}, \zeta_{i_{q\zeta}}}{[\xi_{i_{q\xi}}]^3 - [\zeta_{i_{q\zeta}}]^3)^{2/3}} \right. \\
& \times \frac{f_{j_\zeta j_z}^{\nu-1}}{V(\zeta_{i_{q\zeta}})} \frac{\ell_{j_\xi}^{P_\xi} ([\xi_{i_{q\xi}}]^3 - [\zeta_{i_{q\zeta}}]^3)^{1/3}}{[V(\xi_{i_{q\xi}}) - V(\zeta_{i_{q\zeta}})]} \\
& \left. \times W_{i_{q\zeta}}^{P_\zeta} (\xi_{\min}, [\xi_{i_{q\xi}}]^3 - [\xi_{\min}]^3)^{1/3} \right]
\end{aligned} \tag{12.521}$$

- The total problem matrix is obtained by summarizing the sub-matrices:

$$[L]_{I_Q J} = \sum_{q=1}^7 [L_q]_{I_Q J} \tag{12.522}$$

In the above equations, the heaviside function is defined with the following properties:

$$H(\Psi) = \begin{cases} 0 & \text{for } \Psi \leq 0 \\ 1 & \text{for } \Psi \geq 0 \end{cases} \tag{12.523}$$

Thus, with the Heaviside function special care is introduced at the boundaries of the  $\xi$ -domain in order to preserve the mass of the system.

The *Picard iteration technique* is generally employed in the nonlinear coalescence birth and death terms. The term  $f_{j_\zeta j_z}^{\mathcal{P}, \nu-1}$  in the coalescence birth term is approximated as:

$$f_{j_\zeta j_z}^{\nu-1} = \sum_{j_\xi}^{P_\xi} f_{j_\xi j_z}^{\nu-1} \times \ell_{j_\xi}^{P_\xi} (\xi_{i_{q\zeta}}) \tag{12.524}$$

The source term vector is given as:

$$[\mathbf{g}]_{I_Q} = 0 \tag{12.525}$$

Considering the weak formulation of the least-squares method. Based on the boundary conditions presented in this section, the boundary condition matrix  $B$ , defined by (12.481), is given as:

$$B = \begin{bmatrix} \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix} & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \\ \vdots & \vdots & \ddots & \vdots \\ \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \\ \vdots & \vdots & \ddots & \vdots \\ \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} & \dots & \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix} \end{bmatrix} \quad (12.526)$$

where the sub-matrices are of dimension  $(P_\xi + 1) \times (P_\xi + 1)$ . Moreover, the boundary condition vector is given by

$$\begin{aligned} [\mathbf{f}_I]_{I_Q} = & [f(\xi_0, z_0), f(\xi_1, z_0), \dots, f(\xi_{P_\xi}, z_0), f(\xi_0, z_1), \\ & 0, \dots, f(\xi_0, z_2), 0, \dots, \dots, f(\xi_0, z_{P_z}), 0, \dots]^T \end{aligned} \quad (12.527)$$

The computation of the problem operator matrix  $[L]_{I_Q J}$  (12.515)–(12.522) may be performed in an uncomplicated non-optimized manner as illustrated in the pseudo code 2. The interpolation technique and the estimation of the  $f_{j_z j_z}^{\nu-1}$  are illustrated in relation to the integral approximation of the coalescence birth term (12.521). Due to the non-linearity of the PBE, the computations must be iterated until convergence. However, the non-optimized implementation structure presented in the pseudo code 2 is not computationally efficient. In particular, the estimation of the points and weights required in the integrals, and the computation of the Lagrange polynomials are time consuming. Moreover, the number of loops should be reduced to make the computation as efficient as possible. Thus, a significantly more computational efficient structure is sketched in pseudo code 3. In this case, the quadrature points and weights, coalescence frequency kernel and the Lagrange polynomials applied in the interpolations, that are related to the integral approximations of the coalescence birth and death terms, are computed and stored before the iteration loop is entered. By noticing that  $[L_7]_{I_Q J}$  is zero for  $j_z \neq i_{qz}$  due to the property of the Lagrange polynomials, a loop can be avoided by setting  $j_z = i_{qz}$  (see code line 15 in pseudo code 3). Furthermore, a reduction in computational cost can be obtained noticing that the computation of  $f_{j_z j_z}^{\nu-1}$  is not a function of the  $i_{q\xi}$ -index.

It is noted that the convection, growth and breakage terms are linear. Hence, it is not necessary to repeat the computation of (12.515)–(12.519) within the iteration loop. The convective term in physical space is the simplest term to implement. Pseudo code 4 shows the computation of the convective term,  $[L_1]$  (12.515). The algorithm for convection in the property coordinate is presented in pseudo code 5. The algorithms of the breakage death and birth terms are presented in pseudo codes 6 and 7, respectively.

The algebraic system (12.401) can be achieved following the steps of the pseudo code 8. However, for a programming language like MATLAB, it is significantly faster to utilize the matrix operation properties of the program. That is, the computational costs are reduced by computing  $A$  and  $F$  by (12.483)–(12.484), respectively, which avoids the use of more time consuming loops.

## 12.13 Solution of Linear Equation Systems

For steady-state models and models discretized by implicit schemes the result of a discretization process is a system of algebraic equations, which are linear or non-linear according to the nature of the partial differential equation(s) from which they are derived. However, all the existing equation solvers are designed for linear systems. In the non-linear case, the discretized equations must thus be solved in an iterative manner that involves guessing a solution, linearizing the equations about that solution, solving the linearized equations by a linear equation solver, and improving the solution. This process is repeated until a converged result is obtained. Although many procedures can be used to solve the algebraic equations, the available computer resources is a serious constraint. This means that, whether the equations are linear or not, efficient methods for solving linear systems of algebraic equations are required. There are two basic families of solution techniques for linear algebraic equations: Direct- and iterative methods. A well known example of direct methods is Gaussian elimination. The simultaneous storage of all coefficients of the set of equations in core memory is required. Iterative methods are based on the repeated application of a relatively simple algorithm leading to eventual convergence after a number of repetitions (iterations). Well known examples are the Jacobi and Gauss-Seidel point-by-point iteration methods. The discretization of the dynamic 3D multi-fluid model equations, for example, normally leads to a large number of sparse linear algebraic equations. Computer efficiency and storage are thus important aspects to consider when selecting an optimal solver for these problems. Direct methods are usually robust at the cost of large storage requirements. In contrast, iterative methods need less storage capacity while their performance may be problem dependent. Iterative

solvers that take advantage of the sparsity of the discretization matrix are thus generally preferable for problems comprising a large number of variables.

### 12.13.1 Point-Iterative Methods

Consider a system of  $n$  equations and  $n$  unknowns in matrix form,

$$\mathcal{A}\mathbf{x} = \mathbf{b} \quad (12.528)$$

This problem can be expressed in an element form where the coefficients of matrix  $\mathcal{A}$  can be seen explicitly:

$$\sum_{j=1}^n a_{ij}x_j = b_i \quad (12.529)$$

In the Jacobi method, we rearrange the system of equations to place the contribution due to  $x_i$  on the LHS of the  $i$ th equation and the other terms on the RHS, and we divide both sides of the equation by  $a_{ii}$ .

The iteration equation for the *Jacobi method* is written as:

$$x_i^\nu = -\sum_{\substack{j=1 \\ j \neq i}}^n \frac{a_{ij}}{a_{ii}} x_j^{\nu-1} + \frac{b_i}{a_{ii}}, \quad i = 1, 2, 3, \dots, n \quad (12.530)$$

The iteration equation for the *Gauss-Seidel method* is obtained employing the last available values within the iteration process:

$$x_i^\nu = -\sum_{j=1}^{i-1} \frac{a_{ij}}{a_{ii}} x_j^\nu - \sum_{j=i+1}^n \frac{a_{ij}}{a_{ii}} x_j^{\nu-1} + \frac{b_i}{a_{ii}}, \quad i = 1, 2, 3, \dots, n \quad (12.531)$$

The convergence rate of the Jacobi and Gauss-Seidel methods depends on the properties of the iteration matrix. By experience, it has been found that these methods can be improved by the introduction of a relaxation parameter  $\alpha$ . Consider the Gauss-Seidel method, it can be rewritten as:

$$x_i^\nu = x_i^{\nu-1} - \alpha \left[ \sum_{j=1}^{i-1} \frac{a_{ij}}{a_{ii}} x_j^\nu - \sum_{j=i}^n \frac{a_{ij}}{a_{ii}} x_j^{\nu-1} + \frac{b_i}{a_{ii}} \right], \quad i = 1, 2, 3, \dots, n \quad (12.532)$$

When  $\alpha = 1$ , the original Gauss-Seidel method is recovered. Other values of the parameter  $\alpha$  yields different iterative sequences. If  $0 < \alpha < 1$  then the procedure is an under-relaxation method, else with  $\alpha > 1$  we have obtained an approach that is called the successive over-relaxation (SOR) technique. Unfortunately, the optimum

value of the relaxation parameter is problem and grid dependent, hence it is difficult to give precise guidance. Besides, the convergence rate of the point-iterative methods rapidly reduces as the grid is refined.

### 12.13.2 The Tri-Diagonal Matrix Algorithm

The matrices derived from partial differential equations are always sparse, i.e., most of their elements are zero. For one-dimensional systems the discretization process leads to tri-diagonal systems, a system with only three non-zero coefficients per equation. Since the systems are often very large we find that iterative methods are generally much more economical than direct methods. Jacobi and Gauss-Seidel iterative methods are easy to implement in simple computer programs, but they can be slow to converge when the system of equations is large. Hence they are not considered suitable for CFD simulations. The tri-diagonal matrix algorithm (TDMA) of Thomas [233] was commonly used in the period from the late 1960s to the early 1990s. The TDMA is a direct method for one-dimensional situations, but it can be applied iteratively, in a line-by-line fashion, to solve multi-dimensional problems (in a line wise Gauss-Seidel approach). There are, however, other algorithms which may be more robust concerning stability, but TDMA requires a minimum of storage and is often less expensive than the alternative techniques.

For convenience in presenting the TDMA algorithm, a somewhat different nomenclature will be used [164]. Suppose the grid points were numbered  $1, 2, 3, \dots, N$ , with points 1 and  $N$  denoting the boundary points. Consider a system of equations that has a tri-diagonal form:

$$a_i \phi_i = b_i \phi_{i+1} - c_i \phi_{i-1} + d_i \quad (12.533)$$

for  $i = 1, 2, 3, \dots, N$ . Thus, the variable  $\phi_i$  is related to the neighboring variables  $\phi_{i+1}$  and  $\phi_{i-1}$ . To account for the special form of the boundary-point equations, set  $c_1 = 0$  and  $b_N = 0$ , so that the variables  $\phi_0$  and  $\phi_{N+1}$  will not have any meaningful role to play. When the boundary values are given, these boundary point equations take a rather trivial form. For example, if  $\phi_1$  is given, we have  $a_1 = 0$ ,  $b_1 = 0$ ,  $c_1 = 0$ , and  $d_1 =$  the given value of  $\phi_1$ .

The basic equation above can be rewritten as:

$$\phi_i = \frac{b_i}{a_i} \phi_{i+1} - \frac{c_i}{a_i} \phi_{i-1} + \frac{d_i}{a_i} \quad (12.534)$$

These equations can be solved by forward elimination and back-substitution.

In the forward elimination process we seek a relation:

$$\phi_i = P_i \phi_{i+1} + Q_i \quad (12.535)$$

after we have just obtained:

$$\phi_{i-1} = P_{i-1}\phi_i + Q_{i-1} \quad (12.536)$$

Substitution of Eq. (12.536) into (12.533) leads to:

$$a_i\phi_i = b_i\phi_{i+1} - c_i(P_{i-1}\phi_i + Q_{i-1}) + d_i \quad (12.537)$$

which can be rearranged to the form of Eq. (12.535). In other words, the coefficients  $P_i$  and  $Q_i$  is then given by:

$$P_i = \frac{b_i}{a_i - c_i P_{i-1}} \quad (12.538)$$

$$Q_i = \frac{d_i + c_i Q_{i-1}}{a_i - c_i P_{i-1}} \quad (12.539)$$

These are recurrence relations, since they give  $P_i$  and  $Q_i$  in terms of  $P_{i-1}$  and  $Q_{i-1}$ . At the boundary points we see that for  $i = 1$ ,  $P_1 = \frac{b_1}{a_1}$  and  $Q_1 = \frac{d_1}{a_1}$ , and for  $i = N$  we obtain  $P_N = 0$  and  $Q_N = 0$ .

For the *back-substitution* we use the general form of the recurrence relationship (12.535).

The iterative procedure is considered to give a converged solution if the absolute normalized residuals for all the variables as well as the mass source  $b$  of the pressure correction equation are less than a prescribed small value, denoting the convergence criterion. The absolute normalized residual is defined as:

$$R_{\psi}^{\nu} = \frac{\sum_{\text{all nodes}} |\sum_{nb} a_{nb}\psi_{nb} + S_C - a_P\psi_P|^{\nu}}{F_{in,\psi}} \quad (12.540)$$

and for the pressure correction equation:

$$R_{\text{mass}}^{\nu} = \frac{\sum_{\text{all nodes}} |b|^{\nu}}{M_{in,\text{mass}}} \quad (12.541)$$

The  $F_{in,\psi}$  denotes the total inflow of the property  $\psi$  into the calculation domain and  $M_{in,\text{mass}}$  represents the total inflow of mass. The prescribed small threshold value used to define the convergence criterion is problem dependent and may vary with grid resolution. Nevertheless, the iteration is generally aborted when the normalized residuals for all the variables fall below  $10^{-3}$ .

Note that this solver fail to converge when applied to algebraic equation systems which are not diagonally dominant. For non-linear and multi-dimensional problems, the algorithm is used in a line-wise Gauss-Seidel approach. The convergence rate for linear multi-dimensional problems is generally severely degraded when only one

dimension can be considered at the time, so multidimensional iterative algorithms may be preferable.

### 12.13.3 Krylov Subspace Methods

The conjugate gradient algorithm of Hestenes and Stiefel [84] and the bi-conjugate gradient algorithm of Fletcher [60] and their preconditioned versions [205] are presented in the following sections. Consider a system of linear algebraic equations written on the form  $\mathcal{A}\mathbf{x} = \mathbf{b}$ . The basic idea of the Krylov subspace methods is to project a large problem onto a Krylov subspace by constructing a basis of the subspace. The Krylov subspace methods form an orthogonal basis of the sequence of successive matrix powers times the initial residual (the Krylov sequence). The approximations to the solution are then formed by minimizing the residual over the subspace formed. The projected subspace problem is solved by a standard well established technique before an approximate solution of the original problem is recovered from the solution of the projected problem. The numerous variants of the Krylov subspace methods arise from different choices of basis of the Krylov subspace. The prototype method in this class is the conjugate gradient method (CG). Another popular method in this class, the bi-conjugate gradient method (BCG) is more advanced and better suited for solving problems giving rise to unsymmetric  $\mathcal{A}$ -matrices. Several extensions of the BCG-method have been developed (e.g., the Conjugate Gradient Squared (CGS) method, the bi-orthogonal Conjugate Gradient Stabilized (BCGSTAB), etc.), intending to reduce the computational costs of the BCG method. The generalized minimal residual method (GMRES) proposed by Saad and Shultz [204] is also designed for unsymmetric matrices and is one of the most advanced methods in this class that among other things may treat nearly singular systems, but also one of the most computationally intensive methods.

In cases where iterative methods are employed to solve large, sparse linear systems, both the efficiency and robustness of these methods can be significantly improved by use of preconditioners. A preconditioner  $\mathcal{M}$  of a matrix  $\mathcal{A}$  is a matrix such that  $\mathcal{M}^{-1}\mathcal{A}$  has a smaller condition number than  $\mathcal{A}$ . The condition number associated with such a problem is a measure of that problem's amenability to digital computation, that is, how numerically well-posed the problem is. A problem with a low condition number is said to be well-conditioned, while a problem with a high condition number is said to be ill-conditioned. In particular, if  $\mathcal{M}$  is a symmetric, positive definite matrix<sup>14</sup> that approximates the original  $\mathcal{A}$  matrix but is easier to invert, the original problem  $\mathcal{A}\mathbf{x} = \mathbf{b}$  can be solved indirectly by solving  $\mathcal{M}^{-1}\mathcal{A}\mathbf{x} = \mathcal{M}^{-1}\mathbf{b}$ . However, the advanced preconditioners are generally more computationally expensive than the simpler ones. Although the number of iterations is normally reduced

<sup>14</sup> The matrix  $\mathcal{M}$  is symmetric if  $\mathcal{A} = \mathcal{A}^T$ . The matrix is said to be positive definite if the Euclidean inner product  $(\mathbf{x}, \mathcal{M}\mathbf{x}) > 0$  whenever  $\mathbf{x} \neq 0$  [205]. The Euclidean inner product between two vectors  $\mathbf{x}$  and  $\mathbf{y}$  is defined as  $(\mathbf{x}, \mathbf{y}) = \mathbf{x}^T \mathbf{y} = \sum_{l=1}^n x_l y_l$ .

with increasing complexity of the preconditioner, the total computational cost may not necessarily be improved. An aim when designing appropriate preconditioners is to find a suitable balance between the computational time required by the preconditioner and the solver. One simple, but computationally inexpensive and effective preconditioner suitable for diagonally dominant matrices is the *Jacobi preconditioner*. This preconditioner contains only the diagonal elements of the  $\mathcal{A}$ -matrix:

$$\mathcal{M} = \text{diag}(\mathcal{A}) \quad (12.542)$$

More complex preconditioners are the incomplete LU-preconditioners (ILU) given on the form:

$$\mathcal{M} = \mathcal{L}\mathcal{U} \quad (12.543)$$

in which  $\mathcal{L}$  and  $\mathcal{U}$  are the lower- and upper triangular matrices, derived by Gauss-elimination where certain fill elements are ignored (hence the name incomplete).

The most efficient Krylov subspace method is the method of Conjugate Gradients (CG) by Hestenes and Stiefel [84]. If  $\mathcal{A}$  is symmetric positive definite, the solution of the problem  $\mathcal{A}\mathbf{x} = \mathbf{b}$  corresponds to determining a local minimum of the quadratic function:

$$f(\mathbf{x}) = \frac{1}{2}\mathbf{x}^T \mathcal{A}\mathbf{x} - \mathbf{b}^T \mathbf{x} \quad (12.544)$$

The basis used in this method is conjugate search directions and orthogonal residuals<sup>15</sup> which is equivalent to finding a minimum point along the search directions.

### 12.13.3.1 The Conjugate Gradient Algorithm

In a linear system  $\mathcal{A}\mathbf{x} = \mathbf{b}$  where the matrix  $\mathcal{A}$  is symmetric and positive definite, the solution is obtained by minimizing the quadratic form (12.544). This implies that the gradient,  $f'(\mathbf{x}) = \mathcal{A}\mathbf{x} - \mathbf{b}$ , is zero. In the iteration procedure an approximate solution,  $\mathbf{x}_{m+1}$ , can be expressed as a linear combination of the previous solution and a search direction,  $\mathbf{p}_m$ , which is scaled by a scaling factor  $\alpha_m$ :

$$\mathbf{x}_{m+1} = \mathbf{x}_m + \alpha_m \mathbf{p}_m \quad (12.545)$$

An indication of how far the approximated solution is from the real solution is given by the residual:

$$\mathbf{r}_{m+1} = -f'(\mathbf{x}_{m+1}) = \mathbf{b} - \mathcal{A}\mathbf{x}_{m+1} = \mathbf{r}_m - \alpha_m \mathcal{A}\mathbf{p}_m \quad (12.546)$$

---

<sup>15</sup> If the matrix  $\mathcal{A}$  is symmetric, then two vectors  $\mathbf{x}$  and  $\mathbf{y}$  are conjugate or  $\mathcal{A}$ -orthogonal if the  $\mathcal{A}$ -inner product  $(\mathbf{x}, \mathbf{y})_{\mathcal{A}} = (\mathcal{A}\mathbf{x}, \mathbf{y}) = (\mathbf{x}, \mathcal{A}\mathbf{y}) = 0$  holds [205]. Vectors are orthogonal if  $(\mathbf{x}, \mathbf{y}) = 0$ .

In order to determine scaling factor and thereby the step length, the quadratic function  $f(\mathbf{x}_{m+1})$  has to be minimized with respect to  $\alpha_m$ :

$$\frac{d}{d\alpha_m} f(\mathbf{x}_{m+1}) = f'(\mathbf{x}_{m+1})^T \frac{d\mathbf{x}_{m+1}}{d\alpha_m} = -\mathbf{r}_{m+1}^T \mathbf{p}_m = 0 \quad (12.547)$$

By using the definition the residual (12.546) in (12.547) and switching to the inner product notation  $\mathbf{r}_{m+1}^T \mathbf{p}_m = (\mathbf{r}_{m+1}, \mathbf{p}_m)$  results in:

$$\alpha_m = \frac{(\mathbf{r}_m, \mathbf{p}_m)}{(\mathcal{A}\mathbf{p}_m, \mathbf{p}_m)} \quad (12.548)$$

If the next search direction is a linear combination of the previous search direction scaled by a factor  $\beta_m$  and the residual  $\mathbf{r}_{m+1}$ :

$$\mathbf{p}_{m+1} = \mathbf{r}_{m+1} + \beta_m \mathbf{p}_m \quad (12.549)$$

A consequence of (12.549) and (12.547) is:

$$(\mathbf{r}_m, \mathbf{p}_m) = (\mathbf{r}_m, \mathbf{r}_m + \beta_{m-1} \mathbf{p}_{m-1}) = (\mathbf{r}_m, \mathbf{r}_m) \quad (12.550)$$

Then (12.548) becomes:

$$\alpha_m = \frac{(\mathbf{r}_m, \mathbf{r}_m)}{(\mathbf{p}_m, \mathcal{A}\mathbf{p}_m)} \quad (12.551)$$

Moreover, it can be shown that the residuals are orthogonal when requiring conjugate search directions, i.e.  $(\mathbf{p}_m, \mathcal{A}\mathbf{p}_{m-1}) = (\mathcal{A}\mathbf{p}_m, \mathbf{p}_{m-1}) = 0$

$$\begin{aligned} (\mathbf{r}_{m+1}, \mathbf{p}_m) &= (\mathbf{r}_{m+1}, \mathbf{r}_m + \beta_{m-1} \mathbf{p}_{m-1}) \\ &= (\mathbf{r}_{m+1}, \mathbf{r}_m) + (\mathbf{r}_m - \alpha \mathcal{A}\mathbf{p}_m, \beta_{m-1} \mathbf{p}_{m-1}) \\ &= (\mathbf{r}_{m+1}, \mathbf{r}_m) = 0 \end{aligned} \quad (12.552)$$

The conjugacy constrain is also applied when determining the scaling factor,  $\beta_m$ , from (12.549):

$$\beta_m = -\frac{(\mathbf{r}_{m+1}, \mathcal{A}\mathbf{p}_m)}{(\mathbf{p}_m, \mathcal{A}\mathbf{p}_m)} \quad (12.553)$$

This equation can be reformulated by using (12.546), (12.552) and (12.551):

$$\beta_m = \frac{1}{\alpha_m} \frac{(\mathbf{r}_{m+1}, \mathbf{r}_{m+1} - \mathbf{r}_m)}{(\mathbf{p}_m, \mathcal{A}\mathbf{p}_m)} = \frac{1}{\alpha_m} \frac{(\mathbf{r}_{m+1}, \mathbf{r}_{m+1})}{(\mathbf{p}_m, \mathcal{A}\mathbf{p}_m)} = \frac{(\mathbf{r}_{m+1}, \mathbf{r}_{m+1})}{(\mathbf{r}_m, \mathbf{r}_m)} \quad (12.554)$$

Putting these relations together gives the following algorithm:

**ALGORITHM 1** The conjugate gradient (CG) algorithm.

$m = 0$

$\mathbf{p}_m = \mathbf{r}_m = \mathbf{b} - \mathcal{A}\mathbf{x}_m$

**while** not convergence **do**

$$\alpha_m = \frac{(\mathbf{r}_m, \mathbf{r}_m)}{(\mathbf{p}_m, \mathcal{A}\mathbf{p}_m)}$$

$$\mathbf{x}_{m+1} = \mathbf{x}_m + \alpha_m \mathbf{p}_m$$

$$\mathbf{r}_{m+1} = \mathbf{r}_m - \alpha_m \mathcal{A}\mathbf{p}_m$$

$$\beta_m = \frac{(\mathbf{r}_{m+1}, \mathbf{r}_{m+1})}{(\mathbf{r}_m, \mathbf{r}_m)}$$

$$\mathbf{p}_{m+1} = \mathbf{r}_{m+1} + \beta_m \mathbf{p}_m$$

$$m = m + 1$$

**end while**

The result is  $\mathbf{x}_{m+1}$ .

### 12.13.4 Preconditioning

Preconditioning is a technique which improves the condition number of a matrix and thereby increases the convergence rate of Krylov subspace methods. Thus, if the preconditioner  $\mathcal{M}$  is a symmetric, positive definite matrix, the original problem  $\mathcal{A}\mathbf{x} = \mathbf{b}$  can be solved indirectly by solving  $\mathcal{M}^{-1}\mathcal{A}\mathbf{x} = \mathcal{M}^{-1}\mathbf{b}$ . The residual can then be written as:

$$\mathbf{z}_{m+1} = \mathcal{M}^{-1}\mathbf{r}_{m+1} = \mathbf{z}_m - \mathcal{M}^{-1}\alpha_m \mathcal{A}\mathbf{p}_m \quad (12.555)$$

Using this relation, the condition (12.547) can be expressed in terms of the  $\mathcal{M}$ -inner product:

$$(\mathbf{r}_{m+1}, \mathbf{p}_m) = (\mathcal{M}\mathbf{z}_{m+1}, \mathbf{p}_m) = (\mathbf{z}_{m+1}, \mathbf{p}_m)_{\mathcal{M}} = 0 \quad (12.556)$$

The new search direction is now a linear combination of the previous search direction and  $\mathbf{z}_{m+1}$ :

$$\mathbf{p}_{m+1} = \mathbf{z}_{m+1} + \beta_m \mathbf{p}_m \quad (12.557)$$

With the same procedures used in the previous section the scaling factors,  $\alpha_m$  and  $\beta_m$ , then becomes:

$$\alpha_m = \frac{(\mathbf{z}_m, \mathbf{z}_m)_{\mathcal{M}}}{(\mathcal{M}^{-1}\mathcal{A}\mathbf{p}_m, \mathbf{p}_m)_{\mathcal{M}}} = \frac{(\mathbf{z}_m, \mathbf{r}_m)}{(\mathcal{A}\mathbf{p}_m, \mathbf{p}_m)} \quad (12.558)$$

$$\beta_m = \frac{(\mathbf{z}_{m+1}, \mathbf{z}_{m+1})_{\mathcal{M}}}{(\mathbf{z}_m, \mathbf{z}_m)_{\mathcal{M}}} = \frac{(\mathbf{r}_{m+1}, \mathbf{z}_{m+1})}{(\mathbf{r}_m, \mathbf{z}_m)} \quad (12.559)$$

This result comprises an algorithm that can be summarized as follows:

**ALGORITHM 2** The preconditioned conjugate gradient (CG) algorithm

```

 $m = 0$ 
 $\mathbf{r}_m = \mathbf{b} - \mathcal{A}\mathbf{x}_m$ 
 $\mathbf{p}_m = \mathbf{z}_m = \mathcal{M}^{-1}\mathbf{r}_m$ 
while not convergence do
   $\alpha_m = \frac{(\mathbf{z}_m, \mathbf{r}_m)}{(\mathbf{p}_m, \mathcal{A}\mathbf{p}_m)}$ 
   $\mathbf{x}_{m+1} = \mathbf{x}_m + \alpha_m \mathbf{p}_m$ 
   $\mathbf{r}_{m+1} = \mathbf{r}_m - \alpha_m \mathcal{A}\mathbf{p}_m$ 
   $\mathbf{z}_{m+1} = \mathcal{M}^{-1}\mathbf{r}_{m+1}$ 
   $\beta_m = \frac{(\mathbf{z}_{m+1}, \mathbf{r}_{m+1})}{(\mathbf{z}_m, \mathbf{r}_m)}$ 
   $\mathbf{p}_{m+1} = \mathbf{z}_{m+1} + \beta_m \mathbf{p}_m$ 
   $m = m + 1$ 
end while

```

A weakness of the CG-method is the restriction to symmetric matrices. Thus, there is no guarantee for convergence when applying the algorithm to equation systems that are not symmetric. For that reason, for the flow models only the Poisson equation is normally solved using the CG-method, the other equations are solved using the bi-conjugate gradient method (BCG) of Fletcher [60] which is a generalization of the CG-method for solving systems of equations that are not necessarily symmetric or positive definite. With a doubling of the computational costs per iteration, non-symmetric systems can be converted into a symmetric system of double size:

$$\begin{bmatrix} 0 & \mathcal{A}_k \\ \mathcal{A}_k^T & 0 \end{bmatrix} \begin{bmatrix} \mathbf{x}_k^* \\ \mathbf{x}_k \end{bmatrix} = \begin{bmatrix} \mathbf{b}_k \\ \mathbf{b}_k^* \end{bmatrix} \quad (12.560)$$

However, since the expanded system is indefinite the minimization argument of the CG-method becomes ineffective. The CG-method is thus modified by replacing the orthogonal sequence of residuals by two mutually orthogonal sequences. In addition, the conjugacy constraint of the search directions is replaced by a corresponding conjugacy constraint of the two mutual search directions.

#### 12.13.4.1 The Bi-Conjugate Gradient Algorithm

The BCG-method is an extension of the CG-method for systems that are not symmetric or positive definite. Systems involving non-symmetric matrices, can be turned into symmetric systems on the form (12.560). Due to the indefinite matrix in this expanded system, the original CG-method is somewhat modified since the minimization argument becomes ineffective. The residual norm may even increase during iterations. With the following constrains:

$$(\mathbf{r}_{m+1}, \mathbf{r}_m^*) = (\mathbf{r}_m, \mathbf{r}_{m+1}^*) = 0 \quad (12.561)$$

$$(\mathcal{A}\mathbf{p}_{m+1}, \mathbf{p}_m^*) = (\mathcal{A}\mathbf{p}_m, \mathbf{p}_{m+1}^*) = 0 \quad (12.562)$$

the BCG-method can be derived in the same manner as the CG-method.

**ALGORITHM 3** The bi-conjugate gradient algorithm

$m = 0$

$\mathbf{p}_m^* = \mathbf{p}_m = \mathbf{r}_m^* = \mathbf{r}_m = \mathbf{b} - \mathcal{A}\mathbf{x}_m$

**while** not convergence **do**

$$\alpha_m = \frac{(\mathbf{r}_m, \mathbf{r}_m^*)}{(\mathbf{p}_m^*, \mathcal{A}\mathbf{p}_m)}$$

$$\mathbf{x}_{m+1} = \mathbf{x}_m + \alpha_m \mathbf{p}_m$$

$$\mathbf{r}_{m+1} = \mathbf{r}_m - \alpha_m \mathcal{A}\mathbf{p}_m$$

$$\mathbf{r}_{m+1}^* = \mathbf{r}_m^* - \alpha_m \mathcal{A}^T \mathbf{p}_m^*$$

$$\beta_m = \frac{(\mathbf{r}_{m+1}, \mathbf{r}_{m+1}^*)}{(\mathbf{r}_m, \mathbf{r}_m^*)}$$

$$\mathbf{p}_{m+1} = \mathbf{r}_{m+1} + \beta_m \mathbf{p}_m$$

$$\mathbf{p}_{m+1}^* = \mathbf{r}_{m+1}^* + \beta_m \mathbf{p}_m^*$$

$$m = m + 1$$

**end while**

The preconditioner is introduced in the same manner as in the CG-algorithm, leading to Algorithm 4.

**ALGORITHM 4** The preconditioned bi-conjugate gradient algorithm

$m = 0$

$\mathbf{r}_m^* = \mathbf{r}_m = \mathbf{b} - \mathcal{A}\mathbf{x}_m$

$\mathbf{p}_m^* = \mathbf{p}_m = \mathbf{z}_m^* = \mathbf{z}_m = \mathcal{M}^{-1} \mathbf{r}_m$

**while** not convergence **do**

$$\alpha_m = \frac{(\mathbf{z}_m, \mathbf{r}_m^*)}{(\mathbf{p}_m^*, \mathcal{A}\mathbf{p}_m)}$$

$$\mathbf{x}_{m+1} = \mathbf{x}_m + \alpha_m \mathbf{p}_m$$

$$\mathbf{r}_{m+1} = \mathbf{r}_m - \alpha_m \mathcal{A}\mathbf{p}_m$$

$$\mathbf{r}_{m+1}^* = \mathbf{r}_m^* - \alpha_m \mathcal{A}^T \mathbf{p}_m^*$$

$$\mathbf{z}_{m+1} = \alpha_m \mathcal{M}^{-1} \mathbf{r}_{m+1}$$

$$\mathbf{z}_{m+1}^* = \alpha_m \mathcal{M}^{-1} \mathbf{r}_{m+1}^*$$

$$\beta_m = \frac{(\mathbf{z}_{m+1}, \mathbf{r}_{m+1}^*)}{(\mathbf{z}_m, \mathbf{r}_m^*)}$$

$$\mathbf{p}_{m+1} = \mathbf{z}_{m+1} + \beta_m \mathbf{p}_m$$

$$\mathbf{p}_{m+1}^* = \mathbf{z}_{m+1}^* + \beta_m \mathbf{p}_m^*$$

$$m = m + 1$$

**end while**

The initial guess required in the iteration process is normally set equal to the variable values at the previous time step. The variable values at the current time level are expected to be close to the values at the previous time level. This is not necessarily true for the pressure correction due to the short time scales associated with the pressure. Thus, the initial guess for the pressure corrections are normally set to zero.

Both preconditioners are normally very robust and efficient, but the ILU-preconditioner can introduce small numerical perturbations due to floating point round-off error. Thus, simulations of symmetric problems may give non-symmetric results after some time. For this reason the Jacobi preconditioner is recommended.

### 12.13.4.2 Convergence Criteria

The solver must stop when an acceptable accurate solution is found. A stop criterion must thus be defined by a sufficiently small residual value or preferably a norm<sup>16</sup> of the residual [205]. In the non-preconditioned CG-method it is natural to use the 2-norm since the euclidean inner product  $(\mathbf{r}, \mathbf{r})$  is already calculated as part of the algorithm. This is not the case neither in the preconditioned version of the CG-solver nor the BCG-methods. In these methods extra computations are thus required to calculate the stop criterion. For that reason, the less expensive infinity-norm is frequently used as stop criterion for these solvers. One possible criterion is that the norm of the residual must fall below a specific value  $\|\mathbf{r}\|_m < \epsilon$ . However, this criterion is difficult to use when employing the  $p$ -norm since this norm is grid dependent. Besides, the tolerance  $\epsilon$  has to be fit to the system under consideration since the residuals in the various systems may approach different values due to round-off errors. The first issue may be solved by requiring the norm of the residual to fall below some small fraction of the norm of the initial residual  $\|\mathbf{r}_m\| < \epsilon\|\mathbf{r}_0\|$ . However, situations where the initial guess is close to the solution may cause infinite looping since the algorithm is not able to fulfill the stop criterion due to the round-off errors. The most frequently used stop criterion is defined requiring that the norm of the residual must fall below a small fraction of the norm of the source term  $\|\mathbf{r}_m\| < \epsilon\|\mathbf{b}\|$ .

### 12.13.5 Multigrid Solvers

In this section the basic concepts of the multigrid solvers are outlined. Details of the advanced multigrid procedures may be found in the appropriate literature [23–25, 79, 91, 92, 188, 189, 196, 249, 256].

Multigrid acceleration of the Gauss-Seidel point-iterative method is currently used in many commercial CFD codes to solve the system of algebraic equations resulting from the discretization of the governing equations. For this reason, the basic principles and nomenclature must be known by the users of commercial codes and in particular for researchers that are making their own codes.

Consider a large system of algebraic equations arising from the discretization of the governing equations on a reactor flow domain:

---

<sup>16</sup> Several stop criteria can be defined in terms of different norms of the residual [205]. The general  $p$ -norm of a vector is defined as  $\|\mathbf{r}\|_p = (\sum_{i=1}^n |r_i|^p)^{1/p}$ . When  $p$  tends to infinity, the vector norm becomes  $\|\mathbf{r}\|_\infty = \max |\mathbf{r}|$ .

$$\mathcal{A}\mathbf{x} = \mathbf{b} \quad (12.563)$$

If we solve this system with an iterative method, we obtain an intermediate solution  $\mathbf{x}^\nu$  after  $\nu$  iterations. This intermediate solution does not satisfy (12.563) exactly, and to determine the error in  $\mathbf{x}^\nu$  we define the residual as follows:

$$\mathbf{r}^\nu = \mathbf{b} - \mathcal{A}\mathbf{x}^\nu \quad (12.564)$$

In the multigrid concept it is essential to define an error vector  $\mathbf{e}$  as the difference between the true solution and the intermediate solution:

$$\mathbf{e}^\nu = \mathbf{x} - \mathbf{x}^\nu \quad (12.565)$$

Subtracting  $\mathcal{A}\mathbf{x}^\nu = \mathbf{b} - \mathbf{r}^\nu$ , i.e., a rearranged form of (12.564), from (12.563) gives the following relationship between the error and the residual vector:

$$\mathcal{A}\mathbf{e}^\nu = \mathbf{r}^\nu \quad (12.566)$$

The residual vector can then be calculated at any stage of the iteration process by substituting the intermediate solution into (12.564).

Multigrid methods are designed to exploit the inherent differences of the error behavior when performing iterations on grids of different sizes. It has been established theoretically that the solution error has components with a range of wavelengths that are multiples of the grid spacing. The iteration methods cause rapid reduction of the error components with short wavelengths up to a few multiples of the grid spacing. However, the long-wavelength components of the error representing several multiples of the grid spacing tend to decay very slowly as the iteration count increases. The short-wavelength errors in a particular problem are thus effectively reduced on high resolution grids, whereas the long-wavelength errors decrease rapidly on low resolution grids. Besides, the computational cost of the iterations is larger on finer high resolution grids than on coarse low resolution grids. The extra cost due to iterations on the coarse grids may thus be offset by the benefit of the improved convergence rates.

The basic principles of multigrid solvers may be made clear by a brief sketch of a simple two-stage procedure comprising one fine ( $h$ ) and one coarse ( $2h$ ) grid. In principle, the fine grid solution can be transferred from the fine grid with spacing  $h$  onto any coarse grid with spacing  $ch$ , where  $c > 1$ . However, the process of transferring can be greatly simplified if we use a coarse grid with twice the mesh spacing of the fine grid.

*A two-stage procedure:*

1. *Fine grid iterations.*

In this step we perform iterations on the finest grid with grid spacing  $h$  to generate an intermediate solution  $\mathbf{x}^\nu$  to system  $\mathcal{A}^h\mathbf{x} = \mathbf{b}$ . The number of iterations is normally chosen sufficiently large so that the short-wavelength oscillatory component

of the error is reduced, but no attempt is made to eliminate the long-wavelength error component. The residual vector  $\mathbf{r}^{h,\nu}$  for the solution on this grid satisfies  $\mathbf{r}^{h,\nu} = \mathbf{b} - \mathcal{A}^h \mathbf{x}^{h,\nu}$  and the error vector  $\mathbf{e}^{h,\nu}$  is given by  $\mathbf{e}^{h,\nu} = \mathbf{x} - \mathbf{x}^{h,\nu}$ . The error and the residual is related through the formula:  $\mathcal{A}^h \mathbf{e}^{h,\nu} = \mathbf{r}^{h,\nu}$ .

## 2. *Restriction.*

The solution is now transferred from the fine grid with spacing  $h$  onto the coarse grid with spacing  $2h$ . Due to the larger grid spacing of the coarse grid, the long-wavelength error observed on the fine grid now appears as a short-wavelength error on the new grid and will reduce rapidly.

Instead of solving for the solution vector  $\mathbf{x}^{2h,\nu}$  we work with the error equation  $\mathcal{A}^{2h} \mathbf{e}^{2h,\nu} = \mathbf{r}^{2h,\nu}$  on the coarse grid starting with an initial guess of  $\mathbf{e}^{2h,\nu} = \mathbf{0}$ .

To perform the solution process we need values of the residual vector and the matrix of coefficients. Given the values of  $\mathbf{r}^{h,\nu}$  on the fine grid we must use a suitable averaging or interpolation procedure to find the residual vector  $\mathbf{r}^{2h,\nu}$  on the coarse grid. The coefficients of matrix  $\mathcal{A}^{2h}$  can be recomputed from scratch on the coarser grid or evaluated from the fine grid grid coefficient matrix  $\mathcal{A}^h$  by use of a similar averaging/interpolation procedure as employed for the residual vector.

The cost per iteration on the coarse grid is generally less than on the fine grid, hence we may afford to perform a sufficient number of iterations to get a converged solution of the error vector  $\mathbf{e}^{2h,\nu}$ .

## 3. *Prolongation.*

After obtaining the converged solution of the error vector  $\mathbf{e}^{2h,\nu}$  for the coarse grid, we need to transfer the solution back to the fine grid. However, we have fewer solution points in the coarse grid than nodes in the fine grid. A convenient interpolation operator is required to generate values for the prolonged error vector  $\tilde{\mathbf{e}}^{h,\nu}$  at intermediate points in the fine grid. Linear interpolation is commonly used for this purpose.

## 4. *Correction and final iterations.*

Once we have calculated the prolonged error vector  $\tilde{\mathbf{e}}^{h,\nu}$  we may correct the intermediate fine grid solution by use of the formula:

$$\mathbf{x}^{\text{improved},\nu} = \mathbf{x}^{h,\nu} + \tilde{\mathbf{e}}^{h,\nu} \quad (12.567)$$

Because the long-wavelength error has been eliminated, the improved solution  $\mathbf{x}^{\text{improved},\nu}$  is generally closer to the true solution vector  $\mathbf{x}$ . However, several approximations were made, hence a few additional iterations are performed with the improved solution to iron out any errors that may have been introduced during the restriction and prolongation processes.

In practice, the illustrative two-stage procedure is replaced by more advanced multi-grid cycles in which coarsening and refinement are used with special schedules of restriction and prolongation at different refinement levels. Common choices of multi-grid cycles are the so-called V- and W-cycles.

The simple V-cycle consists of two legs. The calculation starts at the finest level. Iterations at any level are called relaxation. After a few relaxation sweeps on the finest level the residuals are restricted to the next coarse level and relaxation on that level the residuals are passed on to the next coarse level, and so on until the coarsest level is reached. After final relaxation on the coarsest level the prolongation steps are performed on the upward leg of the V-cycle until the finest level is reached. In the W-cycle additional restriction and prolongation sweeps are used at coarser levels to obtain better reduction of long-wavelength errors.

The residual  $r_i^\nu$  of the  $i$ -th equation after  $\nu$ -iterations can be defined as:

$$r_i^\nu = b_i - \sum_{j=1}^n a_{ij}x_j^\nu, \quad i = 1, 2, \dots, n \quad (12.568)$$

The average residual  $\bar{r}^\nu$  over all  $n$  equations in the system may be a useful indicator of the iterative convergence for a given problem:

$$\bar{r}^\nu = \frac{1}{n} |r_i^\nu| \quad (12.569)$$

If the iteration process is convergent the average residual tend to zero, since all contributing residuals  $r_i^\nu \rightarrow 0$  as  $\nu \rightarrow \infty$ . The average residual for a transported property  $\psi$  is frequently normalized considering the ratio of the average residual after  $\nu$  iterations and its value at the beginning of the iterations:

$$R_{\text{norm}}^\nu = \frac{\bar{r}^\nu}{\bar{r}^0} \quad (12.570)$$

The iteration is aborted when the normalized residuals for all the variables fall below  $10^{-3}$ .

### 12.13.6 Parallelization and Performance Optimization

Recent experimental studies on the flow structures of multi-phase chemical reactors like bubble column, fluidized bed and stirred tank reactors have provided insight and evidence of the dynamic nature of these systems. Transient multi-phase flow models are thus required to describe the multi-phase flow structure. Furthermore, due to the relatively high holdup of the dispersed phases in operating reactors, the Euler-Euler multi-fluid modeling framework has been adopted in most cases. An important inherent limitation of dynamic multiphase reactor flow simulations is the computational time requirements, making long time statistics intractable. To reduce the computational time of these reactor model simulations, performance optimization may be performed by selecting optimal solvers for the problem in question and by compiler optimization of the problem dependent code. For very large grids, the optimized

code must be parallelized. The compiler is the primary interface to the processor. High level languages like Fortran and C are translated into the level instructions that can be executed on the processor. Compiler optimization and instruction generation decisions can be influenced with compiler switches. These switches may correspond directly to individual modules for optimization, or influence settings of several modules. The compiler performs many optimizations on the source code based on various assumptions about the program. Typical assumptions are:

- The program is large (does not fit into the cache).
- The program does not violate language standards.
- The program is insensitive to round-off errors.
- All data in the program is alias-ed, unless it can prove otherwise.

If one or more of the basic assumptions do not hold, the compiler should be tuned to the program by changing the compiler switches. Otherwise, the outcome may be erroneous. The source of the problem should be located, and the files where the problem occurs should be optimized with a less aggressive optimization.

For one-dimensional problems the direct TDMA algorithm is an efficient solver. In these cases the solver is computationally inexpensive and has the advantage that it requires a minimum amount of storage. For direct solvers, the number of operations to be performed to obtain the solution of a system of equations can be determined beforehand. However, for multi-dimension problems the TDMA algorithm is applied line by line on a selected plane and then the calculation is moved to the next plane, scanning the domain plane by plane. The method is comprising a line-wise Gauss-Seidel iterative approach, hence the transfer of the boundary information into the calculation domain can be very slow. In these simulations the convergence rate depends on the sweep direction, with sweeping from upstream to downstream along the flow direction producing faster convergence than sweeping against the flow or parallel to the flow direction.

For multi-dimensional flow problems iterative methods are preferred compared to direct methods due to less storage requirements. However, the iterative methods generally converge slower than the direct methods and the number of operations to be performed to obtain the solution of a system of equations can generally not be determined beforehand. The convergence rates of the Jacobi and Gauss-Seidel point-iteration methods can be very slow when the system of equations is large. However, the multigrid acceleration techniques that have been developed recently do improve the convergence rates of these iterative solvers to such an extent that they are now commonly used in commercial codes. The Krylov subspace methods are used in many cases as their convergence rates are comparable with those of the multigrid solvers.

Parallel computers can be divided into two classes, based on whether the processors in the system have their own private memory or share a common memory. In a distributed memory system, the processors communicate with each other by sending and receiving messages through a communication network connecting all the processors. The problem to be solved must be explicitly partitioned by the programmer onto the various processors in such a way that load balancing is maintained

and communication between processors is minimized and well ordered. For some problems it may not be easy or even possible to find a satisfactory means of doing such a partitioning. From a programmers point of view, a shared memory multiprocessor is easier to program. All the processors share access to a common memory via a bus or a hierarchy of buses, and communicate with each other through shared variables in the common memory. This makes it possible for the compiler to find parallelism in scalar programs. The compiler analyzes data dependencies in each loop and if data updated is separate from data used for that update, that loop can be computed in parallel. However, this type of parallelization strategy is usually far from being optimal and explicit parallelism have to be introduced using compiler directives. The drawback with single memory device is limitations in performance, and as processors get faster it is harder to connect a considerable number of them to the same memory. To solve this problem, the shared memory is physically distributed to the nodes which may be a processor or a small group of processors. The memory elements have generally different access times to the processors in the system, hence the machines are called non-uniform memory access-machines (NUMA). The use of caches introduce a problem in finding the right copy of a variable among the multiple copies present in the concurrent hierarchical memory system. Some machines provides a full hardware support for keeping the caches coherent. These machines are called cache coherent non-uniform memory access-machines (CC-NUMA). Programs developed for distributed systems can also execute efficiently on shared memory machines, because shared memory permits an efficient implementation of message passing. The lifetime of supercomputers is relatively short, and when updating the computer, different machine architectures may be chosen. Hence, it is often chosen to program models in such a way that the model domain is explicitly partitioned onto the processors, making it portable between supercomputers of both architectures. The scaling of the model performance with the number of processors is usually better with message passing programming (MPI; message passing interface) than with a compiler parallelized code (Open MP) for relatively small problems. However, the preference of the different programming techniques is under debate. A widely used technique for partitioning the solution of a partial differential equation onto a number of processors is the *domain decomposition method* [148]. The space domain is divided into many sub-domains which have their own sub-boundaries. Each sub-domain is assigned to one processor such that the discretized equation system, which is split into sub-systems, one for each sub-domain, may be computed concurrently. This may decrease the convergence rate, but it offers more flexibility and, in most cases, yields a shorter computing time than global parallelization of the single domain solver. The method ensures reasonable load balancing, since the number of grid cells in each sub-domain is approximately equal and the work required for each grid cell is roughly the same. Numerical algorithms, data structures and spatial data dependencies are thus important issues when parallelizing a code. It follows from the single- and multi-fluid models and the standard numerical discretization schemes that the discretized equations may contain both explicit and implicit variable dependencies. The Explicit dependencies require local data communication only, whereas the implicit dependencies may require both local and global communication.

The bottleneck in the Poisson equation algorithms is generally the pressure or pressure correction data communication that is required for every iteration performed within each time step of the integration. Introduction of preconditioners on parallel architectures may not be as favorable as on a single processor due to extra communication costs.

Lindborg et al. [135] did evaluate the performance of several methods for solving the Poisson equations in dynamic 2D fixed bed reactor model simulations. The solvers evaluated were the TDMA-algorithm with and without a global block correction (multigrid) procedure [91, 92] and several variants of the CG and BCG Krylov subspace methods with and without preconditioners (Jacobi and ILU). Compiler optimization did have a larger impact on the computational time than the parallelization of the code. The BCG methods were considered the optimal Krylov subspace method alternatives as they are designed to solve problems on the form  $\mathcal{A}\mathbf{x} = \mathbf{b}$  with non-symmetric  $\mathcal{A}$  matrices. The GMRES methods are designed to solve problems on the same form and may be even more reliable and converge also for almost singular  $\mathcal{A}$  matrix systems but is also more complex to program and computational time intensive, hence not included in the test program. The CG-algorithms are also designed to solve problems on the same form and are much less computationally expensive for symmetric problems and may also converge for some non-symmetric problems. The plain and the preconditioned conjugated gradients algorithms were shown to be the best performing solvers in the test by Lindborg et al. [135] solving the close to symmetric set of Poisson equations. In the test by Lindborg et al. [135], the CG Jacobi method was the most efficient algorithm tested for large computational loads. The optimal processor configuration for a tube with a large length to diameter ratio was shown to be the one which have all the processors in one line in the axial dimension, provided that the resolution in the radial direction is not too high.

## Chapter 13

# Experimental Techniques

A problem associated with the use of average multiphase models for chemical reactor performance analyzes is the requirement of experimental data enabling proper model validation. The choice of averaging procedure will depend on the type of system that is to be described, and some general guidelines may be drawn. Steady state models can be validated using time averaged data. If homogeneous systems are considered, then a volume average approach may be used for modeling. If a system cannot be considered homogeneous or steady, as is the most common case, then an ensemble averaging technique is preferred from a mathematical point of view. For the flow patterns in chemical reactors the small and large time or spatial scales can hardly be separated, and thus the time and spatial averages can at most be viewed as coarse approximations of the ensemble average. Based on this interpretation it may be concluded that the ensemble average operator is preferable for modeling chemical reactors. However, both conceptual, practical and economical considerations regarding how to obtain experimental data for parameter fitting and model validation should be considered before any firm conclusion is drawn. As the key to accurate modeling to a large extent lies in the closure laws applied, we seek guidelines in order to close the models successfully based on accurate interpretations of the empirical data information available. First, as shown in the previous chapters, the averages can be mathematically defined in a number of ways, but it is convenient to ensure that the mathematical definition has a measureable physical significance. Second, the local time average and instantaneous space average operators could in some flow situations be directly related to experiments. In most flow situations, however, the separation of scales are severe and these two averaging approaches are not convenient. Third, the partial differential equations (PDEs) resulting from the averaging procedures are based on the continuous function assumption, and thus can be solved with finer and finer numerical resolution in time and space intending to improve the accuracy of the numerical representation of the proposed PDEs (e.g., for the FDM this numerical approach is associated to a truncated Taylor series approximation convergence). No harm occurs when the numerical resolution becomes finer than the averaging scales (in time and space) determining the basis for the model formulation, as the closure

laws and parameter values are linked to the experimental data on the averaging scales. The PBEs are solved on fine scales, but representing physics on the averaging scales. For this reason, proper model validation can only be performed on scales larger than the averaging scales. Fourth, the use of experimental data on discrete particle characteristics like shape and size to validate the Euler/Euler type of multifluid models are not straight forward. The basic conceptual problem is obvious considering the average models, as a number of particle diameters (e.g., drag-, equivalent or volume-, and surface or area diameters) as well as various velocity measures (e.g., number averaged-, particle volume or mass averaged-, and time weighted velocities) of the dispersed phases may be derived from the experimental data. It follows that all the averaging approaches have their advantages and disadvantages, both from a theoretical and a practical point of view. It seems that there is no approach that is favorable in general. In practical situations where the space or time averaging approaches seem to fulfill the conditions for separating the important scales, these approaches should be adopted since they allow proper validation to be performed. For very complex flows, like those observed in most multiphase chemical reactors, the important scales can hardly be separated. The experimental methods required validating ensemble averaged models are cumbersome and tedious to operate (very expensive and not practical). In these cases the ergodic hypothesis has usually been invoked, assuming that the time averaged data can be used for the validation of ensemble averaged models. It is thus an artificial debate whether or not the statistical averages effectively have any advantages over the other two approaches, since in practice we need to resort to coarse approximations validating any of these model formulations for such flow situations. These limitations also define the accuracy which can be expected analyzing the model results, as we cannot properly distinguish between the different averages.

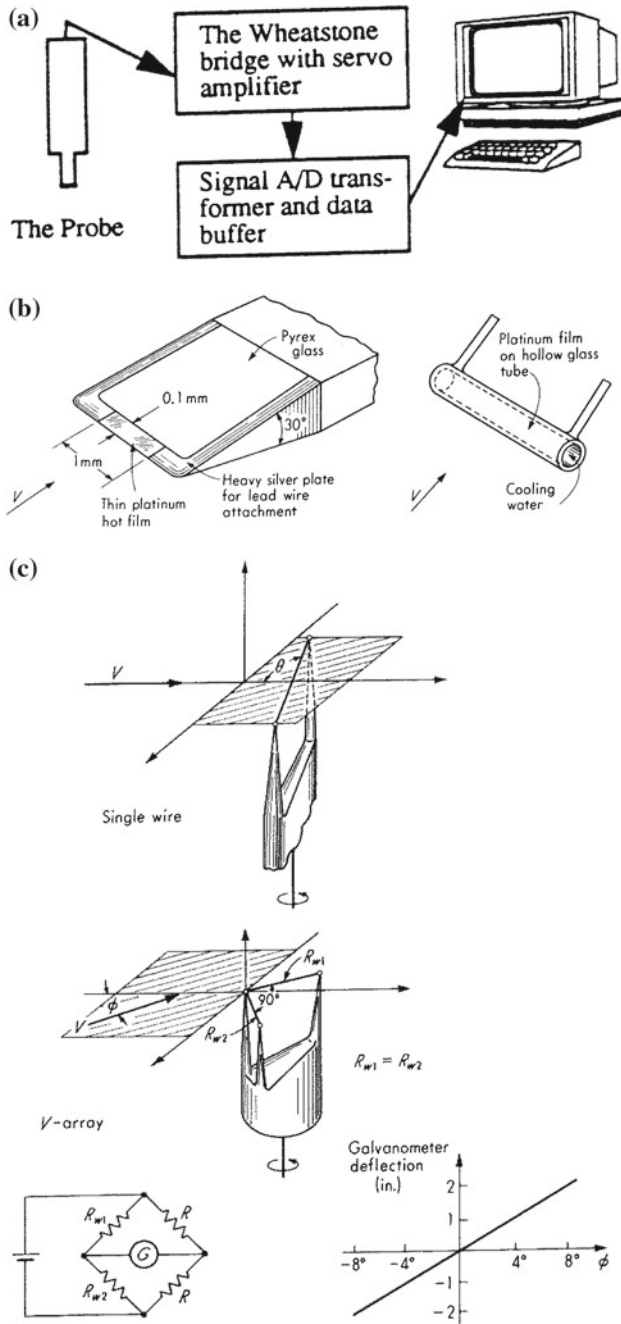

A critical review of some of the currently used measurement techniques for characterizing multiphase flow systems is presented, describing the working principles of the individual techniques and identifying the averaging procedures that have been applied interpreting the data for each technique.

### 13.1 Hot-Film Anemometry

Thermal hot-wire and hot-film anemometers (HFA) have been available for measuring instantaneous single phase fluid velocity for about a century. The small size of the sensor and good frequency response makes them especially suitable for turbulence investigations. These techniques are thus commonly used in many engineering disciplines.

### ***13.1.1 Basic HFA Principles:***

The thermal hot-wire and hot-film anemometers were designed to measure fluid velocity by sensing the changes in heat transfer from a small, electrically heated sensor exposed to the fluid motion [73]. The earliest work on the hot-wire technique frequently referred in the literature is that by King [100]. Hot-wire probes are mainly used in gas flows due to their small size and well defined calibration characteristics. To obtain a good frequency response most hot-wire sensors have diameters of  $5\text{ }\mu\text{m}$  or less. Such thin wires are very fragile, and hot-film probes are normally used for measurements in liquid flows due to their sturdier construction. Measurements in liquids by hot-film anemometry first became a practical option with the development of the hot-film probe in the mid 1950s by Ling and Hubbard [115]. The hot film anemometer (HFA) technique enables measurements of one, two or all three components of single phase continuous flow fields by using one, two or three resistance sensors located locally in the flow. The constant temperature anemometer system is based on variations in the convective heat loss of heated resistance sensors located in the flow. The method utilizes the physical phenomenon that the convective heat transfer coefficient depends on parameters as velocity, temperature and pressure of the medium. The velocity measurements are performed at constant temperature and pressure. The instantaneous heat loss of the sensor is thus assumed to be a Favre averaged measure of the instantaneous velocity of the flow. The constant temperature anemometer consists of a Wheatstone bridge and a servo amplifier, as illustrated in Fig. 13.1. The velocity changes influence on the temperature of the resistance sensor, which is restored by adjusting the bridges operating voltage. The voltage is thus a measure of the flow velocity. The anemometer signals (from the servo amplifier) are sampled using an A/D converter and the results are fed into a computer for processing. In addition to velocity, for single phase flows this type of sensor also provides information on temperature. Another important feature of this method is that it is applicable to dense gas dispersions. The first local flow characteristics of dispersed gas–liquid bubbly flows were performed using the HFA technique. In bubbly flows the liquid velocity data was filtered discarding the signals from the bubbles. However, in addition to the velocity and temperature information obtained for single phase flows, this type of sensor also provides local information on the gas time fractions. It was thus proposed that the HFA signal variations due to the presence of bubbles, quantified by comparing the time periods in which the sensor is exposed to the gas phase and to the liquid phase respectively, enable the determination of the local gas volume fraction as well. The technique is, for single phase flow measurements, concerned with high resolution, very low noise level and low costs. Furthermore, the velocity measurements are repeatable with accuracy limited by errors of a few percent. For multiphase measurements the accuracy of the velocity measurements is lower. It has further been verified, by comparing the integrated local HFA void data with the overall gas holdup in the vessel, that the real gas fraction fields are significantly underestimated by the HFA technique. According to Wang et al. [206], this is due to deformation and deflection of the bubbles by the probe.

### ***13.1.2 Characterization of Reactor Flows with HFA***

The first flow characteristics of single phase stirred tank reactors were performed using the HFA technique. For example, Güntel and Weber [77] used a hot-wire technique to measure instantaneous fluid velocities in the bulk flow and between the impeller blades in baffled stirred vessels. The HFA technique was later used to measure the first instantaneous fluid velocities in dispersed two-phase (gas–liquid) dispersions. Attempts were also performed to measure the local gas void fraction. Many examples of such investigations of two-phase bubble column flows can be found in the literature [67, 72, 76, 135, 199].

### ***13.1.3 HFA Limitations***

The HFA technique causes flow disturbance since the probe is an invasive device. Further disadvantages are that the velocity is not measured directly but deduced from a measurement of convective heat transfer from the sensor. Heat losses from the sensor other than by convection cause errors. The method may also be concerned with uncertainties caused by calibration shifts due to contaminations.

### ***13.1.4 Suggested HFA Literature***

Reviews of the HFA method, considering setups, strengths, limitations, and comparisons with other velocimeters can be found in the books of Goldstein [73] and Doebelin [54]. More practical aspects of the application of hot-film anemometry characterizing liquid flows has been outlined by Bruun [29].

## **13.2 Laser-Doppler Anemometry**

During the last four-five decades, the laser-Doppler anemometry (LDA) has become a commonly used experimental technique to measure the instantaneous velocity of seeded single phase flows, and dispersed two-phase flows of very low concentration. A major reason is that LDA is a non-invasive optical technique and does not disturb the flow. Moreover, the LDA system has a high spatial resolution with a fast dynamic response and range.

### ***13.2.1 Basic LDA Principles:***

Laser Doppler anemometry utilizes the Doppler effect to measure instantaneous particle velocities [5, 97, 213]. The laser Doppler technique generally uses a collimated, monochromatic and coherent laser as light source. Lasers with wavelengths  $\lambda$

in the visible spectrum (390–750 nm) are commonly used. The Doppler effect occurs when a source of a wave and the observer are in relative motion. In one interpretation the laser-Doppler method is based on the measurement of the Doppler-shift of laser light scattered from small tracer particles carried along with the fluid. If the particles suspended in a flow are illuminated with a laser beam, the frequency of the light scattered from the particles is different from that of the incident beam. This difference in frequency, called the *Doppler shift*, is linearly proportional to the particle velocity. According to the Lorenz-Mie theory, the light is scattered in all directions at once, but only the light reflected in the direction of the LDA receiver is considered. The incoming light has the velocity  $c$  and the frequency  $f_i$ , but due to the particle movement the light observed from the seeding particle has a different frequency  $f_s$  which is scattered towards the receiver. Hence, the seeding particle acts as a moving transmitter, and the movement introduces additional Doppler-shift in the frequency of the light reaching the receiver. Based on Doppler theory, the frequency of the light reaching the receiver can be calculated as:

$$f_s = f_i \left[ \frac{1 - \mathbf{e}_i \cdot \frac{\mathbf{v}_p}{c}}{1 - \mathbf{e}_s \cdot \frac{\mathbf{v}_p}{c}} \right] \approx f_i \left[ 1 + \frac{\mathbf{v}_p}{c} \cdot (\mathbf{e}_s - \mathbf{e}_i) \right] = f_i + \Delta f \quad (13.1)$$

in which  $\mathbf{v}_p$  represents the particle velocity,  $c$  is the speed of light in the medium surrounding the particle ( $|\mathbf{v}_p| \ll c$ ,  $c = f_i \lambda$ ) and the unit vectors  $\mathbf{e}_i$  and  $\mathbf{e}_s$  described the direction of the incoming and scattered light, respectively.

Relation (13.1) shows that in principle the particle velocity can be determined from measurements of the Doppler shift  $\Delta f$ . For this reason the system interpretation is named the *Doppler-shift* method. However, in practice this frequency shift can only be measured directly for very high particle velocities. For this reason the Doppler-shift interpretation is not commonly used in practice.

### 13.2.2 Practical LDA Configuration

A number of different optical configurations were proposed during the earlier days of laser-Doppler anemometer systems, they can all be classified as special interferometers in which one of the following interference effects occurs [58]:

1. Scattered light from one laser beam interferes with un-scattered light from another beam (reference beam anemometer).
2. Scattered light from one laser beam interferes with scattered light from another beam (dual beam or differential Doppler or fringe anemometer).
3. Light scattered from a single beam in two different directions interferes (single beam or two scattered beam anemometer).

Laser-Doppler velocimetry requires a light signal that oscillates at the Doppler shift frequency. This is usually obtained by subtracting the illuminating wave frequency

from the total frequency. The technique whereby this is accomplished is called *optical heterodyne detection* or optical mixing [73]. There are three distinct types of LDA optical systems, corresponding to the three different methods of combining the Doppler shift phenomenon with the optical heterodyne technique to produce a flow measuring instrument. The three types of optical systems are named the *reference-beam-*, the *dual-beam-*, and the *dual-scatter* systems. Figure 13.2 shows typical optical systems used in practice. Other optical systems previously proposed are not commonly used, mainly because the small aperture required to limit the measurement volume also leads to a highly reduced intensity level of the detected light and the difference frequency is dependent on the receiver position. The *modern* LDA optical arrangement thus corresponds to the dual-beam system. *Forward scatter* and *backscatter* refer to the locations of the collecting aperture that receive light scattered forward from the illuminating beams and the scattered backward, respectively. The majority of light from commonly used seeding particles is scattered away from the transmitting laser, and in the early days of LDA, forward scattering was thus commonly used, meaning that receiving optics was positioned opposite of the transmitting aperture [97]. Much less light is scattered back towards the transmitter, but the advances in the technology has made it possible to make reliable measurements even on these faint signals. Today backward is the usual choice of LDA, as this design allows for the integration of transmitting and receiving optics a common housing saving a lot of tedious and time-consuming work aligning separate units. Forward scattering LDA is however, not completely obsolete since in some cases the improved signal-to-noise ratio makes forward-scatter the only way to obtain measurements at all. Experiments requiring forward scatter might include; High speed flows, requiring very small seeding particles, which stay in the measuring volume for a very short time, and thus receive and scatter a very limited number of photons. Transient phenomena which require high data rates in order to collect a reasonable amount of data over a very short period of time. Very low turbulence intensity, where the turbulent fluctuations might drown in noise, if measured with backscatter LDA. There are significant differences among the properties of the signals produced by these systems. In particular, the strengths and signal-to-noise ratios of the signals may differ substantially in a given application. These differences arise primarily because of differences in the efficiency with which scattered light is collected and heterodyne mixing is accomplished. It can be shown that the size of the scatter-light collecting aperture is severely restricted for both the reference-beam system and the dual-scatter system, the former because large apertures cause poor mixing efficiency, and the latter because the Doppler frequency shifts varies over the aperture [73]. Thus, only the dual-beam system is capable of effectively utilizing a large light-collecting aperture to produce strong signal, and for this reason it is the most commonly used type of LDA. The following discussion is thus restricted to the dual-beam system. It is noted, however, that other types of LDA arrangements can be superior for particular applications.

The more widely used optical configuration, the dual-beam configuration, is based on two incident waves. In this configuration a real measurement volume is formed at the intersection of the two incident waves and the scattered waves are detected with

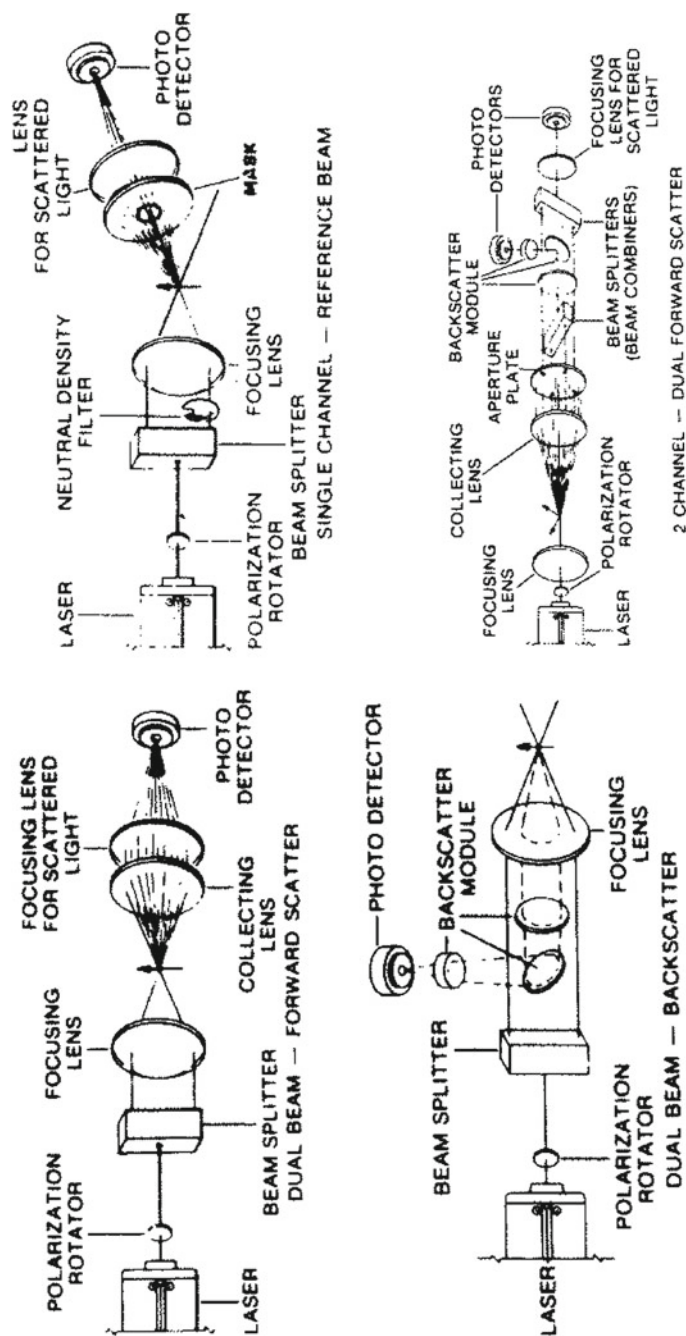

Fig. 13.2 The Laser Doppler Anemometry (LDA) method. Practical LDV systems for dual-beam, reference-beam, and dual-scatter modes [73]. The figure is reproduced from Goldstein [74] (p. 181) with permission from Hemisphere Publishing Corporation

a single detector. It is further noted that the difference frequency is independent of the receiver position for the dual-beam configuration. Moreover, the beat frequency typically lies in a much more manageable frequency range for signal processing compared to the signal obtained from the other LDA configurations. The difference (beat) frequency  $f_D$  is obtained through the optical mixing of waves with frequencies  $f_{s,1}$  and  $f_{s,2}$  on the detector. The interference of two beams crossing in the measuring volume creates a fringe pattern. For very small tracer particles, the illustrative fringe model can be used to explain the measurement principle of the laser Doppler technique. This model is only valid for small particles because only under this condition can the amplitude and phase, or the intensity of the field be considered constant.

In a second optical system interpretation, such a real fringe system being created in the beam crossover region is considered. The LDA is thus implemented by splitting a laser beam to have two beams that intersect at a common point thus the light scattered from the two intersecting laser beams is mixed. In this way both incoming laser beams are scattered towards the receiver, but with slightly different frequencies due to the different angles of the two laser beams. When two wave trains of slightly different frequency are super-imposed, the beat frequency phenomenon occurs due to the two waves intermittently interfering with each other constructively and destructively. The beat frequency, also referred to as the Doppler frequency  $f_D$ , corresponds to the difference between the two wave frequencies. Since the two incoming waves orientate from the same laser, they also have the same frequency  $f_1 = f_2 = f_i$ :

$$\begin{aligned} f_D &= f_{s,2} - f_{s,1} = f_2 \left[ 1 + \frac{\mathbf{v}_p}{c} \cdot (\mathbf{e}_s - \mathbf{e}_2) \right] - f_1 \left[ 1 + \frac{\mathbf{v}_p}{c} \cdot (\mathbf{e}_s - \mathbf{e}_1) \right] \\ &= f_i \left[ \frac{\mathbf{v}_p}{c} \cdot (\mathbf{e}_1 - \mathbf{e}_i) \right] = \frac{2 \sin(\theta/2)}{\lambda} v_{p,n} \end{aligned} \quad (13.2)$$

where  $\theta$  is the angle between the incoming laser beams,  $\mathbf{v}_{p,n}$  the particle velocity vector and  $v_n$  the velocity component in the plane of the laser beams, and perpendicular to their bisector.

From the above relation it is seen that the Doppler frequency is directly proportional to the particle velocity component in the plane of the laser beams, and perpendicular to their bisector, and thus can be calculated directly from  $f_D$ :

$$v_{p,n} = \frac{\lambda}{2 \sin(\theta/2)} f_D \quad (13.3)$$

in which  $v_{p,n}$  is also referred to as the particle velocity component normal to the fringe plane.

Strictly speaking, the laser Doppler technique is an indirect measuring technique because it measures the velocity inhomogeneities in the flow, typically tracer particles. These tracers represent the fluid flow velocity only if no appreciable slip velocity is present. Otherwise the slip velocity must also be determined. In particular, if these tracer particles are small, in the order of microns, they can be assumed to be good flow tracers following the flow and thus their velocity corresponds to the fluid velocity.

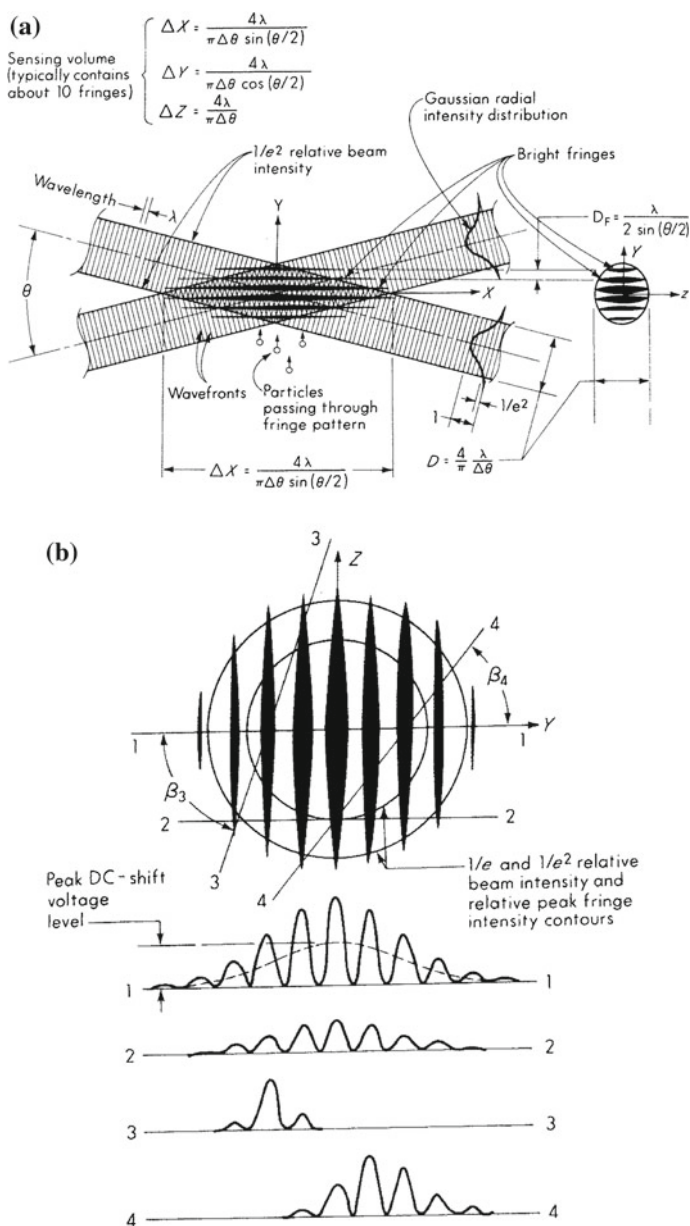

Actually, seeded tracer particles are not always necessary. The microscopic particles normally present in liquids may be sufficient, however gas flows often need to be seeded. In addition to the Doppler frequency, giving information about the particle velocity, there exists a lower frequency signal caused by the physical phenomenon that the light intensity is Gaussian-distributed over the cross-section of the beams. The intensity is thus largest when the particle is in the middle of the control volume and decreases in all directions. This signal is called the pedestal. The Doppler and pedestal signals are usually separated by filtering devices.

### ***13.2.3 Principle of Dual-Beam LDA Explained by the Fringe Model***

Instead of applying the classical Doppler shift model for describing the operation of the laser Doppler anemometer, Rudd [172, 173] introduced the more intuitive fringe model which was considered equivalent for most purposes. The fringe model is much simpler than the classical Doppler shift model since it avoids reference to the Doppler shift effect, see model illustrations in Fig. 13.3a and b. Unfortunately, the fringe model is not entirely correct and may predict unrealistic results [73, 172, 173, 213]. However, the fringe model has been frequently applied in the literature because it presents a useful way to interpret the signal recorded by the photo-detector in terms of the interference fringe pattern generated at the beam crossing. The rigorous Doppler shift model is much more complex and difficult to visualize in an intuitive manner [58, 172, 173, 213].

The basic components in a dual-beam LDA anemometry system are the laser, the beam splitter, the transmitting and receiving optics, the photo detectors, the signal processor, and a data analysis system. A Bragg cell is normally used as the beam splitter. The output of the Bragg cell is two beams of equal intensity with two different frequencies, one un-shifted  $f_D$  and the other shifted beam  $f_{D,\text{shifted}}$ . These are focused into optical fibers bringing them to a probe containing transmitting optics. In this probe, the two parallel beams from the fibers are focused through a lens into the measurement volume, where the beams intersect. Depending on the transmitting lens and optical system, the size of the measurement volume is typically between a few millimeters and a few centimeters long. The light intensity is modulated due to interference between the laser beams. This produces parallel planes of high light intensity, known as fringes. The fringe distance  $D_F$  is defined by the wavelength  $\lambda$  of the laser light and the angle between the beams  $\Theta$ . The velocity information comes from the light scattered by the particle as it moves through the measurement volume. The scattered light is collected by a receiving lens and focused on a photo detector, producing a signal. Figure 13.3a and b give an overview of a measuring volume with fringes. Based on the fringe model the distance between the fringes,  $D_F$ , is solely a function of wavelength,  $\lambda$ , of the laser light and intersecting angle,  $\Theta$ , (the angle between the two beams):

**Fig. 13.3** The LDA dual-beam fringe model. **a** Principle of the fringe model [54]. **b** Electronic signals from velocimeter and comparison of processors [54]. Lower part of figure: Signal amplitude vs. particle position for a number of particle trajectories. The indicated fringe width is proportional to the local peak fringe intensity. The Fig. **a** and **b** are reproduced from Doebelin [54] (pp. 613–614) with permission from McGraw-Hill Education

$$D_F = \frac{\lambda}{2\sin(\frac{\theta}{2})} \quad (13.4)$$

The frequency of this signal,  $f_D = 1/T$ , becomes a linear function of the velocity of the particle.  $T$  is the time for the particle to cross one fringe. The particle velocity is thus calculated from the Doppler frequency and the fringe distance:

$$v_{p,n} = f_D \times D_F = f_D \times \frac{\lambda}{2\sin(\frac{\theta}{2})} \quad (13.5)$$

where  $T = \frac{D_F}{v_{p,n}}$ .

Actually,  $v_{p,n}$  denotes the absolute velocity of the particle in the direction  $n$  that is perpendicular to the bisector of the two incident laser beams.

A drawback of the LDA technique described so far is that negative velocities  $v_{p,n} < 0$  will produce negative frequencies  $f_D < 0$ . However, the receiver can not distinguish between positive and negative frequencies, and as such, there will be a directional ambiguity in the measured velocities.

To detect the direction of flow, a frequency shift for one of the beams is introduced by placing a Bragg cell in the path of one of the laser beams. The Bragg cell adds a fixed frequency shift  $f_0$  to the diffracted beam, which then results in a measured frequency of a moving particle expressed through a modified form of (13.3):

$$f_{D,\text{shifted}} \approx \frac{2 \sin(\theta/2)}{\lambda} v_{p,n} + f_0 \quad (13.6)$$

The Bragg cell will thus ensure a measurable positive Doppler frequency  $f_{D,\text{shifted}}$ , as long as the particle velocity does not introduce a negative frequency shift numerically larger than  $f_0$ . This procedure establishes a moving pattern of fringes that produces bursts of frequency  $f_{D,\text{shifted}}$  which permits unambiguous determination of velocities greater than  $-D_F f_0$  [97].

### 13.2.3.1 Primary and Secondary Measurement Quantities

The laser Doppler technique samples the flow velocity at discrete times corresponding to the passage of a particle through the intersection volume. The velocity sampled at these times can be considered as a primary measurement quantity or raw data. The derivation of flow parameters or secondary measurement quantities, such as mean flow velocity, turbulence level or turbulence spectra, requires further data processing. The statistical quantities most frequently computed from the measured instantaneous velocity data are the mean (number or time average) particle velocity components ( $\bar{v}_i$ ), the standard deviation ( $\sigma_i$ ) and the turbulent intensity ( $I_i$ ). The index  $i$  denotes the axis direction, thus  $i = 1, 2, 3$ .

The mean velocity is given by:

$$\bar{v}_i = \frac{1}{N} \sum_{m=1}^N v_{p,i,m} \quad (13.7)$$

The apparatus is generally adjusted such that the normal velocity component  $v_{p,n}$  corresponds to the velocity component in axis direction  $i$ .  $N$  denotes the total number of sampled particles and the integer  $m$  indicates the individual measurements.

The unbiased variance is given by:

$$\sigma_i^2 = \frac{1}{N-1} \sum_{m=1}^N (v_{p,i,m} - \bar{v}_i)^2 = \frac{1}{N-1} \sum_{m=1}^N v'_{i,m} v'_{i,m} = \overline{v'_i v'_i} \quad (13.8)$$

with no summation of repeated indexes.

The standard deviation ( $\sigma_i$ ) corresponds to the rms particle velocity:

$$\sigma_i = v_i^{\text{rms}} = \sqrt{\frac{1}{N-1} \sum_{m=1}^N (v_{p,i,m} - \bar{v}_i)^2} = \sqrt{\overline{v'_i v'_i}} \quad (13.9)$$

with no summation of repeated indexes.

The turbulence intensity is defined as:

$$I_i = \frac{\sigma_i}{\bar{v}_i} \quad (13.10)$$

with no summation of repeated indexes.

The covariance is computed as:

$$\text{covar}(v_i, v_j)_{i \neq j} = \frac{1}{N-1} \sum_{m=1}^N (v_{p,i,m} - \bar{v}_i)(v_{p,j,m} - \bar{v}_j) = \overline{v'_i v'_j} \quad (13.11)$$

where  $i, j$  denote the vector components.

The accuracy of the particle velocity measurements is normally approximated to  $\pm 5\%$  of the maximum velocity for a well-aligned system.

### 13.2.4 Advantages of LDA Compared to Pitot Tubes and HFA

The main advantages of laser Doppler anemometry (LDA) relative to pitot tubes and hot-film anemometers (HFA) include:

1. Measurements of particle velocity is direct rather than by inference from pressure (pitot tube) or heat-transfer coefficient (hot-film).
2. No *physical object* need to be inserted into the flow (i.e., except for the tracer particles) thus it is undisturbed by measurement.
3. Sensing volume can be very small.

### ***13.2.5 Characterization of Reactor Flows with LDA***

One of the first successful measurement using LDA were reported by James et al. [96]. They performed cold flow studies and measured the velocity of water mist (droplets in air) and two types of solid particles of about micrometer size in air. Ciofalo et al. [43] and Brucato et al. [28] present reviews on the experimental results obtained in stirred vessels, and they stated that the laser Doppler velocimetry (LDA) has been applied in most experimental studies on the single phase flow fields in both baffled and unbaffled stirred tanks determining instantaneous velocities. Attempts have also been made to measure the instantaneous liquid velocity in bubbly flows having low to intermediate gas fractions by the LDA technique. Becker et al. [20] did perform LDA measurements to characterize the unsteady behavior of the continuous liquid phase in flat bubble column with rectangular cross-section and essentially two-dimensional flow structure at low gas fractions. The local liquid velocities along two perpendicular directions were measured by LDA. It was found that LDA is restricted to a small gas-holdup because the bubbles disturb the penetration of the laser beams into the middle of the apparatus. Therefore, a micro-turbine anemometer was used for velocity measurements in the middle of the apparatus. Typical void fractions were up to about 5 %. Five years later, Becker et al. [21] employed LDA measuring velocity time series from both flat and cylindrical bubble columns. Comparing the velocity time series certain differences were observed. The dynamic flow behavior in flat columns was considered deterministic, while the corresponding flow behavior in cylindrical columns was considered chaotic and thus impossible to described by deterministic models. Flat columns were thus proposed as a useful tool for the validation of dynamic flow models. The bubble size distribution and void fraction were not measured by LDA in these investigations. In the same time period, a similar study was performed by Mudde et al. [144] using LDA to measure the axial and tangential liquid velocity components close to the wall in three cylindrical bubble columns with diameters 15.2, 23.4, and 38.4 cm. The superficial gas velocity ranged from 0.6–6.7 cm/s, the upper limit corresponded to a gas fraction of about 25 %. The gas was distributed via a sintered porous plate producing bubbles with an equivalent diameter of about 3 mm. For low to moderate gas fractions, the reduced transparency due to the presence of bubbles that act as scatters for the laser beam prevented the use of LDA operated in the forward scatter mode. The LDA equipment was thus restricted to backscatter providing a relatively low data rate. Moreover, it was found that in the backscatter mode, the data rate can be sufficiently high provided the liquid flow is seeded with small seeding particles. The authors further claimed

that for liquid velocity measurements in bubble column flows, the LDA technique retained the advantageous property of having a sufficiently high data rate. However, the LDA measurements also revealed the disadvantages that the technique is limited to velocity measurements in the outer region of the bubble column because of the reduced transparency due to the presence of bubbles that act as scatters for the laser beam. The ratio of the received (time-averaged) light intensity with bubbles  $I$  to that without bubbles  $I_0$  was given by:

$$\frac{I}{I_0} = \exp\left(-\frac{3}{2} \frac{l}{d_b} \alpha_g\right) \quad (13.12)$$

in which  $l$  denotes the path length through the bubbly flow,  $\alpha_g$  the gas fraction along the path and  $d_b$  the horizontal axis of the bubbles.

In a subsequent study, Mudde and van den Akker [145] measured time series of the vertical component of the liquid velocity in a bubble column of 15 cm diameter using LDA. The data analysis did show that the changes in liquid flow field were smooth when increasing the gas fraction in the low to moderate gas fraction range (about 1–18 %). The flow did show oscillatory behavior at all gas fractions inspected. The authors further concluded that the standard deviation was independent of the gas fraction in the low to moderate gas fraction range, and that the increase in the standard deviation at higher gas fractions can be attributed to an increase in high-frequency turbulence. The bubble size distribution and void fraction were not measured in this study. Deshpande and Joshi [50] performed simultaneous measurements of gas and liquid phase velocities and gas-hold-up in two-phase bubble columns using laser-Doppler velocimeter. The LDA was used in a dual-beam arrangement with a forward scatter mode. In their work, the measurements were performed in a rectangular bubble column. To distinguish between the gas bubble and liquid tracer signals a novel LDA data interpretation method was introduced. At that time, it was considered that the LDA data for two-phase flow exhibit certain characteristics features that differ from LDA data for single phase flow. One of the distinguishing features of two phase LDA, that the shape of the velocity histogram is unsymmetrical as opposed to the symmetric velocity histogram obtained in single phase LDA data, was the commonly used method for distinguishing the signals from the two phases in previous work. However, this method was restricted to dispersions with low gas hold-ups (<12 %) because when the gas hold-up became higher, such methods did not work as the two peaks merge to a larger extent. The authors proposed to utilize another characteristic feature of two-phase LDA data, that the size distribution of arrival time gaps at consecutive data points, to distinguish the signals from the two phases. If the arrival time gap was greater than the proposed arrival threshold and the corresponding difference in velocities was greater than the slip velocity or both the adjoining velocities belong to the gas phase, the time gaps were added to the gas time. The ratio of the gas time to the total measuring time gave the local gas volume fraction. The new data interpretation method used was considered valid up-to a gas holdup up to 26 %. However, the accuracy of their data was not sufficiently verified. Hence, due to the strict LDA requirement of spherical particles, it might be expected that

the uncertainty of the data is quite large. Kulkarni et al. [103] performed simultaneous LDA measurements of two orthogonal velocity components and the intermittent time gaps arising out of bubbles passing through the measuring point. Based on the assumption of axi-symmetry they managed to compute the three-dimensional velocity distribution from the two-dimensional measurement using the so-called Abel's transform [204]. Moreover, in conjunction with the use of probability theory, they also computed the bubble chord length distribution. The superficial gas velocity was maintained at 20 mm/s and the average gas holdup was independently calculated from the difference of the clear liquid height and the dispersion height. They further discuss the restrictive applicability of LDA to denser dispersions due to the bubble-beam interaction causing data corruption from noise and excessive scattering from the bubble surfaces.

### ***13.2.6 LDA Limitations***

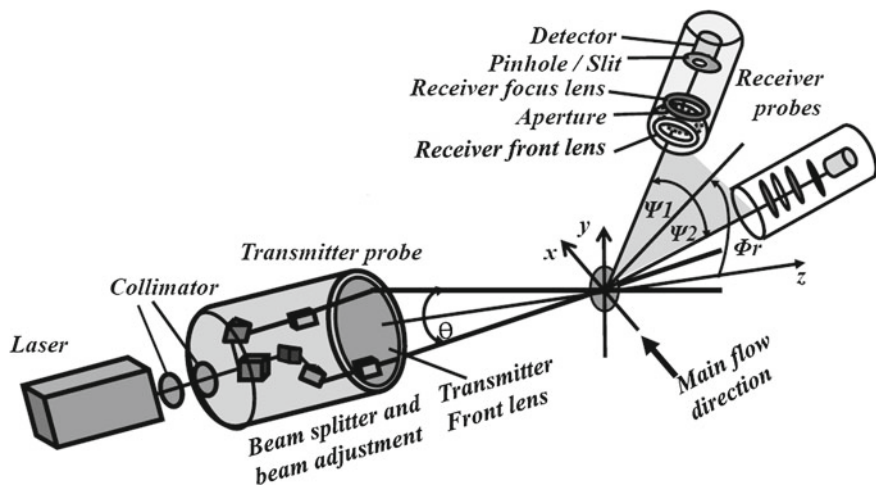

Measuring denser dispersed flows, the solid- and fluid particles may block the required transparent light paths and the light may also be reflected on fluid particle surfaces which prevent valid signals. The application of the LDA technique is thus limited to dilute dispersions.

### ***13.2.7 Suggested LDA Literature***

Further discussion on the LDA theories and different modes of operation can be found in the classic texts of Durst et al. [58], Watrasiewicz and Rudd [213], and the more recent book of Albrecht et al. [5]. Several papers might also be useful [36, 57, 97].

## **13.3 Phase-Doppler Anemometry**

During the last two decades, phase Doppler anemometry has become a commonly used experimental technique to diagnose dilute dispersed flow systems like solids in gas or liquid, droplets in gas (mists or sprays) or liquid, and bubbles in liquid. A major reason is that the basic LDA system part of the equipment is a non-invasive optical technique for measurements of instantaneous velocity and does not disturb the flow. The LDA system also has a high spatial resolution with a fast dynamic response and range. In addition to measuring the instantaneous velocity, LDA extended with phase Doppler anemometry (PDA) equipment have the advantage of simultaneously measuring size and concentration of the spherical particles constituting the dispersed phase.

**Fig. 13.4** The standard optical arrangement for the Phase Doppler Anemometry (PDA) [13, 57]. The incident beams correspond to the same optical arrangement as used in the LDA technique. The two detectors are positioned out of the plane of the incident beams at an angle  $\phi_r$  (named the off-axis angle). The detectors are also placed symmetric out of the  $x - y$  plane by the angles  $\pm\psi$  ( $= \psi_1, \psi_2$ ) (called the elevation angles). The intersection angle of the two beams is denoted by  $\Theta$  (referred to as the beam crossing angle). The figure is drawn based on a similar sketch from Albrecht et al. [5]

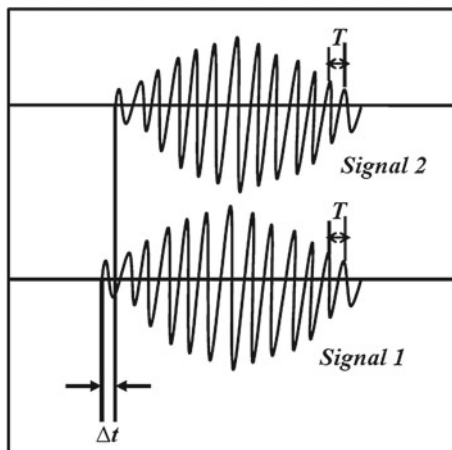

### 13.3.1 Basic PDA Principles

The phase Doppler measurements for particle sizing are usually carried out with standard dual-beam focusing optics [13], designed originally for velocimetry applications. Only the receiving optics are extended to include an additional detector (for particular systems multiple detectors have been added), as sketched in Fig. 13.4. The PDA technique is thus an extension of the LDA method utilizing the phenomenon that the phase shift on the reflected light from the measuring volume include information about particle size. It is pointed out that the basic LDA method is based on the measurement of the Doppler shift of laser light scattered from the dispersed phase particles. The two scattered waves interfere in space and create a beat signal with a frequency which is proportional to the velocity of the particle. The two detectors receive this signal with different phases. The phase shift between these two signals is proportional to the diameter of the particle. The phase difference increases with increasing particle size. This means that the distance between the particle positions where the maximum signal amplitude values are measured is proportional to the particle size,<sup>1</sup> as illustrated in Fig. 13.5. Furthermore, the PDA data treatment of particle size is based on the assumption that the particles have a spherical shape. In 1975 Dust

<sup>1</sup> Note that the phase is a modulo  $2\pi$  function and cannot exceed  $2\pi$ . Therefore, if a particle has a size that causes the phase to go beyond a  $2\pi$  jump, a two-detector PDA cannot discriminate between this size and a much smaller particle.

**Fig. 13.5** Determination of particle size in Phase Doppler Anemometry (PDA). The phase difference between two Doppler bursts is computed from  $\Delta\Phi = 2\pi(\Delta t/T)$ . The figure is drawn based on a similar sketch from Manasse et al. [126]

and Zare [57] were the first to show that there exists a linear relation between the diameter of a spherical particle and the Doppler signals detected at two different points in space. The optical arrangement of a PDA system was established, which was later called the *standard configuration*. This arrangement is characterized by the placement of the photo-detectors at a certain off-axis angle measured against the forward direction in the plane of the laser beams and at elevated angles above and below the bisecting plane between the laser beams. However, the work of Dust and Zare [57] also demonstrated practical problems occurring in measurements of the particle size distributions in two-phase flows. Evidently, the proposed technique needed further development. Six years later, Martin et al. [127] investigated the characteristics of laser-Doppler signals from bubbles and found triple-peak signals from forward scattered light which yield accurate velocity information. These authors also proposed a method for sizing the bubbles by a combination of visibility, pedestal and amplitude of the Doppler signals. The triple-peak technique of bubble sizing was later used by Yu and Varty [236] employing LDA to measure the velocity and diameter of a single stream of nitrogen bubbles in quiescent water. The equipment was set up as a dual-beam LDA. They studied the impact of an optical disturbance generated by additional streams of bubbles. It was found that the probability of detecting a valid signal decreased linearly with increasing bubble flow rate of the additional streams. The range of bubble diameters was 0.8–1.8 mm, and the maximum void fraction was 0.01. Saffmann et al. [174] extended the technique and presented experimental results on bubble size measurements. In 1984 Bachalo and Houser [13] described the first commercial instruments for the PDA method. The practical problems preventing size measurements, as demonstrated by Dust and Zare [57], were solved. Bachalo and Houser [13, 14] measured simultaneously droplet size and velocity in nozzle spray flows using a concept similar to that of Durst and Zare [57]. They employed a dual-beam laser light scatter for large off-axis receiver angles. The technique was named the *Phase Doppler Technique*, since the phase difference between two points

is related linearly to the particle size. The diagnostic technique for the size correlations did utilize the phase shift between two Doppler bursts. The method thus permit simultaneous measurements of the individual particle velocities and the particle size. It was found that the PDA technique has several desirable features including a very wide size range, from microns to millimeters, and good immunity to noise. However, there were still limitations associated to the PDA technique. Most important, the particles have to be smooth and spherical in order to get correct measurements of size, and the required light paths have to be transparent. On condition that one light scattering component, either refraction<sup>2</sup> or reflection, dominates, the time difference  $\Delta t$ , measured as a phase difference  $\Delta\Phi = 2\pi(\Delta t/T)$  (see Fig. 13.5) between a pair of signals, is linearly related to the diameter  $\xi$  of the spherical particle as expressed by the equation [19, 126]:

$$\xi = \frac{1}{2b} \left( \frac{\lambda}{\pi n_c} \right) \Delta\Phi = \Delta\Phi/F \quad (13.13)$$

where  $n_c$  denotes the refractive index of the continuous phase and  $b$  a function of the geometrical arrangement. Approximate model equations for the term  $b$  are given by Manasse et al. [126] for dominant reflected and refracted light. In some more recent papers this relation is somewhat simplified introducing the phase factor,  $F$  [26].

In 1992 Naqwi and Durst [148] showed that the estimation of the transfer function for converting the measured phase into particle diameter may be concerned with large errors. In principle the estimation procedure may cover a diameter range from about 40 nm to an arbitrarily large particle. The accuracy of the phase Doppler measurements is however restricted due to two major assumptions made in the optical design theory. The Mie theory (i.e., Mie [138], see also Horvath [92]) usually provides a sufficient description of the light scattering but is not exact, since the theory is based on the assumptions that the particle is illuminated by a uniform plane wave and that the phase-diameter relationship is linear [126, 187]. The accuracy is further affected by the electronic noise which is introduced during or after conversion of the optical signals into electrical signals, and in the case of dense particulate flows, by multiple scattering. The same year Naqwi and Ziemann [149] were the first to discover the use of planar PDA for the purpose of fine particle sizing. In order to obtain measurable phase shifts of a reasonable order of magnitude even for small particles, the planar PDA set-up was chosen for this purpose. They used a three-detector set-up and a sophisticated signal-processing method to obtain unique information about the size of very small particles. In 1997, Durst et al. [59] reviewed the development and characteristics of planar phase-Doppler anemometry. The weakest point of PDA applications was associated to the accuracy of size measurements because the particle size influences significantly the accuracy of volume flux measurements. It was stated that the most significant effect responsible for the large uncertainties in the size measurements of particles was the Gaussian beam defect or trajectory effect. By

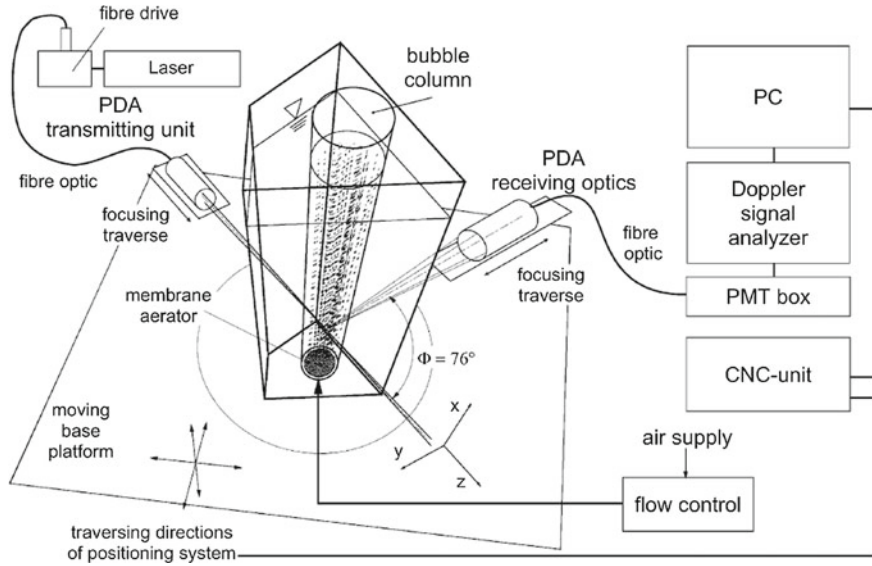

---

<sup>2</sup> Refraction of light is the change in direction of a wave due to a change in its speed. Refraction is described by Snell's law.

theoretical analysis the mechanism was explained. If a large particle penetrates the probe volume, the Gaussian intensity profile of the incident beams causes a non-uniform illumination of the particle and induces reflected and refracted rays which may have roughly equal intensities on the detectors. In particular, for dominating reflected light, this effect results in considerable errors in the size measurements. It was further concluded that the planar PDA was able to suppress this effect.

### 13.3.2 Characterization of Reactor Flows with PDA

In the field of chemical reactor engineering, PDA has been used for simultaneous measurements of instantaneous solid particle velocity, and particle size and concentration in the dilute regions of fluidized beds [9, 22, 130, 131]. In the review by Tayebi et al. [196], numerous applications of PDA for characterizing gas–solid flows in fluidized beds were discussed. These experimental investigations were basically performed to elucidate the complex gas–solid flow behavior in dilute vertical conveying systems. PDA has also been employed to simultaneously measure the instantaneous fluid particle (drop and bubble) velocity, size and concentration in dilute two-phase flows. Morud [141] reported that she did apply LDA/PDA to measure the instantaneous gas velocity in a cylindrical stirred tank. The LDA/PDA equipment was set up in both forward- and back-scatter mode. The axial and radial bubble velocity components were detected in back-scatter mode, where both the transmitter and the receiver were located at the same side of the control volume (see Fig. 13.4). Forward-scatter, in which the receiver is located at the opposite side of the control volume, was used when the tangential velocity was measured. The gas overall holdup, measured as the difference between the pure water height and the dispersion height, was less than 10 %. No bubble size data was presented thus the PDA was not employed in this work. Brenn et al. [26] investigated unsteady two-phase flows with small bubbles in a model bubble column using PDA to measure the velocities of water and bubbles. In addition to the velocity measurements, bubble size and the time-average void fraction of gas were also deduced from the PDA measurement results. It was claimed that since the reflection of light was the dominant scattering mechanism for the given PDA configuration, both the bubbles and the tracers could be measured simultaneously and separated by the diameter information to assign the data to either the dispersed or the continuous phase. The size measurement range of the LDA system is limited in two ways. The laser light wavelength, the PDA configuration and the light scattering mechanism define the so-called phase factor  $F$  in the phase-diameter relationship (13.13) between the particle diameter  $\xi$  and the mutual phase shift  $\Delta\Phi$  between pairs of scattered light signals received by the photo-detectors. The maximum distinguishable phase shift of  $360^\circ$  between two scattered light signals defines the largest particle diameter  $\xi_{\max} = 360^\circ/F$  which can be measured unambiguously. The smallest measurable particle size is limited by the sensitivity of the photo multipliers and the electronics of the signal processors.

**Fig. 13.6** Overview of the bubble column test facility with a Phase Doppler Anemometry (PDA) setup as used by Brenn et al. [26]. The figure is reproduced from Brenn et al. [26] with permission from Elsevier

Thus, the available measurement range was between 10 and 685  $\mu\text{m}$  for the particular setup used by Brenn et al. [26]. The void fraction was computed using the equation:

$$\alpha_g = \frac{\pi}{6} \frac{1}{\Delta t} \sum_{i=1}^N \frac{d_{b,i}^3}{|\mathbf{v}_{b,i}|} \frac{1}{A_{pV,i}} \quad (13.14)$$

in which  $A_{pV,i}$  denotes the effective probe volume cross-section of the PDA system from which scatter light signals could be detected.

The experimental bubble column facility with the PDA set-up used by Brenn et al. [26] is shown in Fig. 13.6. For the applied measuring technique, the bubble column had to provide optical access to the flow. Since the shape of the column cross-section is circular, a refractive index adaption was necessary to avoid refraction of laser light at the curved walls of the column. An observation box with plane glass windows was therefore built around the column and also filled with water with similar refractive index. The windows were arranged in such a way that the optical axes of the PDA transmitting and receiving units were directed normal to the glass walls when arranged at a properly selected relative angle. It was claimed that with this arrangement reliable measurements at closest distances from the walls of 2 mm could be obtained. Test measurements with the PDA system described above showed that the aerator produced bubble sizes between 50 and 1000  $\mu\text{m}$  at air flow rates between 0.25 and 0.5 l/min uniformly over the column cross-section. The spatially average

holdup values were as low as 0.2–0.5 %. The authors claimed that the gas flow rates was kept this low to ensure that the aerator did produce spherical bubbles, which is a prerequisite for the use of PDA as the measuring technique. It was claimed that PDA offers the possibility to overcome some of the shortcomings of other measuring techniques and to provide additional experimental information on bubbly flows. In addition to the well known property that an optical technique like PDA does not influence the flow, they managed, by size discrimination, to measure separately the instantaneous velocities of both the liquid and bubble phases. On the other hand, PDA is restricted to spherical particle shape, so the maximum allowable bubble size is very small compared to those found in industrial applications of bubble column flows.

### ***13.3.3 PDA Limitations***

Measuring denser dispersed flows the solid- and fluid particles may block the required transparent light paths and the light may also be reflected on fluid particle surfaces which prevent valid signals. The application of the PDA technique is thus limited to dilute dispersions even with forward scattering LDA.

For gas–solid suspensions, as occurring in the CFB risers, the PDA technique is limited to a mean solid volume fraction of the order of 1–2 %. For transparent fluid particles the PDA technique is limited to a dispersed phase fraction of the same order.

### ***13.3.4 Suggested PDA Literature***

Further discussion on the LDA and PDA theories and different modes of operation can be found in the classic texts of Durst et al. [58], Watrasiewicz and Rudd [213], and the more recent book of Albrecht et al. [5]. Several papers might also be useful [13, 14, 57, 59, 97, 126, 234].

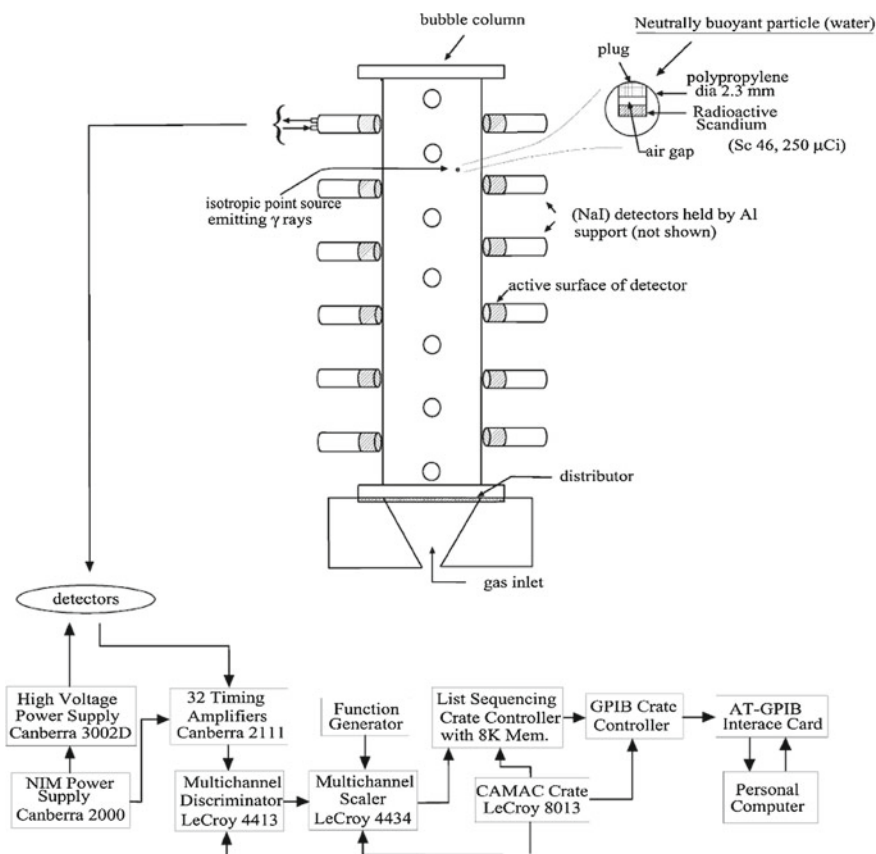

## **13.4 Computer Automated Radioactive Particle Tracking**

Many dense multiphase reactor flow systems are opaque making the high resolution laser-based techniques developed for transparent single phase flows inadequate for characterizing such dense systems behavior. The Radioactive Particle Tracking (RPT) technique constitutes a non-invasive tracer technique that enables the movement of the individual radioactive tracer particle to be monitored. The fundamental idea behind the Computer Automated Radioactive Particle Tracking (CARPT) technique is to computer automate the RPT technique determining Eulerian time average velocity, Reynolds stresses and turbulent kinetic energy. This technique can be used in dense dispersions and is applicable to studies at high pressure and temperatures.

### ***13.4.1 Basic CARPT Principles:***

During the developing process, the CARPT technique was first applied in a bubbling fluidized bed by Kondukov et al. [101] to measure the trajectory of single tracer particles. They used six scintillation detectors mounted in pairs along three perpendicular axes. Depending on gas velocity, the particle position was determined continuously every 0.25 and 0.5 s. The lack of a proper data acquisition system, at that time, prevented quantitative results. In the subsequent development and investigations of gas–solid mixtures in fluidized beds and of gas–liquid and gas–liquid–solid systems in bubble columns more sophisticated designs of the CARPT with up to 32 detectors were employed. The working principles of the CARPT facilities first developed in Urbana Champaign is described in the following. The CARPT facility was later built at the Chemical Reaction Engineering Laboratory (CREL) at Washington University in St. Louis.

In this CARPT facility a single radioactive particle ( $^{46}\text{Sc}$ ) emitting  $\gamma$ -radiation of constant energy is introduced into the vessel to be characterized. The radioactive tracer particle is dynamically similar to either the continuous fluid (restricted to liquids) or solid particle phase. Radioactive particles with different densities are used for characterizing the flow of the individual phases (i.e., liquid and/or solid phases). A single neutrally buoyant particle is used to map the flow field of the continuous phase. Alternatively, a particle dynamically similar to a dispersed solid phase can be used to map the motion of the solid particles. The vessel is then operated at steady superficial velocities, while the position of this single radioactive particle is detected and monitored in time by an array of NaI scintillation detectors strategically located all around the vessel (see Fig. 13.7). The method utilizes the physical phenomenon that the intensity of the  $\gamma$ -rays arriving at each detector is a function of the distance between the tracer and detector. The frequency of  $\gamma$ -rays (intensity) arriving at each detector decreases with increasing distance between the tracer and the detector. The intensity at each detector is converted to the corresponding instantaneous distance between the tracer and the detector. This is obtained by using a pre-established distance—radiation intensity relationship obtained by prior calibration of the detection system at each detector and particle position. The instantaneous position of the radioactive particle is then accurately calculated from the distances obtained for all the detectors using a regression least squares method. Conventionally, CARPT calibration was done by positioning the tracer particle at about 1000 known locations and recording the counts obtained at each detector (nowadays alternative methods exist). Once the calibration is complete, the tracer particle is let loose in the system and the operating conditions are controlled and kept constant for many hours while the particle is tracked. The quantities computed from CARPT experiments are Lagrangian particle trajectories. Time differentiation of the displacements yields Lagrangian ensemble average particle velocities taken to represent the velocities at the center of each cell. Eulerian time average velocities, stresses and kinetic energy can then be computed.

**Fig. 13.7** A sketch of the CARPT facility with a neutrally buoyant tracer particle. The figure is reproduced from Degaleesan et al. [47] with permission from Elsevier

### 13.4.2 Characterization of Reactor Flows with CARPT

Radioactive particle tracking has been used by different research groups to determine solids motion in various multiphase systems that are widely used in chemical and petroleum industries, such as bubble columns, fluidized beds and liquid–solid risers. The CARPT technique also provide time averaged fluid velocities provided that neutrally buoyant tracer particles are used. In chemical reactor engineering, the CARPT technique was first used to measure the time average solid motion in gas fluidized beds. Lin et al. [113] developed a radioactive particle tracking facility and studied the motion of solids in a gas fluidized bed. They located 12 scintillation detectors around the bed, and used the redundancy of detectors to improve the accuracy of the measurements. They determined Eulerian time averaged solid velocities, solids concentration, and Lagrangian auto-correlations of the fluctuating velocities.

They showed how the gross solid circulation pattern in bubbling fluidized bed changes with gas velocity. The facility was built in Urbana Champaign, Illinois. Moslemian et al. [143] used the same facility to study the motion and mixing of solids in a gas fluidized bed. This technique assisted in producing gross scale mapping of the particle circulation patterns in bubbling fluidized bed revealing the so-called *Gulf stream effect* produced by an uneven distribution of solids at the base of the vessel [137]. Seo and Gidaspow [178] did develop an experimental technique for measuring time-averaged volume fractions of particles and of the gas in fluidized beds involving particles of two sizes using two radiation densimeters (an X-ray- $\gamma$ -ray method). In such fluidized beds, the coarse and the fine particles segregate. The boundary line of segregation was found as a function of jet velocity and grid flow rate. Dudukovic and co-workers [51, 52, 142] did apply the CARPT technique to measure both the time average fluid- and solid particle velocities in two- and three-phase bubble column reactors as well as the time average solid motion in a liquid–solid riser [171]. Yang et al. [228] studied the liquid phase mixing mechanisms in bubble columns using the CARPT technique. In the same time period, Sannæs [175] did visit the Chemical Reaction Engineering Laboratory (CREL) at Washington University in St. Louis, to study the solids movement and local solids concentration in column slurry reactors using the CARPT facility. Weinell et al. [214, 215] performed similar measurements in a cold flow circulating fluidized bed pilot scale combustor (CFBC). In their system, sand was recirculated by means of air. A computer aided radioactive particle tracking (CARPT) facility which detects single radioactive particles, was developed and applied to determine the dynamic picture of the particle trajectories in the boiler. A  $\gamma$ -ray emitting tracer particle was introduced in the system and followed by a number of scintillation detectors placed along the riser. A similar CARPT system employing eight NaI detectors has been developed for tracking particle moving in a three-phase fluidized bed reactor in Montreal, Canada.

### 13.4.3 CARPT Limitations

The main disadvantages of CARPT are that the fabrication of the tracer particles for CARPT is time consuming and costly, and the calibration procedure is labor intensive. In addition, the CARPT studies are very computer storage and computer time intensive. For characterizing liquid flows, the tracer ability to follow the liquid phase may give rise to errors that must be quantified. Moslemian et al. [142] found that the error due to slip between the liquid and the tracer particle was at most 1.09 cm/s for the mean liquid velocity. The statistical nature of the radiation from the tracer particle may also introduce errors that might be reduced by increasing the strength of the tracer particle. However, if the the tracer particle is too strong, the detectors may also be saturated when the particle is very close. Longer sampling times can also reduce this error. The errors in position and velocity estimates were largest near the distributor where all the detectors were located above the particle. Moreover, the solid angle effect due to the more effective radiation detection on the

side face of the NaI crystals, was affecting the intensity significantly. The overall solid angle effect computed from the specific effects from each of the detectors was believed to be canceled out and thus considered small. It was further found that the fluctuating void fractions cause the standard deviation of the radiation to increase. This is because the attenuation is different for liquids (water) and gases (air). This error can not be reduced via calibration, but only via the introduction of more detectors. Finally, the nuclear measuring techniques have the disadvantage of being hazardous and expensive compared to other techniques. Special lead insulated facilities are required together with advanced safety protocols and regulations.

#### ***13.4.4 Suggested CARPT Literature***

Detailed reviews of the CARPT technique have been given by Devanathan et al. [51, 52], Moslemian et al. [142] and Sannæs [175] including the principles of operation, calibration and discussions of problems/difficulties related to this technique. A brief description of the set-up can also be found in the thesis by Sannæs [175]. Duducovic [55] presented a survey on the use of nuclear techniques to characterize opaque multiphase reactor flows, and Chaouki et al. [36] reviewed the non-invasive Tomographic and velocimetric techniques for monitoring multiphase flows.

### **13.5 Computed Tomography**

Tomography generally denotes a group of non-intrusive and in most cases non-invasive techniques that can be used for the reconstruction of the cross-sectional distribution of the different phases in multiphase (reactive) flow systems. The basic aim of modern tomography is to determine the distribution of materials in some region of interest by obtaining a set of boundary measurements using sensors that are distributed around the periphery of a vessel or a pipeline [60, 94, 193, 202, 235]. From these measurements it is often desirable and often possible to derive other parameters of interest such as velocity, flow regime, etc. Tomography relies on the measurement of a physical quantity that is different between the existing phases. Typically a source of energy (described through a wave form of different frequencies) is imposed on the vessel from one orientation and a number of measurements are taken by distributed sensors to create a projection of data. The source is then moved to provide another projection and so on around the vessel until a frame of data is accumulated. There are many possible sources of energy thus there are many types of tomography sensors, including ionizing radiation (e.g., X-ray and  $\gamma$ -ray), optical, positron emission (PET), nuclear magnetic resonance (NMR), acoustic (including ultrasound), electrical (i.e., capacitive, conductive and inductive) and microwave. These tomography techniques mainly differ in the sensors used and signal obtained to form an image. A particular tomography technology is normally favored over the others for a certain application

based on cost, acquisition speed, image reconstruction speed, safety, simplicity, resolution, applicability to vessels with complex geometry, and the nature of the processes under investigation [212]. Therefore, the choice depends on the subject under investigation [94]. The term *process tomography* thus refers to a whole range of non-invasive visualization techniques, which is relatively new (since the late 1980s) and still developing. This survey is restricted to the tomography techniques most frequently employed in the fields of chemical engineering and multiphase flows, thus emphasis is placed on selected electrical (i.e., electrical capacitance (ECT) and electric inductance tomography (EIT)) and nuclear (i.e., X-ray and  $\gamma$ -ray) tomography technologies. ECT is among the most favored tomography technologies in terms of cost, speed, safety, applicability to vessels of various geometries, and simplicity [212].

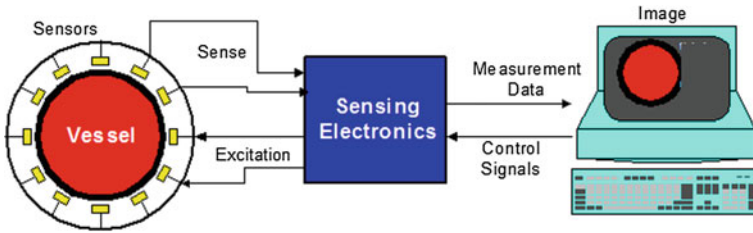

### 13.5.1 Basic Principles of Computed Tomography

The tomographic techniques can be divided into two groups [202, 235]:

1. *Hard-field tomography*: In this class of tomography, the path of the signal is known to follow a straight line and the only affect on the detected signal strength is due to material along that path. Typically, this results in linear field lines. Hard-field techniques are thus also referred to as linear-field tomography. Nuclear ( $\gamma$ - and X-ray) tomography belongs to this category.
2. *Soft-field tomography*: In contrast, for soft-field tomography, the material throughout the subject affects the signal strength. Typically, this results in non-linear field lines which makes reconstruction a much more demanding challenge. Soft-field tomographic techniques are thus also called non-linear-field tomography. Electrical tomography belongs to this category.

#### 13.5.1.1 Electrical Tomography

Electrical tomographic techniques, despite their relatively modest image resolution, have received considerable attention mainly because of their potentially high imaging speeds (i.e., 1 ms might be achievable) and relatively low cost, non-intrusive and non-hazardous nature [60, 156, 193, 222]. The group of electrical tomographic techniques can themselves be further sub-divided into sub-categories and considerable interest has been given to methods based on the measurement of the passive electrical quantities, resistance (impedance), capacitance and inductance. Electrical tomography systems comprise sensors, measurement electronics, switching electronics, signal conditioning, analogue/digital conversion, communications and a computer hosting control and data processing, including inversion, analysis and display algorithms [235]. A schematic representation of a typical system is shown in Fig. 13.8. For capacitance and inductance systems the electrodes are frequently noninvasive, lying outside the vessel wall. For resistance measurements the electrodes are usually

**Fig. 13.8** A typical electrical tomography system [235]. The figure is provided by Professor Trevor York that also gave permission to reproduce the figure in this book (personal communications)

invasive but not intrusive. However, for vessels with conducting walls it is necessary in all cases for the electrodes to be located inside the vessel. Electrical impedance tomography (EIT) is based on the measurement of resistance and reactance patterns and can produce conductivity ( $\sigma$ ) and permittivity ( $\epsilon$ ) images. Electrical capacitance tomography (ECT) involves the measurement of capacitance profiles and generates images of permittivity distributions. Mutual inductance tomography, also referred to as electromagnetic inductance tomography (EMT), employs inductance measurements to extract tomographic data related to permeability ( $\mu$ ) and conductivity ( $\sigma$ ) distributions. Hence, the electrical techniques can be divided in three categories based on the electrical quantities of the imaged mixture. These quantities are the magnetic permeability ( $\mu$ ), electric permittivity ( $\epsilon$ ) and electrical conductivity ( $\sigma$ ). The relationships of these quantities are based on the Maxwell's equations [41]. The electric conductivity is a measure of the ease with which a material conducts electricity. The electric permittivity is a measure of how readily the charges within a material separate under an imposed electrical field. High-conductivity materials allow the passage of both direct and alternating currents. High-permittivity materials allow the passage of only alternating currents. Both of these properties are of interest in industrial applications, because different fluids and solid materials have different conductivities and permittivities. In Electrical Impedance Tomography (EIT) the quantity to be imaged is actually the impedivity which is the inverse of the admittivity, including both the electric conductivity and permittivity. That is, the admittivity  $\gamma$  is given by  $\gamma(x, \omega) = \sigma(x, \omega) + i\omega\epsilon(x, \omega)$ , where  $\omega$  denotes the angular frequency of the applied current [41]. In some situations the real part of the impedivity may dominate in which case the technique is named Electrical Resistance Tomography (ERT). When the imaginary part of the admittivity dominates the technique is named Electrical Capacitance Tomography (ECT). ECT has been developed for imaging industrial processes containing dielectric (non-conducting) materials [94, 118, 193, 202, 211, 212, 229]. It is based on boundary measurements of the changes in capacitance that are caused by the change in dielectric material distribution. The capacitance measurements are taken from a multi-electrode sensor (typically 8 or 12) surrounding an industrial process vessel or pipeline. For capacitance measurements, electrodes must have a large surface area in order to provide sufficient signal. Electrodes are often located outside the vessel such that the technique is noninvasive

as well as non-intrusive. An ECT system consists of three major components (see Fig. 13.8): the ECT sensor that registers the physical responses from the material mixture being measured, an excitation and measurement circuitry that drives the sensor and conditions the received signals, and a data acquisition and coordination system to provide control signals for the sequential excitation of the electrodes and reconstruct tomographic images of the region of interest. The electrodes are excited one by one and the capacitance values between the excited electrode and the remaining ones are measured, yielding  $N(N - 1)/2$  independent measurements for  $N$  electrodes. The measurement protocol as described can be imagined as a rotation of the electrical field around the column cross-section in discrete steps with an angle  $\alpha = 360^\circ/N$  [60, 202]. This is analogous to the source-detector movement in computerized tomography used in medical imaging. In most ECT systems, the frequency of the electrical signal that imposes the electrical field in the measurement domain is of the order of 1 MHz. This allows the measurement time per electrode-pair to be kept short. This is an advantage over the nuclear techniques, where speed is an issue. However, the imaging speed is still a bottleneck in ECT applications because it directly affects the ability in capturing the dynamics of the processes. Currently, the maximum scanning speed achieved by ECT is reported to be 300–1000 frames per second. The cross-sectional distribution of permittivity is reconstructed from these capacitance measurements mathematically using some algorithm. The distribution of the phases in the flow cross section can then be inferred from the permittivity distribution. ECT is regarded as soft-field tomography and requires complicated image reconstruction due to the non-linear relationship between the measurements and the permittivity distribution. Compared with other tomography modalities, ECT offers some advantages, such as no radiation, rapid response, relatively low cost, being non-intrusive and non-invasive, and withstanding high temperature and pressure. If the electrical field inside the measurement plane does not enclose free electrical charge, the relationship between the spatial distribution of the permittivity and the measured capacitance can be derived from Maxwell's equations and expressed as [31, 60, 94, 202, 229]:

$$\nabla \cdot [\epsilon(x, y) \nabla \phi(x, y)] = 0 \quad (13.15)$$

$$C_{ij} = \frac{Q_i}{V_{ij}} = -\frac{1}{V_{ij}} \int \int_{\Gamma} \epsilon(x, y) \nabla \phi(x, y) d\Gamma_i \quad (13.16)$$

where  $\nabla$  is the gradient operator,  $\epsilon(x, y)$  is the permittivity distribution in the sensing field,  $\phi(x, y)$  is the electrical potential distribution,  $V_{ij}$  is the potential difference between two electrodes  $i$  and  $j$  forming the capacitance,  $\Gamma_i$  is the electrode surface and  $Q_i$  the induced charge on sensor  $i$ .

The boundary conditions when one electrode is excited with a fixed voltage  $V_0$  and all other electrodes are kept at zero potential, as occurs during the measurement procedure, were specified as [60]:

$$\phi = V_0 \quad (\text{for the excited electrode}) \text{ and} \quad (13.17)$$

$$\phi = 0 \quad (\text{for others}) \quad (13.18)$$

The reconstruction algorithms for the ECT and ERT have many similar features as both of these tomographic modalities are governed by similar partial differential equations (i.e., (13.15) and (13.22), respectively). Some important concepts related to the reconstruction algorithms are those of forward and inverse problems. The forward problem consists in the mapping of a set of theoretical field variables into a set of experimentally measured results. In the case of ECT, it would be the calculation of capacitance values for a given distribution of dielectric permittivity inside a sensor. The solution would consist of solving (13.15) with the associated boundary conditions, followed by the calculation of a set of integrals like (13.16). The inverse problem, on the other hand, is defined as finding the theoretical field variables from the measured results. This is equivalent to finding the material distribution inside a sensor from a set of measured capacitance values. This problem is referred to as *reconstruction* and remains one of the most difficult and challenging problems of electrical tomography. In general terms, the relationship between measured values of electrical capacitance and the material distribution in the space between electrodes can be written symbolically form as:

$$C = \mathcal{F}[\epsilon(\mathbf{r})] \quad (13.19)$$

where  $C$  denotes a matrix of all available capacitance measurements. In general terms  $\mathcal{F}$  denotes a non-linear operator, which in the present case consist in three steps: (1) Solving (13.15)  $N - 1$  times with appropriate boundary conditions for each electrode excitation. (2) calculating the flux distribution for each solution. (3) Calculating capacitance matrix  $C$  using (13.16). The aim of the image reconstruction is to obtain the reciprocal of operator  $\mathcal{F}$  which would give the original distribution of dielectric properties  $\epsilon = \epsilon(\mathbf{r})$  from the measurement of capacitance:

$$\epsilon(\mathbf{r}) = \mathcal{F}^{-1}[C] \quad (13.20)$$

The commonly used algorithm to reconstruct the voidage distribution is the linear back projection (LBP) algorithm [60, 118, 193, 202, 235]. In this procedure the operator  $\mathcal{F}$  is linearized by use of the so-called hard-field assumption. The linearization and discretization process can be expressed as:

$$\mathbf{C} = \mathbf{S}\mathbf{G} \quad (13.21)$$

in which  $\mathbf{C}$  denotes the capacitance vector,  $\mathbf{S}$  the sensitivity matrix (projection matrix) which is the response of a particular electrode-pair to a small change of the otherwise uniform permittivity distribution in a particular location, and  $\mathbf{G}$  the image vector. The LBP algorithm solves this (usually ill-posed) problem as a back projection process by approximating  $\mathbf{S}^T \mathbf{S}$  by the identity matrix. Further details on the algorithm are

given by [60, 94, 118]. The LBP approach is fast, but offers qualitative images with low spatial resolution only. Various methods have been developed to improve the image quality. These methods can generally be classified in two categories: iterative algebraic reconstruction techniques and neural networks. These methods clearly outperform LBP in accuracy, but at a much higher computational cost. A typical iterative algorithm starts out with an initial guess of the distribution, that could, for instance, have been generated from the measurements obtained using LBP, a forward solver, typically a FEM model, predicts the measured boundary values. For ECT this is the inter-electrode capacitances and for ERT the voltages. The predicted and measured values are compared and the resulting errors are fed back, via the inverse algorithm, to give an improved estimate of material distribution. This iteration is repeated until the magnitude of the error vector is below some defined threshold of tolerance. For real time applications, LBP is at present the only alternative. However, obtaining good spatial resolution remains a major challenge in ECT. In addition, the presence of electrostatic charges in the imaging domain negatively influences the validity of ECT maps. Another challenge is reconstructing solids distribution maps for systems of which the particle permittivity changes over time.

The basic aim of ERT is to determine the distribution of electrical conductivity from measurements of voltage around the periphery of a vessel or a pipeline. ERT is used to image mixtures where the continuous phase is conductive and the dispersed phase insulating or conducting to a lesser degree [94, 211, 235]. In this case, the electrodes are relatively small and mounted in contact with the conducting materials at the inside surface of a pipe (or vessel) wall and directly in contact with the fluids. Alternatively, a conductive ring (also in contact with the fluids) can be used. A number of different excitation current patterns are applied and the resultant voltages are measured. Usually a pair of electrodes are excited with a current source and the resulting potential difference is measured between pairs of electrodes. These data are then used to construct a conductivity distribution inside the sensor, which reflects the physical distribution of the mixture components. It has been used for imaging hydrocyclones, mixing processes and multiphase flows. This soft-field sensing technique provides high sensitivity near the vessel walls but it is poor in the center of the region. The operation of the ERT systems is basically the same as of the ECT systems except that a high-impedance measurement frontend is needed for conductive loads. Thus ERT uses current injection techniques with voltage measurement circuits. Similarly to ECT, the conductive ring sensor of ERT can be treated as an electrostatic field problem and can be characterized by [60, 94]:

$$\nabla \cdot [\sigma(x, y) \nabla \phi(x, y)] = 0 \quad (13.22)$$

where  $\nabla$  is the gradient operator,  $\sigma(x, y)$  is the conductivity distribution in the sensing field and  $\phi(x, y)$  is the electrical potential distribution.

The boundary conditions are given by [60, 94, 207]:

$$\int_{\Gamma_1} \sigma \frac{\partial \phi}{\partial n} ds = I, \quad \int_{\Gamma_2} \sigma \frac{\partial \phi}{\partial n} ds = -I \quad (13.23)$$

$$\phi/\Gamma_n = \text{constant} \quad (n = 1, 2, \dots, N) \quad (13.24)$$

$$\frac{\partial \phi}{\partial n}|_{\Pi} = 0 \quad (13.25)$$

where  $\phi$  is the potential distributions in response to the presence of currents  $I$ ,  $\Gamma_1$  and  $\Gamma_2$  are the electrical contact domain for current injecting presenting Neumann conditions,  $\Gamma_n$  are electrical contact domains and  $\Pi$  represents other domains on the external boundary of the conductive ring.

Mutual Inductance Tomography, also known as Electro-Magnetic inductance Tomography (EMT), is the least mature electrical tomography technique. EMT is one of the computerized tomography technologies based on electromagnetic theory. Nevertheless, the EMT offers a number of advantages, such as flexibility in sensor design and no contact with the sensing zone. An EMT sensor consists of a set of excitation coils, which produce a magnetic field within a cross section of a pipeline or vessel. A set of detection coils is used to detect the changes in the magnetic field due to changes in permeability and conductivity inside the vessel. To achieve a high sensitivity, a high excitation frequency is needed. So far, the image resolution of EMT is poor. The EMT is applicable for processes involving mixtures of ferromagnetic and/or conductive materials.

For a body having electrical and magnetic material properties that are linear, isotropic and non-dispersive, the EMT sensors are governed by [94, 156, 211]:

$$\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H} \quad (13.26)$$

$$\nabla \times \mathbf{H} = (\sigma + j\omega\epsilon)\mathbf{E} \quad (13.27)$$

$$\nabla \cdot (\epsilon\mathbf{E}) = \rho \quad (13.28)$$

$$\nabla \cdot (\mu\mathbf{H}) = 0 \quad (13.29)$$

where the Maxwell's equations are given in complex vector notation.  $\nabla$  is the gradient operator,  $\mathbf{E}$  is the electric field strength,  $\mathbf{H}$  is the magnetic field strength,  $\omega$  is the applied angular frequency,  $j = \sqrt{-1}$  is the complex index,  $\mu$  is the magnetic permeability,  $\sigma$  is the electrical conductivity,  $\epsilon$  is the permittivity distribution in the sensing field, and  $\rho$  denotes the charge density.

The induced voltage,  $V$  is given by:

$$V = -\frac{j\omega}{I} \int_{\text{coil}} \mathbf{A} \cdot \mathbf{J} dv \quad (13.30)$$

where  $I$  is the total current through the coil,  $\mathbf{A}$  is the magnetic vector potential and  $\mathbf{J}$  is the current density.

The goal in electrical impedance (EIT) tomography is to reconstruct the resistivity or more general the admittivity distribution of the interior of the vessel or pipeline based on the knowledge of the injected currents and measured voltages on the surface

[94, 193, 207, 235]. Typically electrodes are attached to the wall of the vessel and small alternating currents are applied to some or all the electrodes. The resulting electrical potentials are measured, and the process may be repeated for numerous different configurations of the applied current. Several different electrode designs have been used, and their shapes are influenced by a number of factors, including the measurement protocol. The simplest of these involves passing current through two electrodes, and recording the potential difference, in pairs, between the remaining electrodes. The source and detector electrode pairs are multiplexed, which simplifies the measurement electronics, and so the same electrodes are used in turn for both source and detection. EIT involves injecting currents into the material being imaged, so the bulk phase must be electrically conducting and make contact with the electrodes. EIT can then be used to produce images based upon variations in conductivity. The EIT is thus used to investigate processes where the continuous phase is electrically conducting whereas the dispersed phase could be conducting or insulating. The walls of the vessel or pipe are usually non-conducting. The traditional EIT sensors were basically applied to the aqueous-based fluids that possessed continuous admittance. With large bubbles and foams present, some of the electrodes may lose their contact with the electrical conductive fluid and thus the measurements from a traditional EIT sensor might be erroneous. Moreover, the electric sensing techniques are normally fast but with low spatial resolution and are inexpensive compared to the other techniques. Several methodologies have been used to reconstruct EIT images. One methodology that has been used to reconstruct EIT images is the complete electrode model (CEM) [41, 186]. The CEM takes into account the discrete electrodes, effects of the contact impedances between the electrolyte and the electrodes and also the shunting effect of the electrodes. The CEM can be written in the form [41, 186, 207]:

$$\nabla \cdot (\gamma \nabla \phi) = \nabla \cdot ((\sigma + i\omega\epsilon) \nabla \phi) = 0 \text{ in } \Omega \quad (13.31)$$

$$\phi + z_l \gamma \frac{\partial \phi}{\partial n} = \phi + z_l (\sigma + i\omega\epsilon) \frac{\partial \phi}{\partial n} = V_l \text{ on } e_l, l = 1, 2, \dots, L \quad (13.32)$$

$$\int_{e_l} \gamma \frac{\partial \phi}{\partial n} dS = \int_{e_l} (\sigma + i\omega\epsilon) \frac{\partial \phi}{\partial n} dS = I_l \text{ } l = 1, 2, \dots, L \quad (13.33)$$

$$\gamma \frac{\partial \phi}{\partial n} = (\sigma + i\omega\epsilon) \frac{\partial \phi}{\partial n} = 0 \text{ on } \partial\Omega \text{ off } \bigcup_{l=1}^L e_l \quad (13.34)$$

A reduced set of governing equations can be used for EIT when a low frequency or direct current is used, i.e.,  $\omega \approx 0$ , thus the complete model is approximated as [203]:

$$\nabla \cdot (\sigma \nabla \phi) = 0 \text{ in } \Omega \quad (13.35)$$

$$\phi + z_l \sigma \frac{\partial \phi}{\partial n} = V_l \text{ on } e_l, l = 1, 2, \dots, L \quad (13.36)$$

$$\int_{e_l} \sigma \frac{\partial \phi}{\partial n} dS = I_l \text{ } l = 1, 2, \dots, L \quad (13.37)$$

$$\sigma \frac{\partial \phi}{\partial n} = 0 \text{ on } \partial\Omega \text{ off } \bigcup_{l=1}^L e_l \quad (13.38)$$

where  $L$  denotes the number of electrodes,  $\phi = \phi(x, y)$  denotes the electrical potential,  $\sigma = \sigma(x, y)$  represents the conductivity (the admittivity is assumed to be real),  $e_l$  denotes the  $l$ 'th electrode,  $z_l$  represents the effective contact impedance between the  $l$ 'th electrode and the electrolyte (also real),  $V_l$  represents the potentials on the electrodes,  $I_l$  denote the injected currents and  $\mathbf{n}$  is the outward unit normal. In addition, the following two conditions for the injected currents and measured voltages are needed to ensure the existence and uniqueness of the solution:

$$\sum_{l=1}^N I_l = 0, \quad \text{conservation of charge,} \quad (13.39)$$

$$\sum_{l=1}^N V_l = 0, \quad \text{choice of ground.} \quad (13.40)$$

In order to solve the CEM a suitable numerical method (i.e., FDM, FVM, FEM, SEM, SM) is required since in general cases the analytical solution can not be found (to the non-linear problem).

In addition to ECT, ERT, EMT and EIT, there are other emerging techniques, such as multi-modality tomography (MMT). A multi-modality system makes use of two or more different sensing entities to locate or measure different constituents in the object space. For some processes, two electrical tomographic techniques have to be combined to give meaningful measurement results [222]. Similarly, due to the need for distinguishing three components, dual-modality tomography systems are required, which can measure two distinct physical properties of the fluid. For example, for fluids whose continuous phase is an electrical insulator, a combination of capacitance and  $\gamma$ -ray tomography could be used. When the continuous phase is conducting, resistance and  $\gamma$ -ray tomography could be employed. Other options include the combination of capacitance and resistance.

### 13.5.1.2 Nuclear Tomography

A second class of tomographic techniques makes use of nuclear fields [202]. In this case, a source generates high-energy photons that travel through the system. Nuclear Computed Tomography (CT) techniques based on  $X$ - and  $\gamma$  radiation are alternative devices to the electrical techniques. In the case of using a nuclear technique, the basic principle of CT technique is similar to that of the CARPT technique [95]. The main difference between the two methods is that the CT method is a kind of *transmission tomography* technique, whereas the CARPT method is a kind of *emission tomography* technique. The CARPT technique is based on information obtained by detection of a tracer particle which is located inside a vessel. The nuclear CT technique performs an analysis based on radiation attenuation alone a beam through a cross-section of an object [27]. The same detectors may be used in both methods. The older literature distinguished between  $X$ - and  $\gamma$  radiation on the basis of wavelength, with

radiation shorter than some arbitrary wavelength, defined as  $\gamma$ -rays. Thus,  $\gamma$ -rays was defined as nuclear radiation of high frequency and therefore high energy. However, because of a broad overlap in energy ranges obtained in recent years, the two types of nuclear radiation are now normally defined by their origin:  $X$ -rays are emitted by definition by electrons outside the nucleus, while  $\gamma$ -rays are emitted by the nucleus. Historically, the  $\gamma$ -rays radiation was considered more energetic than the  $X$ -rays providing a deeper penetration into the opaque systems. Nowadays, these methods might be considered equivalent. In the nuclear techniques the rays (e.g.,  $X$ - and  $\gamma$ ) from a source penetrate an object for a few seconds and an image of the density distribution is produced based on differences in the nuclear rays attenuation detected by the scintillation detectors [196]. If a sufficient number of scan projections (multi-angle scan) are taken, this allows direct determination of the void fraction at any location in the flow field.

The traditional  $\gamma$ -ray CT facility built at the Washington University in Saint Louis, sketched in Fig. 13.9, consist of one  $\gamma$ -ray source (to all directions) and 11 detectors that can be located around the column wall at a certain axial level at the time. The multi-beam  $\gamma$  scan is obtained by rotating this device from 0 to 360° around the column. Among the suggested techniques for reconstruction are convolution or filtered back projection, algebraic reconstruction and estimation-maximization (E-M) algorithms. Kumar and Dudukovic [106] considered the E-M procedure to be more accurate than the alternative algorithms. In this CT unit about 4000 projections were achieved with a spatial resolution of 5 mm and density resolution of 0.04 g/cm<sup>3</sup>. The scanning time was about 45 min in order to achieve a time-average density distribution. It was claimed that the spatial resolution of this type of scanner can be improved further with smaller scintillation detectors and a stronger source.

The measurement principle is transmission. For a monochromatic beam of high energy photons with initial intensity  $I_0$ , the *Lambert-Beer law* describes the transmission through a material of constant density:

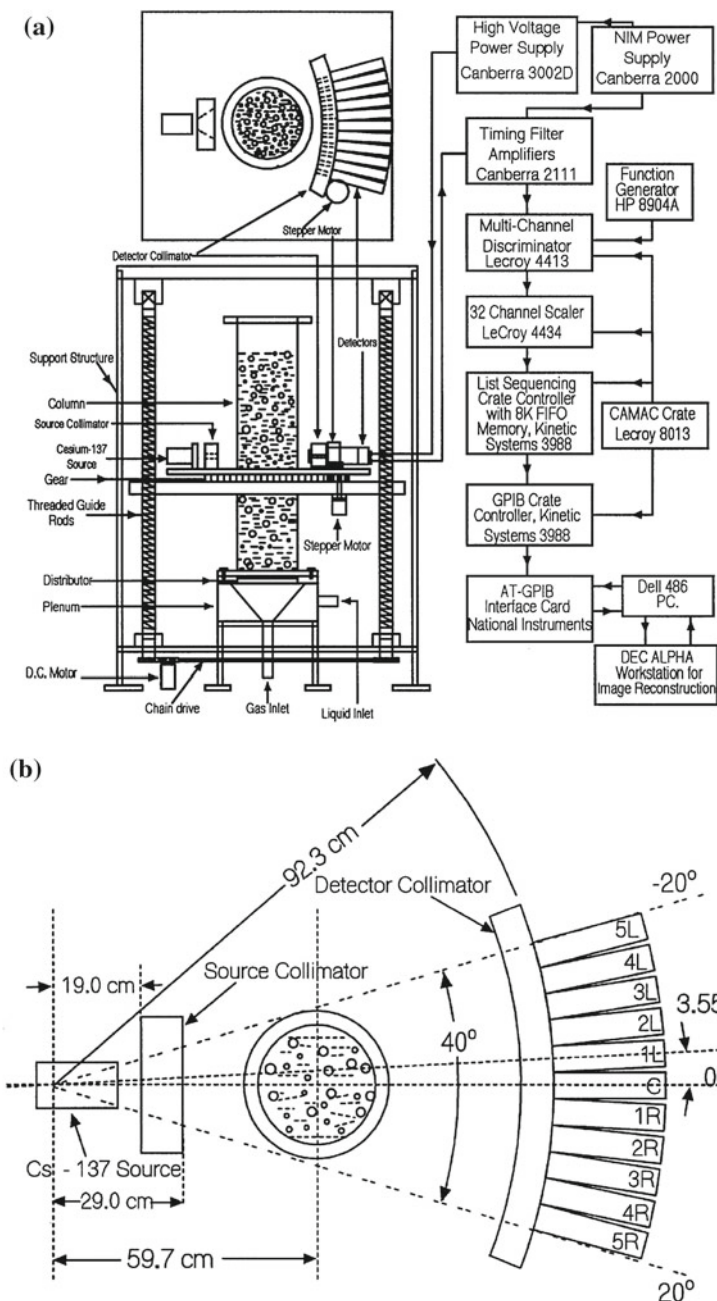

$$\frac{I(x)}{I_0} = \exp(-\mu x) \quad (13.41)$$

with  $\mu$  the attenuation coefficient,  $x$  the thickness and  $I(x)$  the intensity after passage.

For a beam along a path of varying density, i.e. varying attenuation, the measured intensity is the integral effect of the local attenuation with the local attenuation coefficient:

$$\frac{I(x)}{I_0} = \exp \left[ - \int \mu(x) dx \right] \quad (13.42)$$

Due to the high energy, the photons travel in straight lines. Only via an interaction with the system material will they deviate from this line upon which they are not measured. By measuring over a large number of independent lines, sufficient information can be collected for a tomographic reconstruction. Compared to Electrical Tomography, the nuclear techniques are slow. This is a consequence of safety issues and the random nature with which the photons are generated when employing nuclear sources

**Fig. 13.9** The CT facility. **a** Experimental setup for CT scanning. **b** Details of source-detector configuration for CT. The figures are reproduced from Chen et al. [40] with permission from Elsevier

such as  $^{137}\text{Cs}$ . The latter creates inherent noise in the measured beam intensity (the inverse of the square root of the number of photons counted). Consequently, the measuring time cannot be made short without the use of excessively strong sources. For material mixtures, adapted forms of the Lambert-Beer law are generally employed. For example, considering  $\gamma$ - and X-ray densimetry to characterize gas–particle two-phase mixtures within fluidized beds, the intensity  $I(x)$ , is frequently determined from the Lambert-Beer law on the form [146, 147]:

$$I(x) = I_0 \exp [ -((1 - \alpha_g)\mu_p + \alpha_g\mu_g)d ] \quad (13.43)$$

where  $\mu_p$  and  $\mu_g$  denote the linear absorption coefficients of the particle and gas phases,  $\alpha_g$  is the volume fraction of the gas phase and  $d$  is the inner diameter of the system. It is noted that the attenuation characteristics of the fluidized bed wall is incorporated in  $I_0$ , and both  $\mu_p$  and  $\mu_g$  are in principle functions of the photon energy  $E$ .

### 13.5.2 Chemical Reactor Characterization by CT:

Fluidized beds, slurries and many other multiphase flows are opaque and the powerful, laser based techniques of fluid mechanics can not be used to characterize these systems. However, solids are to some extent transparent to electrical fields and radiation such as  $\gamma$ - and X-rays that may penetrate these multiphase systems [147].

#### 13.5.2.1 Electrical Tomography

Xie et al. [222] and Tapp et al. [193] presented surveys of potential chemical engineering applications of two electrical process tomography techniques: electrical capacitance tomography (ECT) and electrical impedance tomography (EIT). It was explained that electrical resistance tomography (ERT) can be considered a particular case of electrical impedance tomography which is thus often also referred to as EIT. Common applications of electrical tomography techniques includes [94, 222]: gas–oil two-phase flow imaging using ECT, depressurization study of vessels using ECT, hydro-cyclone separator imaging using ERT. Electrical tomography has also been applied to chemical engineering processes [193], including: bubble columns, fluidized beds, pneumatic transport, liquid mixing, cyclonic separation, pressure filtration, liquid pipe-flow, polymerization, emergency depressurization, and paste extrusion. For heterogeneous systems comprising materials with different electrical properties, ECT and EIT can monitor dynamic processes such as: mixing; separation; pneumatic, hydraulic and belt-conveyed transportation; particle concentration distributions; and flow regimes. These sensors can also be used to monitor chemical reactions and temperature variations, if the electrical properties change during the process. Liu et al. [118] considered ECT to be a successful technology

for imaging industrial processes containing dielectric materials such as gas–solid flows in circulating fluidized bed. Information about phase fraction distributions, flow regime, gas and solids velocities, gas–particle interaction, particle boundary interaction and the influence of gas on the solids flow were provided.

More recently, Wang et al. [212] proposed the electrical capacitance volume tomography (ECVT) to obtain instantaneous 3D images.

ERT has been proved to be a powerful tool for mapping the concentration and velocity distributions of the second phase in two-phase flows, where electrical differences between the two-phase fluids exists [210]. Lucas et al. [121] measured the solids volume fraction and velocity distributions in vertical upward and inclined solids–liquid flows using dual-plane ERT. They found that the estimates of the mean solids volume fraction and the mean solids velocity were in good agreement with the true values of these variables, whereas the estimates of the solids volumetric flow rate were less accurate. Holden et al. [89] did image the stirred-vessel macro-mixing using ERT. The ability of the system to distinguish different flow patterns from two types of impellers in 3D and to monitor mixing processes at plant scale has been demonstrated by monitoring the dispersion of a brine pulse tracer.

### 13.5.2.2 Nuclear Tomography

Both electrical, X-ray and  $\gamma$ -ray CT techniques have been designed to measure cross-sectional density distributions in industrial vessels like two-phase fluidized beds. Halow and co-workers [78, 79] did conduct extensive research on the use of capacitance techniques to measure bed levels, solids flow rates and gas bubble phenomena in fluidized beds. The behavior of gas bubbles, bubble growth and splitting, the effects of gas distribution, elevated temperatures, and pressure in gas–solid fluidized beds using X-ray images have been investigated by Rowe and coworkers [168–170] at University College London (UCL) [232]. The application of  $\gamma$ -rays to high-velocity fluidized systems has been developed extensively to provide quantitative measurements of the solids concentration and distribution, particularly in catalytic crackers [10, 18, 106, 128, 176]. Gas-bubble size and frequencies in fluidized beds under different operating conditions have been studied by a number of investigators using density gauge type devices which could travel vertically up and down the bed vessels. Reviews of the application of  $\gamma$ -radiation absorption in determining the fluidized bed properties are given by Weimer et al. [216], Simons et al. [182] and Tayebi et al. [196]. These techniques enabled gross scale mapping of the particle circulation patterns in bubbling fluidized bed revealing the so-called *Gulf stream effect* produced by an uneven distribution of solids at the base of the vessel [137]. In the past the traditional nuclear techniques were rather slow due to inherent noise. The frame rate (temporal resolution) that could be obtained was thus normally low (the total measurement time is of the order of one hour), thus only time-average volume fraction distributions were reconstructed. High spatial resolution requires relatively long measuring times as compared to the electrical techniques, slowing down this technique. The electrical tomography techniques are generally much faster, giving

a high temporal resolution. However, the electrical tomography techniques suffer from the soft-field effects characteristic of techniques with low penetrating abilities. Nuclear densimetry has hard-field properties with higher penetrating abilities. This fundamental difference results in differences in sensor design, imaging speed, image reconstruction algorithms and also cost [229]. Mudde et al. [146] reexamined the  $\gamma$ -ray densimetry with focus on reduction of sampling times and the ability to virtualize evolving structures within fluidized beds. A multiple fan beam configuration using static  $^{137}\text{Cs}$  sources was evaluated by performing simulated reconstructions of the two-dimensional void fraction distribution within a 400 mm diameter fluidized bed. Results from both three and five source systems were presented, which they claimed showed that spatial and temporal resolutions of 10 mm and 10 ms are achievable. Mudde et al. [147] performed a feasibility study of a time-resolving X-ray tomographic system for investigating the phase distribution of fluidized beds. The X-ray CT system employed was built at the Technical University of Delft (TU Delft) in the Netherlands [160]. It was found that it was possible to reconstruct objects with a spatial resolution of about 5 mm at a frame rate of 200 Hz. The traditional  $\gamma$ -ray CT facilities have also been used to measure gas volume fractions in two-phase gas–liquid bubble column and stirred tank reactors [40, 106, 117]. Kumar et al. [106] developed a  $\gamma$ -CT scanner for imaging gas-holdup distributions in two phase flow systems such as bubble columns and fluidized beds. The entire scanning assembly had a maximum rotation speed of about 1 rpm. Therefore, the hold-up distributions obtained were time-averaged. The scanning assembly had a central opening large enough for it to be moved up and down with respect to the test section. This latter motion was achieved to accomplish the axial positioning required for scanning different horizontal sections of the vessel. The scanner has been used to study the effects of various parameters such as column diameter, superficial gas velocity, and distributor types in an air–water bubble column. These techniques give volume and time averaged volume distributions. For this reason, the time averaged void fraction data obtained are only suited for validation of time averaged Eulerian models. However, the method is slow and cannot be used to obtain instantaneous data. Chen et al. [40] used the  $\gamma$ -CT to measure time averaged gas void fraction distributions in a 44 cm diameter bubble column for the air–water and air–drakeoil systems at 2.5, 5, and 10 cm/s superficial gas velocities, which cover bubbly, transition, and churn-turbulent flow regimes, respectively. A sketch of the CT facility used in this study is shown in Fig. 13.9a. The configuration of the scanner consists of an array of NaI detectors of 5 cm in diameter (11 detectors) and an encapsulated 100 mCi  $\text{Cs}^{137}$  source located opposite to the center of the array of detectors. The detectors and the source were mounted on a plate, which was rotated around the axis of the column by a step motor controlled through a microprocessor. Moreover, the whole assembly was moved up and down along the column to scan different axial levels of the column. The source collimator provided a fan beam of  $40^\circ$  in a horizontal plane. The source was further collimated using a  $20 \times 10 \times 10$  cm lead brick with a central slit as shown in Fig. 13.9b. Liu et al. [117] used the same  $\gamma$ -CT facility to measure the cross section gas void fraction distribution in a gas–liquid stirred standard Rushton tank of  $20 \times 24 \text{ cm}^2$  with 20 cm static liquid height. Four baffles of 1.6 cm width

were mounted perpendicular to the wall of the tank. The impeller was a disk of 5 cm diameter with six blades of  $17\text{ cm} \times 13\text{ mm}$  symmetrically inserted into 8.5 mm, and it was located at  $1/3$  dimensionless static liquid height and linked with a shaft of 8 mm diameter. A ring sparger of 6.66 cm diameter with 8 holes was set at 1 cm away from the bottom of the tank.

### ***13.5.3 CT Limitations***

A disadvantage associated with all the CT techniques is that they are general very computer storage and computer time intensive.

#### **13.5.3.1 Electrical Tomography**

The electrical techniques suffer from soft-field effects characteristic of electrical methods with low penetrating abilities. This means that a change in the electrical properties in one location changes the field everywhere in the domain. This may cause poor resolution in the center of the bed. The main limitation of the ECT technology is in the inadequate spatial resolution it can provide [212]. The measurement resolution is dependent on the ECT sensor designs and image reconstruction. The resolution of the ECT images can be improved by increasing the number of sensors. However, the highly non-linear reconstruction problem is still considered the main obstacle to increasing resolution [212]. This problem is even more evident in the ECVT volume technology as the non-linearity of the problem is increased substantially [212].

#### **13.5.3.2 Nuclear Tomography**

The primary disadvantage of the nuclear techniques is the low frame rate (temporal resolution) that can be obtained due to inherent noise. High spatial resolution requires relatively long measuring times as compared to the electrical techniques. There are several steps in the raw data interpretation process from measurement signals to tomogram that determine the accuracy of the data. One such step is the noise on the measured data, while a second step is the choice of the reconstruction algorithm [147]. The nuclear measuring techniques have the added disadvantage of being biologically hazardous and expensive compared to other techniques. Special lead insulated facilities are required together with advanced safety protocols and regulations.

### ***13.5.4 Suggested CT Literature***

Xie et al. [222] presented a survey of the electrical tomography techniques for process engineering applications. Various aspects of design, operation and data processing were also described by Tapp et al. [193]. York [235] presented a survey on

the status of electrical tomography for industrial applications. Electrical impedance tomography (EIT) for flow measurements has been outlined by Cheney et al. [41, 186] and Wang et al. [207, 210]. Electrical capacitance tomography (ECT) sensor design has been outlined by Yang [229]. Wang et al. [211] discussed several issues related to the background theory of electromagnetic tomography (EMT), also known as magnetic induction tomography (MIT), which is one of the computerized tomography techniques based on electromagnetic theory.

Several reviews of experimental methods for studying the hydrodynamics of gas–solid fluidized bed can be found in the literature including nuclear measuring techniques [42, 196]. A survey of the historical development of the X-ray techniques has been given by Cheremisinoff [42]. In Dudukovic [55] the use of nuclear techniques in opaque multiphase systems is reviewed. van Ommen and Mudde [202] discussed experimental techniques available for measuring the gas–solid distribution in fluidized beds in a more recent review. A brief survey of nuclear tomographic reconstruction algorithms has been provided by Mudde et al. [146, 147]. Chaouki et al. [36] reviewed the non-invasive Tomographic and velocimetric techniques for monitoring multiphase flows.

## 13.6 Five-Point Electro Conductivity Probe Technique

The five-point electro conductivity probe technique (FPECPT) has been used to measure time averaged bubble size (volume) distribution, absolute bubble velocity and gas volume fraction in gas–liquid dispersions like the two-phase bubble columns and vertical pipe flows. Other similar conductivity probes have also been used [88, 135].

### 13.6.1 Basic Principles of FPECPT

The conductivity probe technique utilizes the difference in electrical conductivity in the various phases. In order to measure bubble characteristics such as the bubble size distribution and bubble motion, a conductivity probe needs at least two sensors. The two-point conductivity probe method requires the bubbles to move along more or less sharply predefined directions. For most conductivity probes, the bubble size and velocity estimation were based on the assumption that the bubble is always moving up vertically (e.g., the one-point probe of Serizawa et al. [179] and the five-point probe developed by Burgess and Calderbank [30]). In addition, these probes can only give bubble chord length, instead of bubble volume equivalent diameter. An improvement in the FPECPT was made by Steinemann and Buchholz [188]. They proposed a similar design as that of Burgess and Calderbank [30]. The difference in design is only that the 4th probe sensor is placed at the same radial position as the 1–3rd sensors. Based on the latter design, Steinemann and Buchholz [188] developed an estimation method for determining not only the bubble size distribution,

bubble velocity and frequency of bubbles, but also direction of bubble motion through analyzing the recorded voltage pulse sequence. This technique does not reject the recorded bubbles that are not symmetrical around the probe axis for the velocity computations. The measurement of the local gas volume fraction is similar to the one-point conductivity probe technique. That is, only the signals of the central sensor (i.e., probe sensor 0 in Fig. 13.10) are used.

The local void fraction  $\alpha_g$  is given by:

$$\beta_g = \sum_m \frac{T_{0,m}}{t_{\text{total}}} \quad (13.44)$$

where  $T_{0,m}$  and  $t_{\text{total}}$  are the gas contact period of the central sensor and total sampling time, respectively. The sum includes all responses, i.e., both true and false bubbles.

Based on these design estimation methods for determining the bubble size distribution, bubble velocity, frequency of bubbles and direction of bubble motion through analyzing the recorded voltage pulse sequence (Fig. 13.10c) is developed. This technique records bubbles which are not symmetrical to the probe axis, and utilizes all the recorded information. The direction of bubble motion is estimated by using the knowledge of the probe geometry. The absolute bubble velocity,  $v_{b,a}$ , the angles between the probe axis and the bubble trajectory (vertical angle),  $\theta$ , and the horizontal angle,  $\varphi$ , must be estimated. Four equations are formulated for the three unknown parameters:  $v_{b,a}$ ,  $\theta$  and  $\varphi$ . Thus, the over-determined system of equations has been solved by a minimization procedure. The false bubbles in this method determine the case in which the computer fails to solve the model equations for the bubble velocity and size. The five-point probe is capable of resolving the direction at which the bubble encounter the probe sensors. It is also possible to estimate the coordinates of bubble surface and thus the bubble size (volume) from the probe signals and the probe geometry, assuming the bubbles to be spheres or ellipsoids. The main advantages of this five-point probe compared to other conductivity probes are that the data treatment and estimation of bubble size and velocity are not based on the assumption that the bubbles always move up vertically in the column. The measurements are found to be repeatable with accuracy limited by errors of 5–10 % [122].

### 13.6.2 Chemical Reactor Characterization by FPECPT

The FPECPT has been used to measure time averaged bubble size (volume) distribution, absolute bubble velocity and gas volume fraction in two-phase bubble columns [72, 76, 95, 122, 230]. Other similar conductivity probes have also been used [88, 135].

Hills [88] was among the first to measure the local gas void fraction in a two-phase bubble column using a One-Point Electro Conductivity Probe (OPECP). The column was made of perspex with ID 138 mm and height 1370 mm. Three different sieve plates were used as gas distributors. Hills [88] did perform measurements at

different radial positions revealing that the radial voidage in the bubble column is non-uniform. Gasche [72] used the FPECPT of Steinemann and Buchholz [188] to measure the local gas void fraction, number average bubble size and number average bubble velocity at three axial levels with up to about 10 radial measuring point positions in a bubble column. The axial gas velocity was computed from the gas bubble velocity data. The system used was air-water. All the measurements were performed for superficial gas velocities (1–8 cm/s) within the homogeneous flow regime. The liquid superficial velocity was 1 cm/s. All the experiments were performed at ambient pressure and temperature. Menzel [135] measured the local gas void fraction in three different bubble columns (two IDs of 15 and 60; three different column heights of 2575, 3455, 5440 mm) and an air-lift reactor (ID 60 cm, height 5440 mm) by use of a One-Point Electro Conductivity Probe (OPECP) with four different gas distributors. It was mentioned that the same type OPECP was used earlier for measuring the void fraction in vertical two-phase (air-water) pipe flows by Serizawa et al. [179]. The systems used by Menzel [135] were air-water, air-water-Isopropanol (0.22 % by weight) and air-Glyzerin in water. The measurements were performed at different heights (1200; 510, 1260, 2460; 2920) in the different column designs. In the air-lift reactor the measurements were performed at level 2920 mm above the distributor. Yao et al. [230] used the same FPECPT as Gasche [72] and performed similar experiments in the same bubble column in Erlangen. Grienberger [76] also used the same FPECPT as Gasche [72] and performed similar experiments in the same bubble column in Erlangen. The systems used by Grienberger [76] were air-water, air-water-alcohols (Ethanol/n-Butanol) and air-water-salts (NaCl) to investigate the effect of these additives on the coalescence properties, gas volume fraction and bubble size distribution of the dispersions. Luo [122] used a similar FPECPT as the group in Erlangen [72, 76, 230] and performed similar experiments in a similar bubble column at NTH in Trondheim. The column was made from Plexiglas with ID 30 cm and height of 4.25 m. Measurements were performed at axial level 2 m above the distributor plate in eight radial positions [0, 0.25, 0.5, 0.6, 0.7, 0.8, 0.9, 0.95] at ambient pressure and at two different temperatures (11–13 and 25–27 °C). Up to eight different gas volumetric fluxes (superficial velocities) were measured [2, 4, 6, 8, 10, 13, 18] cm/s, and three liquid volume fluxes (superficial velocities) were studied [0, 1, 2] cm/s. The system used was air-tap water. Jakobsen [95] summarized the work performed by use of FPECPT at SINTEF Chemistry in Trondheim during the SPUNG (State Program for Utilization of Natural Gas) funded by the Norwegian Research Council in the period of 1987–1993. The column facility built by Luo [122] at NTH in Trondheim was used. An extended measurement series was run in much the same manner as the measurements were performed by the predecessor. The systems used were air-tap water, air-distilled water, air-water-alcohol (propanol), air-water-salt. A few measurements were performed at level 0.3 m in addition to the 2.0 m level as used by Luo [122].

### 13.6.3 FPECPT Limitations

The probe is an invasive device and may give rise to flow disturbance and is also concerned with uncertainties when detecting flow reversal. In addition, the estimation methods may be concerned with large errors when the bubble shape depart from sphere and ellipsoid. The bubble shape may be affected due to wetting problems of the probe which may cause similar errors. The method is of course not suitable for fluids of similar or very low conductivity.

It has been found that the gas volume fraction measurements are underestimated by this technique due to deformation and deflection of the bubbles by the probe [95, 122].

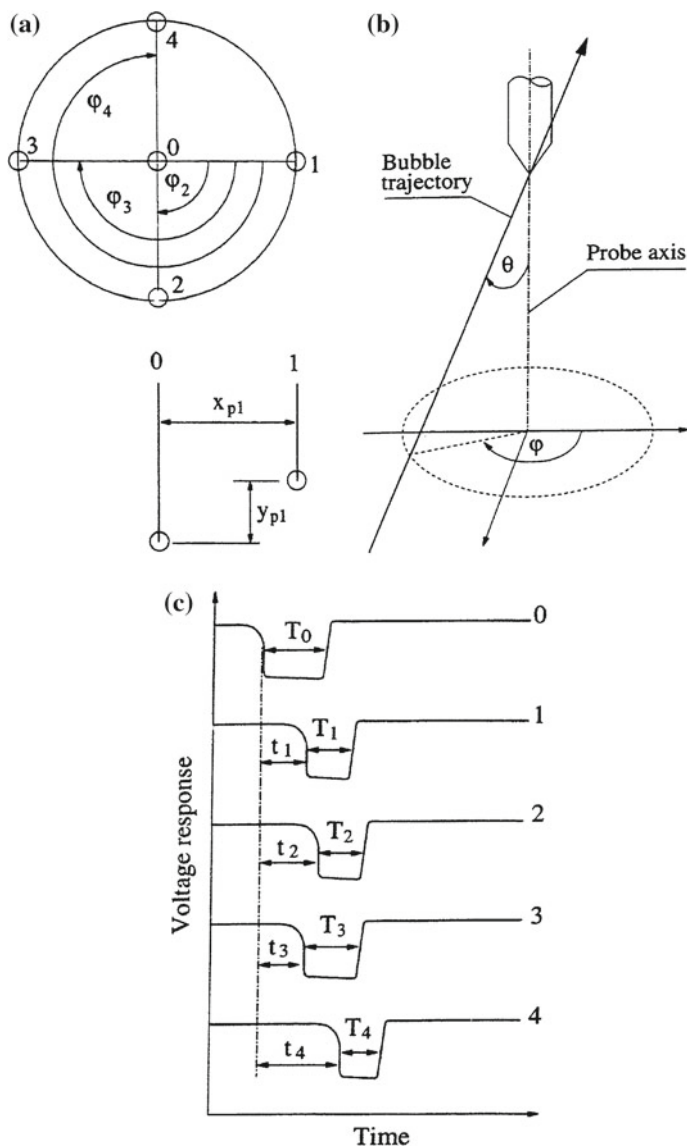

### 13.6.4 FPECPT Literature

The first Five-Point Electro Conductivity Probe Technique (FPECPT) was developed by Burgess and Calderbank [30]. In this technique, the bubble size and velocity estimation were based on the assumption that the bubble is always moving up vertically. An advanced version of the Five-Point Electro Conductivity Probe Technique (FPCPT) probe was designed by Steinemann and Buchholz [188]. The bubble size and velocity estimation were not based on the assumption that the bubble is always moving up vertically but computed from the geometry of the probe design and the signals from the bubbles.

In Fig. 13.10  $T_n$  indicates the pulse duration time caused by the bubble for probe sensor  $n$ .  $t_n$  is the response delay time for probe sensor no.  $i$  relative to probe sensor no. 0.  $\theta$  is the angle between the probe axis and the bubble trajectory.  $\varphi_n$  is the angle of probe sensor  $n$ .  $x_{pi}$  and  $y_{pi}$  are the horizontal distance between probe sensors 0 and  $n$  and vertical distance between probe sensors 0 and  $n$ , respectively.

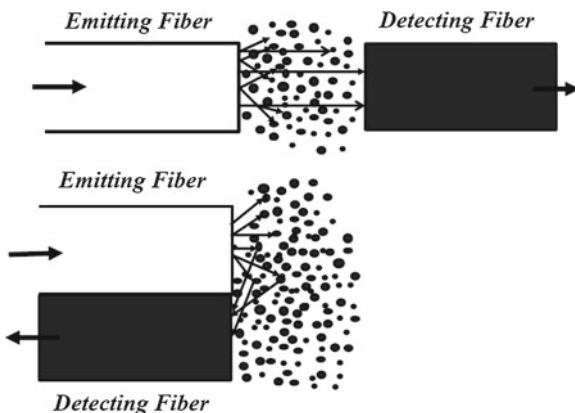

## 13.7 Fiber-Optic Probe Technique

There are basically two physical principles that have been utilized designing F-OPT sensors, light scattering and refraction. Light scattering reflective and transmission based optical fiber techniques have been applied to measure solids velocity distributions, particle concentrations and the cluster structures in fluidized beds. Light scattering extinction based sensors are sometimes used for determining particle size and concentration. Refractive based Fiber-Optic Probe Technique (F-OPT)s have been applied to measure gas fraction, bubble chord length and bubble velocity in gas–liquid and gas–liquid–solid systems. In general, the major purpose developing these probes has been to enable voidage measurements in opaque dense multiphase systems (i.e., gas–solid fluidization and gas–liquid (–solid) bubbly flows). Time-dependent measurements of the dispersed phase volume fraction are essential to

**Fig. 13.10** The Five-Point Electro Conductivity Probe Technique (FPECPT). **a** Probe design of Steinemann and Buchholz [188]. **b** Definition of Bubble movement parameters [122]. **c** Sketch of pulse sequence [122]

understand the flow behavior of dense multiphase mixtures. For dispersions with void fractions greater than a few percent, the optical depth is of the order of several particle diameters [116]. For this reason, the high resolution laser-based techniques developed for transparent single phase flows are inadequate for characterizing dense

**Fig. 13.11** Illustration of the forward light scattering (extinction) (*top*) and light backscatter (reflection) (*bottom*) principles applied in fiber optical probes. The figure is reproduced from Tayebi et al. [196] with permission from Taylor & Francis Ltd

systems behavior. Optical fibers are simple, yield high signal-to-noise ratios, and because of their small sizes create minimum disturbances in the flow yet being invasive techniques [116, 120]. However, the optical fiber based techniques are difficult to calibrate. A major advantage of such systems over others is the high frequency response, limited only by photoelectric electronics and photon statistics. The refractive, reflective and transmission optical sensors used in gas fluidization are based not only on different optical operation principles but have specific applications in terms of the information they can provide. Furthermore, each of these sensor types is subject to different design techniques and criteria, different manufacturing methods and requires appropriate data analysis techniques [34].

### 13.7.1 Basic Principles of F-OPT

Two physical principles have been utilized designing the F-OPT, light scattering and refraction. There are two basic types of light scattering applied in fiber optic sensor design. The first type of light scattering principle is based on *forward* light scattering between emission and detection fibers separated by a short distance (light transmission or extinction concepts), which makes use of the attenuation of a ray of light by solids in the space between the emitter and the detector. The emitter and detector are located right opposite to each other in the same plan with a short distance between, as illustrated in Fig. 13.11 (top). The intensity of transmitted light received by the photo detector is a function of light scattering, which is governed by the concentration of the suspended solid particles between the two fiber ends. Therefore, information such as particle concentration and bubble velocity can be assessed

[34, 42, 116, 196, 218]. These probes have been employed characterizing particulate flows in gas fluidized bed, but not for characterizing bubbly flow in bubble column reactors. The second type of light scattering principle applied in fiber optic sensors is based on light *backscattering* onto an optical fiber system, in which the incident light is reflected off the solid particles and recorded as sketched in Fig. 13.11 (bottom). The light reflected to the detecting fiber(s) is a function of the local particle concentration in front of the probe [196]. The particle concentration can thus be determined from the intensity of the reflected light. Multi-fibre bundles can be employed to obtain particle velocity and flow direction. This method has been used measuring solid particle motion in fluidized bed reactors. In a dense dispersion the probe will distinguish between the gas bubbles and the denser dispersion, in dilute dispersions it will distinguish between clusters and the dilute gas-particle mixture [63, 218]. Optical fiber systems based on light backscattering fall into two main groups [120, 196]. In the first group light is guided through a single fiber and the light backscatter from the suspension returns through the same fiber and is directed to a detector via a beam splitter or another light segregation technique. The single-Fibre-Reflection (SFR) probe system has been successfully applied to measurements of concentrations and velocities in several multiphase flow systems [116, 166, 219]. In this case, the detector signal always increases with the number of particles causing the backscatter. In the second group of fiber optical probe design based on light backscattering, light is guided by one or several bundled fibers to the suspension, while other distinct fiber(s) return the backscatter light directly to the detector. The latter method avoids complex optical paths, hence it is easier to implement. Nevertheless, Louge [120] warned that systems consisting of separate emission and detection fibers are prone to ambiguous signals, which may rise with solid volume fraction at low concentrations, but then fall in denser suspensions. A survey of a few representative investigations is provided. Irrespective of the measuring principle applied (transmission or reflection), either single particles or swarm of particles can be detected depending on the method of signal treatment after the light-receiver [90, 132, 153, 154]. Light transmission (light-extinction methods) is a well-developed technique for determining particle size (for the size range 0–50  $\mu\text{m}$ ) in dilute dispersions (bubble, drops and solid particles) [119]. F-OPT (reflection methods) are frequently used determining solid fraction in (dense) fluidized beds. The forward scattering based miniaturized light probes provide in situ localized measurements. Okhi et al. [153] used such a technique for simultaneous measurements of particle size and local particle velocity. Okhi and Shirai [154] developed a small probe consisting of three fibers bounded together such that the fiber at the center of the bundle provided the illumination that was detected by the other two fibers. The probe was designed primarily to study the movement of solid particles in the bed. However, it was further adapted to investigate bubble flow. The local bubble fraction was found by dividing the mean frequency of the photomultiplier output signal by the stroboscope flash frequency. The mean rise velocity of bubbles was computed from the output signals of the frequency to voltage converts by means of a cross-correlation method [196, 218]. Yasui and Johanson [233] designed one of the first optical sensor based on forward scattering measuring the bubble rise velocity. The methodology proposed has formed the basis for many

subsequent studies [196, 232]. The sensing elements of their probe pair consisted of a light source and a light reflecting prism. The two probes were separated by a short distance and positioned one above the other in a fluidized bed of powders. The bubble rise velocity was estimated from the known distance between the probes and the time lag between the signals. The average thickness or vertical dimension of the bubbles was computed from the ratio of the average width of the oscillogram trace and the average time lag. More recently, Cutolo et al. [45] correlated measurements of solid volume fractions below 16 % by using the forward-scattering theory. However, as shown by the Beer–Lambert law (13.45), forward scattering is often impractical for denser systems [120]. It might be useful to examine the derivation of the specific form of the Beer–Lambert Law given. The transmission probes use light from optical fibers to penetrate the bed section volume under investigation. The intensity of the light beam coming off from the optical fibers and traverses through a particle layer is then reduced as determined by the Beer–Lambert law. The intensity reduction is induced both by scattering and absorption by the particles and these phenomena are collectively named *light extinction*. The law of energy conservation gives:  $I_0 = I_{\text{trans}} + I_{\text{ext}}$ , where  $I_0$  denotes the light intensity emitting from the probe,  $I_{\text{trans}}$  represents the transmitted light intensity, and  $I_{\text{ext}}$  designates the light extinction. In a brief analysis of dilute gas–solid suspensions representative for riser flows, Louge [120] assumed that mono-disperse spheres of diameter  $\xi$  were placed along a cubic lattice of uniform solid volume fraction,  $\alpha_s$ , and found that the light originally of intensity  $I_0$  is extinguished to a value  $I$  after penetrating a distance  $z$  into the suspension:

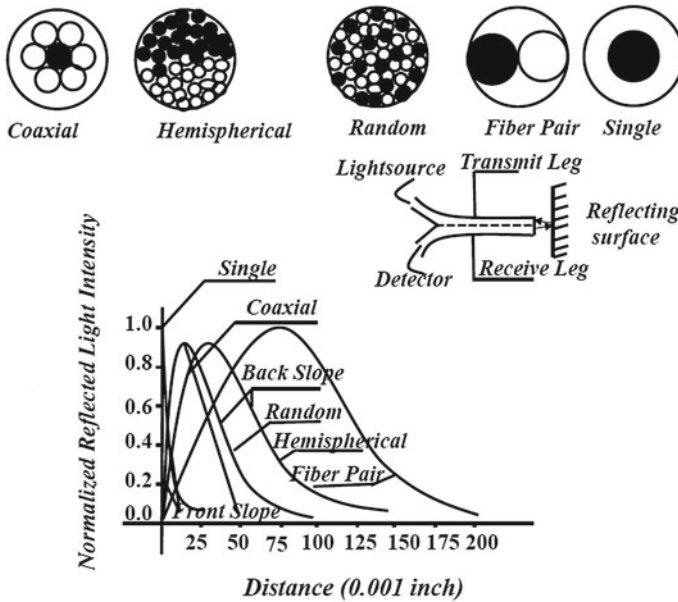

$$I = I_0 \exp \left[ -(3/2) \kappa \alpha_p z / \xi \right] = I_0 \exp \left[ -\frac{z}{l} \right] \quad (13.45)$$

in which  $\kappa$  denotes the extinction coefficient. For typical riser concentrations, the extinction distance  $l$  is very small thus the light intensity extinguishes rapidly as the light goes into the particle mixture.

Shamoun et al. [181] designed a similar light extinction technique for void fraction measurements in bubbly flow (2D distribution of line average of the void fraction). Xu and Lee [224] used a similar forward-illumination light extinction technique for soot measurement. This technique is restricted by line-of-sight measurement but provide time resolved measurements. Since backscattering sensors are simpler and less intrusive than the forward scattering sensors that are impractical for denser systems [116], these techniques have received wider attention [63, 80–82, 90, 91, 98, 120, 132, 195]. Several alternative fiber optical configurations have been described in the literature, some of them are shown in Fig. 13.12.

Reflective probes may be used over the entire rang of particle concentrations, from extremely dilute flows to the fixed bed state for several powder types in gas or liquid media, once they have been suitably calibrated [63, 85, 166, 238]. These probes are also nearly free of interference by temperature, humidity, electrostatics and electromagnetic fields. Lischer and Louge [116] developed a reflective F-OPT specifically for measuring solids concentration. In the fiber optical reflection probe developed by Hartge et al. [82], the emitted light from a laser diode reaches the

**Fig. 13.12** Configurations of reflective optical probes, together with the corresponding characteristic curves. These figures are drawn based on similar sketches in [165]

point of measurement through a light-conducting fiber. The light reflected from the particles was collected and passed through the same fiber. The light is then decoupled using a beam splitter and recorded on a photo-diode. This method enabled a very simple design of the probe tip and manufacture of a small velocity measuring probe by arranging two such fiber tips vertically above each other. The main advantage of this system arrangement is the existence of a characteristic calibration curve of the sensor over the entire range of concentrations from very dilute to the fixed bed state, which is given by the following empirical correlation [98, 218]:

$$V - V_0 = a\alpha_p^k \quad (13.46)$$

in which  $V_0$  is the voltage signal when  $\alpha_p = 0$ , whereas  $a$  and  $k$  are empirical parameters to be fitted by calibration.

Sobocinski et al. [185] developed a novel reflective type fiber-optic sensor for assessing the sizes of certain type of clusters (strands), as well as strand velocity and solids hold-up in gas–solids downward flowing suspensions. In order to calculate average strand velocity, the *cross-correlation method* was employed. The signals from the fiber-optic sensors were analyzed statistically to produce a characteristic time delay  $\tau$  between the signal spectrum from adjacent probes. This characteristic time delay corresponds to the maxima of the normalized cross-correlation function [82, 152, 218, 232]:

$$\phi_{1,2}(\tau) = \lim_{\tau \rightarrow \infty} \frac{1}{T} \int_{t=0}^T v_1(t) v_2(t + \tau) dt \quad (13.47)$$

in which  $\phi_{1,2}(\tau)$  exhibits a maximum where the time delay  $\tau$  is equal to the average delay time between the two signals. Thus, the abscissa value  $\tau_{\max}$  of the maximum of  $\phi_{1,2}(\tau)$  may be used to calculate an average velocity at the point of measurement by simply dividing the separating distances between the two probes by  $\tau_{\max}$  (i.e.,  $\bar{v}_p = \bar{l}/\tau_{\max}$ ) [152].

Farag et al. [65] adapted a pair of the reflective fibre optic sensors, originally developed by Sobocinski et al. [185], for measuring fluid dynamic properties (e.g., bubble fraction and bubble frequency) in a pilot scale turbulent fluidized bed. Each of the probes consisted of one emitter and two receivers. A pair of reflective fibre optic sensors, 3 mm apart, were used to measure fluid dynamic properties. The bubble fractions,  $\beta$ , was defined as the cumulative contact times  $\sum_m t_{p,m}$  divided by the total sampling time  $T$ :

$$\beta = \sum_{m=1}^{np} \frac{t_{p,m}}{T} \quad (13.48)$$

A local time average bubble velocity,  $v_{br,j}$ , was computed dividing the distance separating the upper and lower probes  $\Delta z$ , by  $\tau_{\max}$  (the abscissa time delay at the maximum of the cross-correlation function). The solids hold-up can be computed from (13.49), whereas the strand length formula is deduced from semi-empirical relations. Bubble Contact Length (BCL) was adopted as a characteristic dimension representing bubble size. The BCL was computed by multiplying the bubble velocity by the measured time average bubble contact time ( $t_p$ ). The bubble contact time, the time a probe sees a bubble, was defined as the ratio of the bubble fraction to the bubble frequency. Tayebi [194] developed a novel method for simultaneous measurements of local particle motion, solids volume fractions and bubble properties in multiphase flow systems with high solids concentration such as the dense region of fluidized beds. The method was based on a fiber optical technique and tracer particles. A particle present in the measuring volume in front of the probe was marked with a fluorescent dye. A light source illuminated the particles and the detecting fibers received reflected light from uncoated particles and fluorescent light from the tracer particle. Using optical filters, the fluorescent light was separated out and together with a small fraction of background light from uncoated particles, was used to determine the local flow properties. The method is independent of physical properties of tracer particles such as size distribution, density, and shape. Matsuno et al. [132], Lischer and Louge [116] and Zhang et al. [238] provided surveys of the various calibration methods that have been employed for fiber-optic sensors that measure the particle volume fraction. In principle, the light reflected by a group of particles in front of the fiber optic reflection probe is proportional to their volumetric concentration,  $\alpha_p$ . The precision of these measurements relies entirely upon the precision of the technique used to calibrate the probe. If a dilute, stable flow of particles could be established

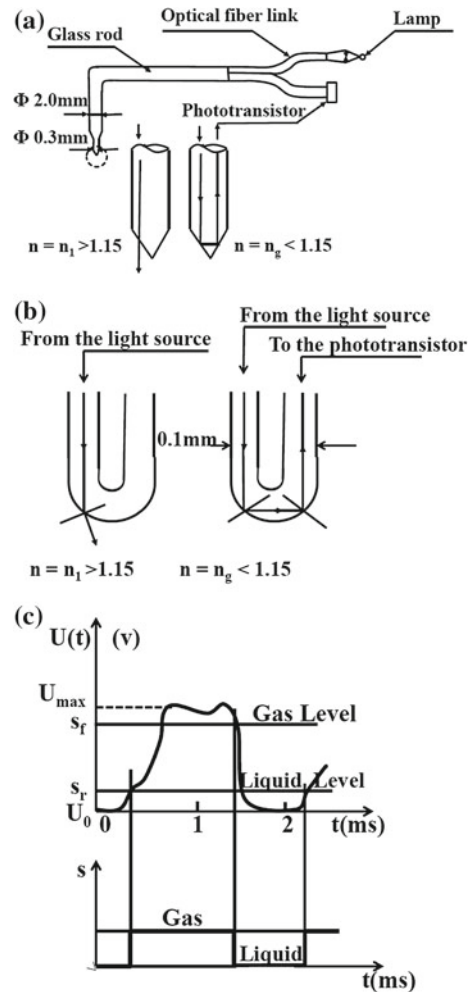

at a known velocity and in a section small enough so that a local measurement could yield a cross-sectionally averaged value, then the following relationship could be used:

$$\alpha_p = \frac{\dot{m}}{v_p A \rho_p} \quad (13.49)$$

where  $\dot{m}$  denotes the particle mass flow rate (kg/s),  $v_p$  the particle velocity (m/s),  $A$  the tube cross-sectional area (m<sup>2</sup>) and  $\rho_p$  the particle mass density (kg/m<sup>3</sup>). The principle of operation of the reflective probes has been outlined by several authors [85, 238]. The *time of flight* of a particle between two optical fibers is determined by cross-correlation of the two voltage (proportional to the reflected light intensity) versus time signals. The time lag corresponding to the maximum value of the cross-correlation function is the time which is then used to the maximum value of the cross-correlation function is the time which is then used to calculate the particle velocity as the effective distance between the fibers is known.

Refraction probes, a third type of F-Opt sensors, have been used to measure local gas volume fraction, local bubble velocity and bubble chord length in two-phase gas–liquid and three phase gas–liquid–solid bubble columns [34, 48]. The design of this optical fibre is based on the difference of refraction indexes between the gas and liquid phases. According to *Snell's law* the angle of total reflection is larger in the liquid than in the gas. These refractive optical fibers have the ability to discriminate between gas and liquid phases only, and thus, this kind of probes are not suitable for gas–solid fluidized beds. If this principle is applied to a fiber having a U-shape the fiber has to be bent as follows [73]: The radius of curvature of the U has to be large enough so that the angle of incidence at the turning point is larger than the angle of total reflection when the same fiber is exposed to gas. If this condition is met, the source light will be conserved in the fiber. However, the U has to be, at the same time, curved in such a way that the radius is small enough to secure an angle of incidence at the turning point smaller than the angle of total reflection for the same fiber dipped in liquid. With this U design the source light will be lost in liquid and conserved when exposed to gas (as illustrated in Fig. 13.13). Therefore, a significant difference can be seen at the detecting end of the fiber each time a gas bubble contacts the *U* probe. In the following, a typical probe design is described, Fig. 13.13a. When a light beam strikes the surface at an angle of 45°, it emerges from the probe or is reflected back, depending upon the refractive indices of the surrounding material,  $n$ , and that of the probe material  $n_0$  according to Snell's law. Thus, for a glass rod when  $n_0 = 1.62$ , if the incident internal angle between the light and the tip is 45°, light is reflected back along the rod if  $n < 1.15$  and exits from the rod if  $n > 1.15$ . This probe can thus be successfully used in gas–liquid systems in which  $n_g < 1.15$  and  $n_l > 1.15$ . The principle of operation of the spherical bulb dual fibre optic probe [34] is similar to the *U*-bend single fibre optic probe which has been described above. These refractive optical fibers have the ability to discriminate between the gas and liquid phases (and, thus, this kind of probes are not suitable for gas–solid fluidized beds), allowing the measurement of the following fluid dynamic parameters: (1) The time averaged local void fraction. (2) The time averaged and/or individual local bubble

**Fig. 13.13** The Fiber-Optic Probe Technique [73]. **a** A typical optical probe system. **b** A U-shaped fiber-optical sensor. **c** A typical optical-probe signal and discrimination method. These figures are drawn based on similar figures in Goldstein [73] (pp. 518 and 520)

rise velocity. (3) The time average bubble frequency. (4) The averaged and/or individual local bubble chord length. The main advantage of the spherical bulb optical fibre compared to the U-shaped probe (both working on the refraction principle) is associated to the size of the probe (the tip diameter of the spherical bulb fibre used is about  $0.4\text{ mm}$ ). The smaller spherical bulb probe requires smaller measuring volume, reduces the flow disturbance, and allows the measurements of smaller bubble sizes [34]. The time averaged local gas fraction was obtained by counting the fraction of the total measuring time when the probe was in contact with the gas phase as described by (13.48). The bubble detection system used by de Lasa et al. [48] was completed by a helium-neon laser beam. The laser was focused on one end of the fiber and was guided through the U-shape tip to the other end. The perturbation of the

returning light generated when gas bubbles contacted the probe, was detected by the photo-detector. The analog signal from the photo-detector was first sent to an operational amplifier for impedance matching, later on to high speed A/D converter for digitizing and finally to a microprocessor for storage and data analysis. Chabot and de Lasa [35] investigated the local gas-phase characteristics in a bubble column using refractive spherical bulb optical sensors. The local gas holdup, bubble rise velocity, bubble chord length, and bubble chord length distribution were measured at several radial and axial locations in a 0.2 m diameter bubble column in the presence of a paraffinic oil and nitrogen. The gas volume flux varies between 2.2–14.7 cm/s, while the operating temperatures studied were:  $T = 100$  and  $175^\circ\text{C}$ . The spherical bulb optical fiber probe used was developed by Chabot [34]. Two such spherical bulb optical fiber sensors were mounted and sealed separated by a vertical distance of 0.5 cm. The gas holdup was defined as the summation of the number of times of gas-sensor contact over the total sampling time. The bubble rise velocity was obtained by dividing the vertical spacing between the two optical sensors (5 mm) by the time delay observed at the peak of the cross-correlation function. The bubble chord length was obtained by multiplying the average bubble rise velocity by the average bubble detection peak duration.

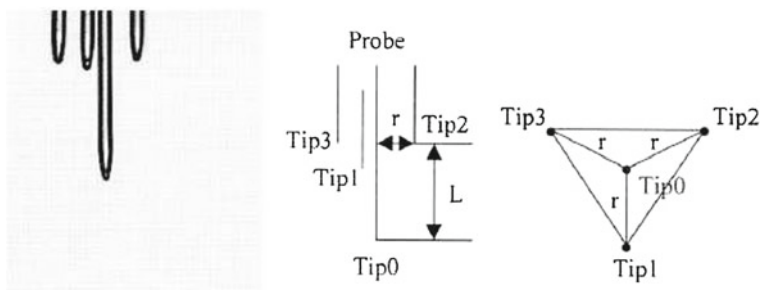

### 13.7.2 Chemical Reactor Characterization by F-OPT

Fiber-optical probes of the reflection type (backscattering) has been used to measure local solid volume fraction, local bubble velocity and bubble chord length (vertical bubble dimension) in fluidized bed reactors operating in different flow regimes.

Oki et al. [151] measured the size of moving solid particles together with the velocity of the particles using a small fiber optical reflection probe. The principle of the measurement was based on the *characteristic length*, which is a product of the particle velocity and the width of the reflected light pulse detected when each particle is illuminated by the optic fiber. The relationship between the characteristic length and the average diameter of a moving spherical particle was determined from model calculations. Morooka et al. [140] employed a light reflection optical probe originally developed by Oki et al. [152] to measure the flow pattern of solid particles in free-board of a gas–solid fluidized bed. The probe consisted of three optical fibers of 120  $\mu\text{m}$  diameter. The central fiber guided the illuminating light to the moving particles, while the other two collected the reflected light from the particles to each photomultiplier. The local velocity of solid particles was calculated by dividing the effective distance between the upper and lower reflecting points by the time lag determined by cross-correlation of the collected signals. More recently, Ege et al. [62, 63] investigated local flow properties and the mechanisms of backmixing in fluidized beds operating in the bubbling and turbulent fluidization regimes through a combined effort of experiments and traditional reactor modeling. The influence of the operating conditions including bed diameter (0.3 and 0.5 m), bed temperature (22–145  $^\circ\text{C}$ ), gas volumetric flux (0.4–0.7  $\text{m}^3/\text{m}^2\text{s}$ ) and static bed height on the reactor flow and

mixing behavior, was studied. The fluidizing gas–solids mixture properties: Fluidizing gas air, spent FCC particles ( $\xi_p = 65 \mu\text{m}$ ), particle density ( $1500 \text{ kg/m}^3$ ). Tracer experiments, using a non-adsorbing tracer gas (He), was performed to study the gas mixing properties. A novel fibre optic sensor probe with a defined illuminated volume using infra-red laser light in a reflection technique was adapted to measure time average values of local flow properties such as bubble fraction, bubble frequency and bubble rise velocity. From these three properties, the bubble flow rate and bubble contact length were derived. Through these five properties a three-phase/two-region reactor model was established to describe the gross scale flow behavior in the turbulent regime. The model incorporated a pseudo-homogeneous annular region together with a two-phase bubble-emulsion flow in the core of the bed.

Fiber-optical probes of the refraction type has been used to measure local gas volume fraction, local bubble velocity and bubble chord length (vertical bubble dimension) in gas–liquid and gas–liquid–solid bubble columns [34, 48]. Cartellier [32, 33] and Julia et al. [99] investigated the performance of optical probes for determining the local void fraction. The impact of the bubble piercing phenomena such as probe–bubble interaction mechanisms were discussed. The voidage was determined in the same way as by Chabot et al [34]. Cartellier [33] made simultaneous void fraction measurements using a single optical probe in gas–liquid two-phase flows. Interface piercing is associated to the wetting and dewetting processes that control the signal transitions between the static levels. These phenomena preclude an accurate localization of the probe/interface contact on each signal. However, the void data was considered weakly sensitive to the detection conditions. Bai et al. [16] used a similar four-point optical fibre probe to measure bubble velocity in bubbly gas–liquid systems. The four-point optical fibre probe can be used to measure bubble velocity, bubble size and gas fraction. At high gas volume fractions the gas–liquid flow system becomes opaque, ruling out non-intrusive optical techniques. The alternative optical fibre probes might be used instead. These techniques have the advantage of low cost, simplicity of setup and easy interpretation of results. Xue et al. [225–227] performed bubble dynamics measurements using a four-point optical refractive probe. The optical fiber probes made use of the difference in the refractive index between the gas phase and the liquid phase and provide a sequence of voltage pulses when a bubble passes by the probe. In comparison with conductivity probes, the optical probes offer several advantages [225]: they can be used in conductive as well as in non-conductive (organic) systems; they have better signal/noise ratio; the presence of a liquid film on the sensor tip reduces the effectiveness of a conductivity probe but not that of an optical probe and the sensitivity of optical probes is therefore higher than that of conductivity probes. However, it has been shown that the bubble dynamics obtained by two-point probes are not reliable [225]. Hence, a four-point probe was designed to improve the measurements of bubble size and velocity. The schematic of the four-point optical probe is sketched in Fig. 13.14. The four-point optical probe and the developed data processing algorithm for the measurement of bubble dynamics were validated by video imaging [226]. Bubble velocity, size, frequency and interfacial area measurements in a bubble column were reported [227]. It was found that in bubbly flows, the radial profiles of specific interfacial area, bubble frequency, and mean

**Fig. 13.14** Schematic of the four-point optical probe. The figure is reproduced from Xue et al. [225] with permission from John Wiley & Sons

bubble velocity are all flat. In the churn-turbulent regime, these profiles became more parabolic in shape. The mean bubble chord length did increase with an increased gas flux until it in deep churn-turbulent flow and then remains almost identical with gas flux. In the wall region the bubble chord length distribution does not change much with the gas volume flux. In bubbly flow, the bubble velocity distribution and bubble chord length distribution were alike at different radial positions, including in the wall region.

In churn-turbulent flow, in the core of the column the bubble velocity and chord length distributions are alike at different radial positions, but in the wall region they are very different from the core of the column. A few reports on the application of optical fibre probes for phase holdup measurements in three-phase fluidized beds have been found, in which the local bubble frequency, the local phase holdups and the local bed porosity were measured [108, 159, 177]. Time-average local gas holdups and bubble frequency were measured independently by an optical fiber probe.

### 13.7.3 F-OPT Limitations

One of the major problems with the forward scattering methods is the disturbance on the flow caused by the probe size, design and construction. Another problem is the limitation of light transmission in the dense regions which makes this system impractical for denser systems. In addition, a disadvantage of the F-OPT technique is that its signal resolution is effected by bubble passage through the line of light transmission and, therefore, provides inaccurate measurements when the detector and transmitter are far apart.

Backscattering optical fiber probes are not without disadvantages either [238]. For instance, the measuring volume at the probe tip apparently decreases as the solids concentration increases. That is, for higher solids concentrations, the probe has a smaller measuring volume and thus provides a more local measurement because particles which could have been in the measuring volume would be blocked by particles in front of them. Also, for multi-fiber probes consisting of separate emission and

detection fibers, Louge [120] warned that, due to the existence of blind spots, those probes are prone to ambiguous signals, which may rise with solids volume fraction at low concentrations, but then fall in denser suspensions. Additionally, this intrusive probe causes flow disruption, the amount of which has not been quantified. Fortunately, this difficulty is small in comparison to the other intrusive methods available for local concentration measurements [120]. The single most difficult problem with fiber optic probes is that the majority of calibration procedures developed to date are inaccurate or problematic because they are based upon faulty assumptions. The measurement accuracy and precision is strongly dependent upon the precision of the calibration technique utilized.

In the case of using refractive optical probes, two major error sources exists. The probe is intrusive causing flow disruption and piercing phenomena associated with the probe wetting properties may make the bubble avoid penetrating the measuring probe.

### ***13.7.4 F-OPT Literature***

F-OPT based on scattering principles (reflection and extinction) have been described in several review papers on experimental techniques in fluidization research [42, 120, 217, 218, 232], in nuclear science and engineering [184], and in oil and gas processing [11].

General theory on the F-OPT refractive techniques are given in the text by Goldstein [73].

## **13.8 Particle Image Velocimetry (PIV) Technique**

The PIV method is a fairly new technique, capable of simultaneous velocity measurements at many points in a plane. This gives information on large scale structures, vorticity, etc. which is very difficult or impossible to obtain from one-point measuring techniques.

The traditional non-intrusive laser based measurement techniques like LDV and flow visualization, did provide either a point measurement or a qualitative indication [38]. The conventional techniques could not provide quantitative and instantaneous flow information for a whole flow plane. The ability to quantify transient multiphase flow phenomena is crucial to the understanding of the flow mechanism and development of fundamental theories. These limitations of the conventional measuring techniques were overcome by the PIV technique which combines the accuracy of LDV with the qualitative information from the flow visualization and is a quantitative technique for measuring the instantaneous flow field for a plane.

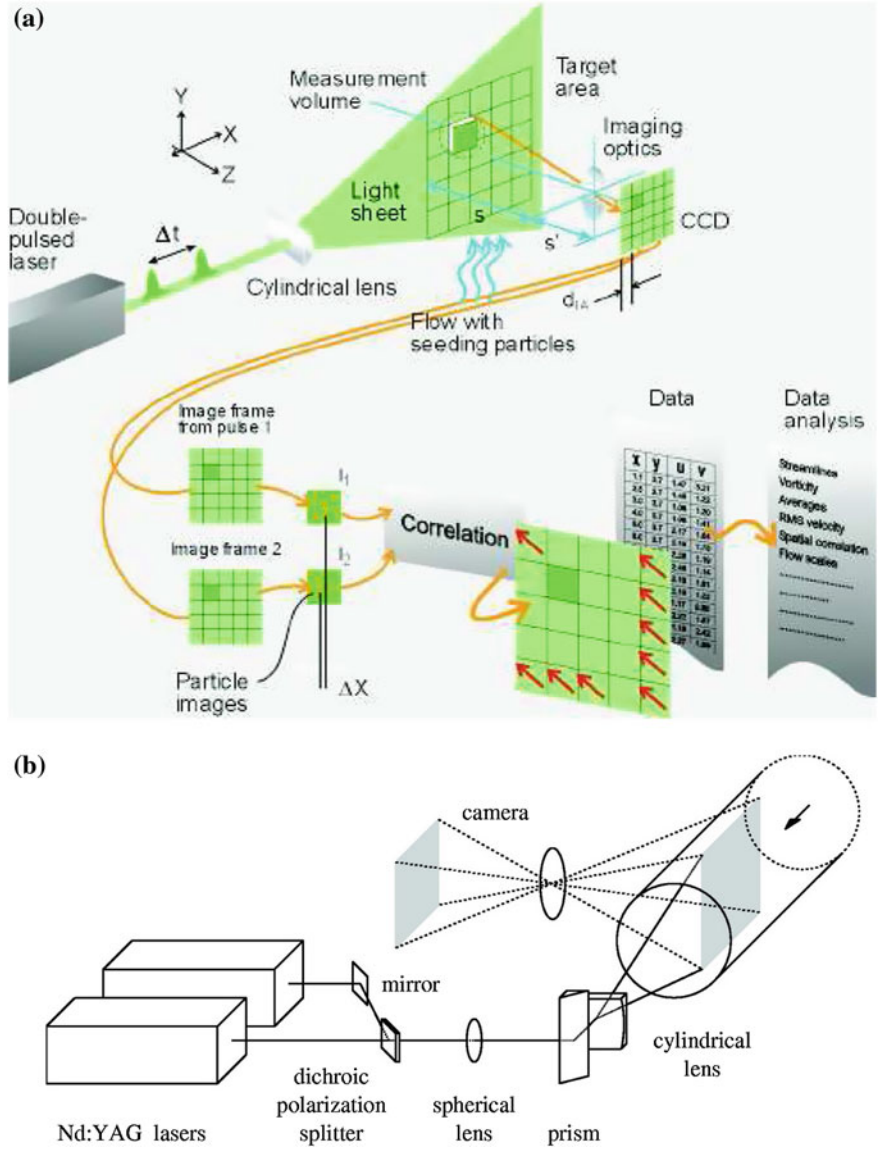

### 13.8.1 Basic Principles of PIV

PIV is a flow visualization technique which provides instantaneous full-field information of a multiphase system for each of its components as it flows through a planar laser-sensed region [2–4, 36, 38]. The flow is seeded with neutral density light scattering particles or with rising dispersed gas bubbles, which scatter the incident sheet of laser, while refractive index matching is necessary to eliminate scattering at the multiphase interfaces and to render the entire system transparent. Any particle velocimetry system consists of laser sheeting, image recording, and particle processing. A typical PIV system setup arrangement and an optical configuration are sketched in Fig. 13.15. A laser sheet illuminating the flow field is multiple pulsed and recorded by a recording medium (photo or video camera) at sequential instances of time. Laser sheets are formed by expanding the circular Gaussian laser emission through a system of mirrors and lenses. Image recording is ensured by CCD video cameras placed perpendicular to the laser propagation beam. The original PIV for single phase flows thus combines the accuracy of LDA with the quantitative information from the flow visualization and is a quantitative technique for measuring the instantaneous flow field for a plane. For dispersed multiphase flow systems, additional properties can be determined. A typical PIV interrogation software identifies particle images, discriminates particle image between different phases, determines phase fractions of each phase, calculates particle sizes and computes displacement between image pairs. From the calculation of displacement, the instantaneous velocities and accelerations are determined. In the previous PIV image processing techniques, velocity information was obtained by relying upon optomechanical processing techniques of photographs which involved Young's fringe combined with the Fraunhofer diffraction concept [38] or fast Fourier transform [1, 69]. In more recent PIV image processing techniques of cross-correlation involved interrogation of two sequentially captured digital image frames in terms of smaller regions or interrogation zones in which the average displacement and, hence, average velocity of the seeds in the interrogation zones is determined [84, 221]. Okamoto et al. [150] provided a brief review of studies conducted with modified cross-correlation techniques, in addition to proposing a new algorithm for calculating displacements between particle clusters which were supposed to be connected by invisible elastic springs. Direct digitization methods in which separate flow images are captured in sequence represent another approach to calculate the velocity field [36].

The current PIV software data analysis is normally based on the comparison of two images recorded with a very small time delay (typically of the order of 1 ms) with a high speed camera. For the analysis, every image is divided into interrogation zones (typically of size  $32 \times 32$  or  $64 \times 64$ ), where cross-correlation on two consecutive images is employed to obtain an average displacement of the particles in the the selected interrogation zone. The basic principle of PIV is to divide the recorded images into  $N \times N$  interrogation areas and use a spatial cross-correlation on two consecutive images to obtain the average displacement of the particles,  $S_p$  [2, 4, 53, 111]. The cross-correlation formula is given as:

**Fig. 13.15** An overview of a typical PIV technique: **a** The Dantec system. The figure is reproduced with permission from Kim D Jensen at Dantec Dynamics Inc (personal communications). **b** The TSI PIV System 400 optical configuration. The figure is reproduced with permission from CQUniversity Australia

$$\hat{R}[x, y] = \frac{1}{N_x N_y} \sum_{i=1}^{N_x} \sum_{j=1}^{N_y} (I'[i, j] - \langle I \rangle)(I''[i + x, j + y] - \langle I \rangle) \quad (13.50)$$

The average image intensity  $\langle I \rangle$  is subtracted from both images before cross-correlation is carried out in order to reduce the background correlation.  $I'[i, j]$  is the intensity of pixel  $(i, j)$  in the first image and  $I''$  is the intensity of pixel  $(i + x, j + y)$  in the second image.

With PIV, the fluid mixture to be characterized is illuminated from behind to obtain high contrast images of shadows of the particles against a bright fluid background (see Fig. 13.15). A high speed camera is normally used to record images of the particles in the illuminated region. In practice, the images are processed using a PIV software. Two and two subsequent images of the flow, separated by a short time delay,  $\Delta t$ , are divided into small interrogation areas. A typical interrogation region may contain images of 10–20 particles [97]. The volume-average displacement  $\mathbf{s}_D(\mathbf{r}, t)$  of the particle images between the interrogation areas in the first and the second image is determined by means of a cross-correlation analysis. When the interrogation areas contain a sufficient number of particle images, the cross-correlation consists of a dominant correlation peak embedded in a background of noise peaks. The location of the tall peak, referred to as the displacement-correlation peak, corresponds to the particle-image displacement. Careful selection of the time between two consecutive images is required to minimize the influence of out-of plane movement of particles [220]. Provided that  $\Delta t$  is sufficiently small, the velocity in the interrogation area,  $\mathbf{v}(\mathbf{r}, t)$  is then determined by dividing the measurement displacement by the image magnification  $M$  and the time delay:

$$\mathbf{v}(\mathbf{r}, t) = \frac{\mathbf{s}_D(\mathbf{r}, t)}{M \Delta t} \quad (13.51)$$

By combining the velocities of all interrogation areas, the instantaneous velocity profile is obtained.

### 13.8.2 Chemical Reactor Flow Characterization by PIV

Hassan et al. [83] were among the first to apply PIV to the simultaneous two-phase and two-dimensional velocity measurement in a rectangular bubble column. Extension of PIV to three-phase systems, such as gas–liquid–solid fluidization, was first reported by Chen and Fan [38]. The velocity fields of gas, liquid, and solids phases, the bubble size distribution, the gas and liquid local volume fractions, and slip velocities were simultaneously measured in the free-board region of a three-phase fluidized bed. In this early study, the PIV image velocity information processing technique was obtained by relying upon optomechanical processing techniques of photographs which involved Young's fringe combined with the Fraunhofer diffraction concept. The local volume fractions were calculated using pixel connectivity algorithms to identify for each spot the boundaries, the corresponding area and centroid, and the average gray level. Based on the knowledge of the size distribution of each phase, the spots are allocated to the phase to which they belong. Fan and co-workers

performed further investigations focusing on the characterization of each phase in more details in 2D and 3D gas–liquid bubble columns [39, 114, 162] and gas–liquid–solid fluidized beds [39, 163, 164]. In a more recent study, Darmana et al. [46] used PIV to measure the bubble velocities in a two-phase pseudo-2D bubble column. The experimental data was used to validate an Euler-Lagrange model for describing the hydrodynamics, mass transfer and chemical reactions for the chemisorption of CO<sub>2</sub> into a NaOH solution. The PIV technique has also been used characterizing the flow in bio-reactors. One recent example is mentioned; Zima-Kulisiewicz et al. [239] employed PIV to characterize the continuous bio-fluid flow in a three phase sequencing batch reactor (SBR). The SBR cycle was used for biological purification of waste-water. In the bio-reactor the formation and growth of granular activated sludge (GAS) with diameter up to 5 mm was produced. The laboratory SBR reactor was fed with a synthetic waste-water and air. The gas–liquid–solid mixture in the SBR reactor was aerated by sandy, cylindrical disperser which was placed on the bottom of the vessel. Both artificial tracer particles and granules themselves were employed to visualize the flow pattern. Ibsen et al. [93] applied PIV to characterize the dilute gas–solid flow in the riser unit of a square cross section circulating fluidized bed (CFB). The PIV technique is limited to dilute flows, thus dense systems and particle cluster flows can not be characterized by this technique. PIV was first applied to dense phase gas-fluidized beds by Bokkers et al. [24], who measured the emulsion phase circulation patterns in freely bubbling gas–solid fluidized bed, in order to validate the extent of particle drift induced by rising gas bubbles predicted by Euler-Lagrange and Eulerian-Eulerian models. In particular, PIV was applied to obtain ensemble average particle velocity profile in the vicinity of the bubble in dense gas–solid fluidized systems. Dijkhuizen et al. [53] extended the PIV technique to enable the simultaneous measurement of the instantaneous velocity and granular temperature distribution in fluidized beds. The granular temperature is an important parameter in the modeling of fluidized beds with Eulerian-Eulerian models using closures for the pseudo–solids–fluid rheology based on the Kinetic Theory of Granular Flow. Laverman et al. [111] performed an experimental investigation of the hydrodynamics of a freely bubbling pseudo-2D fluidized bed, for different superficial gas velocities by using PIV combined with Digital Image Analysis (DIA). The coupling of the two measuring techniques allowed the authors to obtain information on both the bubble behavior and emulsion phase circulation patterns simultaneously. In particular, the instantaneous emulsion phase velocity fields together with detailed information on the bubble phase (local bubble size and velocity distribution, bubble fraction, etc) were obtained. de Jong et al. [49] employed a combination of PIV and Digital Image Analysis (DIA) to simultaneously investigate solids phase and bubble phase properties in membrane-assisted pseudo-2D fluidized beds operated in the bubbling bed regime. The main aim of the experimental investigation was to study the effects of change in gas flow rate inside fluidized bed membrane reactors, where gas is added or extracted through the side-walls of the fluidized bed.

### ***13.8.3 PIV Limitations***

The PIV technique is, like the other laser based techniques, limited to dilute bubble, droplet and particulate flows, due to the requirement of visual accessibility [111]. This puts severe limitations to the application of this method in reactor technology. In particular, characterizing three phase fluidized beds and slurry reactors, the presence of the dispersed solid phase results in blockage of the laser sheet and limits the measurement using PIV to low solid holdups ( $<5\%$ ) [38]. The current PIV image processing techniques of cross-correlation involve interrogation of two sequentially captured digital image frames in terms of smaller regions in which the average displacement and, hence, average velocity of the seeds in the sub-region is determined [84]. Although the cross correlation technique has many advantages, it also have several weak points. For example, it requires a lot of calculation time. Even the fastest computerized image system requires several hours (days) for processing.

### ***13.8.4 PIV Literature***

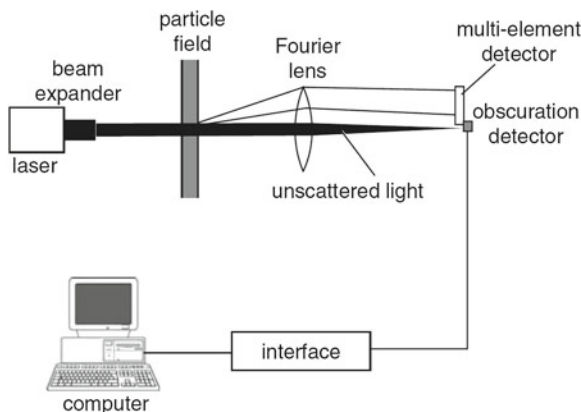

The particle image velocimetry technique has been thoroughly described in the book by Adrian and Westerweel [4], in review papers by Adrian [2, 3], Westerweel [220] and Jensen [97], and in several chapters in the book edited by Gad-el-Hak [69]. Chaouki et al. [36] reviewed the non-invasive Tomographic and velocimetric techniques for monitoring multiphase flows.

## **13.9 Laser Diffraction Technique**

Instruments based on the laser diffraction (LD) principles are designed to measure the particle size distributions (PSD) of fine spherical solid particles in aerosols and suspensions, droplets in aerosols, sprays, mists and emulsions, as well as micro-bubbles in dispersions. The technique is otherwise known as static light scattering (SLS), (near-) forward light scattering, low-angle laser light scattering (LALLS) and Fraunhofer diffraction [136]. The Malvern instrument [125] is representative for this kind of devices.

### ***13.9.1 Basic Principles of Laser Diffraction***

Laser diffraction particle size analysis is based on the physical phenomenon that particles in a laser beam scatter laser light at angles that are inversely proportional to the size of the particles [64, 161, 223]. Thus, larger particles scatter at small forward

**Fig. 13.16** Typical set up of the laser diffraction instrument. The figure is reproduced from Merkus [136] with permission from Springer

angles while small particles scatter light at wider angles [180]. By the use of Fourier and Reverse Fourier optics, this scattering is imaged to an array of detectors at the focal plane of the optics. There is thus a direct relationship between the distribution of the scattered light energy on these detectors and the particle size distribution which gives rise to the light scattering. A typical setup for a conventional LD instrument is sketched in Fig. 13.16. The typical light source is a laser, generating a monochromatic, coherent light beam (e.g., a He–Ne laser). A beam processing unit follows the light source. This unit normally consists of a beam expander with integrated pinholes and lenses to produce an extended parallel light beam. The scattered light is then collected by a positive Fourier transform lens and focused onto a series of detector elements in the near-forward direction. Each element is a photo-diode that converts the incident light energy into a proportional current. The currents are transformed to voltages that are sampled and stored on a computer. After storage, an iterative fitting procedure may be used to determine a particle size distribution that would yield the diffracted light profile as measured by the detector array [105, 136, 139]. Several optical models are commonly used to calculate the PSD: The *Fraunhofer*–, *Mie*– and *anomalous diffraction* theory. The former is based on the approximation that the laser beam is parallel and the detector is at a distance that is very large compared with the size of the diffracting particle [200]. The Mie scattering theory [138] is an exact solution of the Maxwell equations [133, 134] describing propagation of the electromagnetic wave of light in space (see also Horvath [92] and references therein). The theory provides an exact solution for the case of a plane wave on a homogeneous sphere of any size. The Mie theory thus applies rigorously to spherical, homogeneous particles and fits less satisfactorily for non-spherical or non-homogeneous particles. In addition, the theory takes into account phenomena other than diffraction (e.g., transmission through the particle) and therefore requires knowledge of the refractive index of the material tested. The refractive index is a complex number comprised of

(i) a real part ( $n_p$ ) which represents the change in the velocity of light through the tested material compared with the velocity of light in vacuum; and (ii) an imaginary term ( $k_p$ ) which represents the transparency and absorptivity of the material. The Mie theory thus offers an exact solution to the scattering of light from a homogeneous sphere (but not from an irregularly shaped particle). The anomalous diffraction theory proposed by van de Hulst [200] has also found limited application in the early days of particle size measurement for systems that consist of particles that are large with respect to the wavelength of light and with a complex refractive index close to 1.

### 13.9.1.1 Basic LD Modeling Concepts

The fact that the scattering pattern depends on particle size forms the basis for the application of the LD technique for measurement of PSDs. Then, the scattering patterns of single particles in particular the ones for homogeneous, spherical particles are extended to ensembles of particles by assuming that:

- Each particle scatters as an independent entity. This means that light is scattered only once by a single particle (single scattering). Thus, multiple light scattered by a single particle or by a group of particles is absent.
- There is no optical interference between the scattered radiation from different particles.
- Thus, the scattering pattern of an ensemble of particles equals the sum of the patterns of all individual particles in the ensemble.

In general, the scattering intensity of unpolarized light by a single spherical particle can be written as:

$$I(\theta) = \frac{I_0}{2k^2a^2} \left\{ [S_1(\theta)]^2 + [S_2(\theta)]^2 \right\} \quad (13.52)$$

where  $I(\theta)$  represents total scattered intensity as a function of angle,  $\theta$  denotes the angle with respect to forward direction,  $I_0$  is the intensity of the incident light,  $k$  is the wave number  $k = 2\pi/\lambda$ ,  $\lambda$  is the wavelength of the illuminating source in air,  $a$  is the distance from scatterer to the detector, and  $S_1(\theta)$  and  $S_2(\theta)$  denote dimensionless, complex functions, describing the change of amplitude in, respectively the perpendicular and the parallel polarized light as a function of angle and particle diameter.

The different theories have different advantages and disadvantages.

- The *Mie theory* gives the rigorous solution for light scattering by homogeneous spheres, where it accounts for all types of light interaction. As a consequence, this theory requires full knowledge of the optical properties of the particles and the dispersion medium. The Mie theory scattering amplitudes yield [200]:

$$\begin{aligned}
S_1(\theta) &= \sum_{n=1}^{\infty} \frac{2n+1}{n(n+1)} [a_n \pi_n(\cos \theta) + b_n \tau_n(\cos \theta)] \\
S_2(\theta) &= \sum_{n=1}^{\infty} \frac{2n+1}{n(n+1)} [b_n \pi_n(\cos \theta) + a_n \tau_n(\cos \theta)] \quad (13.53)
\end{aligned}$$

The complex Mie coefficients  $a_n$  and  $b_n$  are obtained from matching the boundary conditions at the surface of the sphere. They are expressed in terms of spherical Bessel functions evaluated at  $\alpha$  (i.e., a dimensionless size parameter) and  $m\alpha$ . The intensity of the scattered light (13.52) may then be seen as a function of the wavelength of light,  $\lambda$ , particle size,  $d_p$ , and the complex refractive index  $m$ , of a particle in a medium:

$$I_{\text{scattered}} = I_0(\theta, \lambda, d_p, m) \quad (13.54)$$

in which  $I_0$  represents the intensity of incident light. The complex refractive index,  $m$ , is defined as [136]:

$$m = (n_p - k_p i) / n_m \quad (13.55)$$

where  $n_p$  denotes the real part of refractive index of particle, and  $k_p$  represent the imaginary (absorption) part of refractive index of the particle,  $i = \sqrt{-1}$ , and  $n_m$  denotes the refractive index of dispersion medium.

The major disadvantage for application in particle size analysis is that these optical properties are often not well known. For liquids, the refractive index might be found in handbooks or it may be measured by use of a refractometer. For solids the correct refractive index values are hard to find in the literature as they strongly depend on purity and of the wavelength of the light. For transparent particles, the real refractive index may be measured. For opaque particles, especially the imaginary part is very hard to find. Also, non-sphericity and surface roughness play a role. Thus, sometimes the optical properties are manipulated to reach the best fit to an arbitrary expectation of the size distribution. On the other hand, for liquid droplets and other spherical particles with known refractive index this theory will provide the correct answer. In the sub-micrometer range, i.e., for particles smaller than the wavelength,  $\lambda$ , of light, it is frequently claimed that the Mie theory is required for an adequate description of the forward-scattering patterns [105]. It should be remarked, however, that calculation of scattering patterns of particles larger than about  $100 \mu\text{m}$  with Mie codes requires high precision. In early instruments, these codes contained some short cuts, which may cause errors in the results. Therefore, often Fraunhofer based codes are applied for medium and coarse particles.

- The *Fraunhofer theory* was the basis for the first (approximating) optical model for particle size measurement. For particles with a diameter  $d_p$  larger than the wavelength  $\lambda$ , Fraunhofer diffraction is often assumed [105]. However, only scattering by opaque particles or particles with a large real refractive index ratio  $m$ , i.e., the ratio of the refractive index of scattering particles to that of the fluid,

results in diffraction patterns that are adequately described by Fraunhofer diffraction theory.

The Fraunhofer diffraction theory involves the following assumptions and approximations:

- Particles are considered as circular, two-dimensional, opaque disks.
- It takes into account only the interaction of light at the contour of a particle.
- Only scattering in the near-forward direction is considered ( $\theta$  is small).

Then,

$$S_1(\theta, \lambda, d_p) = S_2(\theta, \lambda, d_p) = \alpha^4 \left[ \frac{J_1(\alpha \sin \theta)}{\alpha \sin \theta} \right]^2 \quad (13.56)$$

With this result, (13.52) simplifies to:

$$I(\theta, \lambda, d_p) \approx \frac{I_0}{k^2 a^2} \alpha^4 \left[ \frac{J_1(\alpha \sin \theta)}{\alpha \sin \theta} \right]^2 \quad (13.57)$$

in which  $\alpha$  denotes a dimensionless size parameter ( $\alpha = \pi d_p / \lambda$ ),  $d_p$  is the particle size, and  $J_1$  is the Bessel function of the first kind of order unity.

The advantage of the application of Fraunhofer theory is that it is relatively simple and that it requires no knowledge of optical properties of the particulate material. This theory also enables calculations of the scattering patterns for non-spherical objects [136]. The drawback is that it yields biased results for (ultra) fine transparent particles.

- The *anomalous diffraction* concept was proposed by van de Hulst [200] as a distinctive term for any theory based on the assumption  $m - 1 \ll 1$  and  $\alpha \gg 1$ . For a system that gives rise to anomalous diffraction, the refraction of light through the particle contributes considerably to forward scattering [105, 200]. In the anomalous diffraction theory for spherical particles, the following assumptions were made:

- All particles are spheres (other particle shapes might also be considered).
- All particles are transparent.
- The difference in refractive index between particles and dispersion medium is smaller than 10%.

Hence, by applying the Huygens' principle to a plane just beyond the sphere ([200], Chap. 11 Sect. 3), the anomalous diffraction scattering amplitudes yield:

$$S_1(\theta, \lambda, d_p) + S_2(\theta, \lambda, d_p) = \alpha^2 \int_0^{\pi/2} (1 - \exp(i\rho \sin \tau)) J_0(\alpha \theta \cos \tau) \cos \tau \sin \tau d\tau \quad (13.58)$$

in which  $\rho = 2\alpha(m - 1)$ ,  $\tau$  is determined from geometrical considerations, and  $J_0$  is the Bessel function of order zero.

In the early days of particle size measurement, the advantage of this relatively simple theory was that it usually describes the scattering patterns of transparent particles of a few micrometers in size in liquid media better than Fraunhofer theory. Similar to the Fraunhofer theory, the anomalous diffraction theory requires no exact knowledge of the refractive index, but it should not be used for opaque particles.

### 13.9.1.2 Particle Size Data Analysis

The different theories find different ranges of application for measurement data interpretation in instruments [6]. The Mie theory holds for all particulate materials in all transparent media—liquids or gases or even transparent solids and thus the instrument is suitable for the measurement of suspensions, emulsions, spray droplets, smokes, vapors or dry powders giving the user unparalleled versatility of measurement capability. The Fraunhofer theory gives good results if the particle size is larger than about 50  $\mu\text{m}$ . It can also be used for opaque, smaller particles. Both Mie and anomalous diffraction theory can be used for transparent particles in the size range of about 1–50  $\mu\text{m}$ . For the latter it is required that the particles have a refractive index ( $n_p$ ) that differs less than 10 % from that of the dispersion medium ( $n_m$ ). For particles in this size range, that are reasonably opaque ( $k_p > 0.5$ ) and/or have  $n_p/n_m > 1.1$ , Fraunhofer and Mie theory can be used. Older instruments and some existing instruments rely only on the Fraunhofer approximation which assumes that the particle is much larger than the wavelength of light employed, all sizes of particle scatter with equal efficiencies, and the particles are opaque and transmit no light [190]. The modern instruments use the full Mie theory which completely solves the equations for interaction of light with matter. This allows accurate results over a large size range. The Mie theory assumes the volume of the particle as opposed to the Fraunhofer theory which represents a projected area prediction. The Malvern Mastersizer S software uses Mie theory to obtain an optical analysis of this light energy distribution to arrive at the size distribution of the particles covering the size range 0.05–900  $\mu\text{m}$  using a single lens, and up to 3500  $\mu\text{m}$  with an extended range system [6]. Scattering angles from 0.01 to 150° are detected in order to cover this wide size range. The system handles measurements of solids particles, droplets and gas bubbles. The Malvern Mastersizer X operates in the size range 0.1–2000  $\mu\text{m}$  (applying the Fraunhofer model). Note that all present instruments use the assumption of spherical particles. Non-spherical particles can be depicted by the incident laser beam in different orientations and, thus, with different cross-sections. As a consequence, such particles will be represented by sets of spheres having different sizes, where the result depends on the particles orientation(s). The favorable features of the LD technique are the large flexibility to different sample types, the wide size range, the high measurement speed and the high precision [136]. The technique is usually applicable for a particle range from 0.1 to 3000  $\mu\text{m}$  depending on the setup of the system, and a particle loading from 0.001 to 1.0 vol% is considered appropriate. Typically, the actual measurement requires a fairly short time span of about 0.01–30 s. The repeatability of the LD technique is normally excellent. However, the resolution of the technique is typically fairly low.

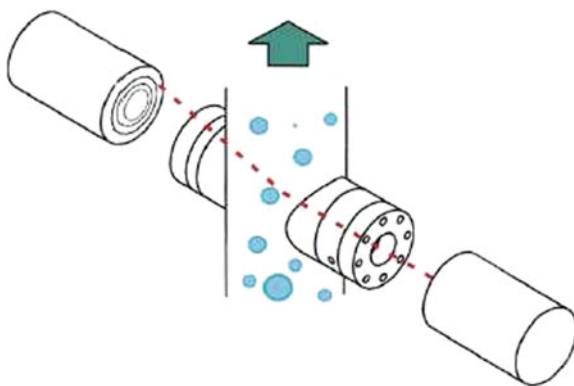

### ***13.9.2 Chemical Reactor Flow Characterization by Laser Diffraction***

The laser diffraction particle sizer techniques have been used to measure spherical solid particle and droplet size distributions in dilute dispersions located in chemical reactor and separation equipment.

Azzopardi [12] reviewed the available information on the creation, size and velocity, and removal of drops in annular two-phase flow. In particular, among the experimental techniques which were available to characterize these flows in the past, in most cases a diffraction technique was used to determine the droplet sizes. The light scattered from an ensemble of particles was captured on a set of annular detectors. Normally, the drop size distribution would be obtained directly from the energy distribution. However, there were mathematical complications. Instead a size distribution was assumed and used to calculate an energy distribution. The values of the parameters describing the size distribution were adjusted until the best fit between measured and calculated energy was achieved. The fitting procedure used by Malvern 2600 Particle Sizer was outlined by Kusters et al. [105] (appendix A). It was mentioned by Azzopardi [12] that instruments based on such a working principle are marketed by a number of companies. Those most commonly used in annular flow work are from Malvern Instruments Ltd.

Setekleiv and Svendsen [180] used the same laser diffraction particle sizer to characterize the ability of mesh pads to separate droplets from the gas stream in a scrubber. Droplets in the size range 30–1000  $\mu\text{m}$  with a bi-modal distribution was obtained at low pressure. A rough sketch of the mounting of the laser diffraction instrument used in this work is shown in Fig. 13.17. Numerous applications of the LD particle sizer for solid particle size distribution measurements characterizing aerosols and suspensions can be found in the literature. Only a few examples of laser diffraction solid particle size distribution measurements relevant for fluidized bed system characterization are mentioned in this report. Garea et al. [71] measured the solid sorbent particle size distribution in a fluidized bed in-duct desulfurization reactor under in-duct conditions by laser diffraction. Ferrer et al. [66] studied fluidized bed combustion of refuse-derived fuel in presence of protective coal ash and measured the fly ash particle size distribution with a laser diffraction method. Tanneur et al. [192] measured the solid particle size distribution in a fluidized bed by use of a diffraction particle size analyzer.

In a couple of particular papers, the application of LD particle sizer to measure the size distribution of micro-bubbles are mentioned. Couto et al. [44] performed micro-bubble size distribution measurements by the laser diffraction technique. It was concluded that the size distribution of micro-bubbles generated for the dissolved air flotation process could be assessed on a fast and reliable way by the application of the laser diffraction technique. The micro-bubble size distribution was measured by the Mastersizer 2000 SM equipment from Malvern Instruments, UK. The instrument specifications state that analysis in the particle range from 0.1 to 2000  $\mu\text{m}$  is possible, and the data interpretation computations could either be performed by use of the

**Fig. 13.17** A sketch of the column test section used by Setekleiv and Svendsen [180]. The test section was designed with window access port for the laser. The figure is reproduced with permission from Elsevier

complete Mie theory or by the Fraunhofer approximation. The authors claimed that both methods gave very similar results. Lida et al. [112] proposed a measuring technique based on Fraunhofer LD for the characterization the temporal development of the bubble populations (size and number distribution) in a sonochemical reactor. The study of sonochemistry is concerned with understanding the effect of sonic waves and wave properties on chemical systems. The acoustic wave disturbance to the laser probe in the sonochemical reaction field was eliminated by temporal separation of the acoustic wave disturbance using pulsed sonication (pulsed LD). The bubble size distribution in the size range from 0.5 to 355  $\mu\text{m}$  was measured with a LD particle size analyzer (Nikkiso, Aerotrak SPR7340, equipped with a He-Ne laser).

### 13.9.3 LDT Limitations

Merkus [136] gives a thorough discussion of the possible error sources related to laser diffraction particle size measurements. An outline of such error sources are provided below:

- (I) Major error sources may be introduced due to improper sample preparation.
- (II) A second main error source is introduced analyzing particles reflecting properties (e.g., non-sphericity, particle surface roughness, optical heterogeneity) that departure from the theoretical model assumptions.

Fraunhofer diffraction versus Mie scattering:

The user must consider the validity of the simplifying assumptions when selecting the Fraunhofer model.

- (i) **Particle Absorption:** If the particles show some transparency (absorption  $< 0.2$ ), then the Fraunhofer approximation will tend to yield inaccurate results below  $50\text{ }\mu\text{m}$  in size. If the absorption is high ( $>0.2$ ), good results may be obtained down to  $2\text{ }\mu\text{m}$  in size, although this does depend on the refractive index.
- (ii) **Particle Refractive Index:** If the refractive index difference between the particle and the surrounding medium is low, then the Fraunhofer model can give rise to significant errors, even up to very large particle sizes ( $>200\text{ }\mu\text{m}$ ).
- (iii) **Particle Size:** If the particle size distribution contains material less than 2 microns in size, the Fraunhofer approximation will lead to an incorrect assessment of the fine particle fraction.

The nature of the errors observed when using the Fraunhofer approximation are not always predictable.

(III) A third source of error is any malfunctioning of the instrument.

Instrument malfunction is either due to a defect or poor control of operation parameters by the operator. A critical evaluation of the use of laser diffraction for particle size distribution analysis was reported by Eshel et al. [64].

The lower size limit for laser diffraction measurements is set by two factors. The first limiting factor is the degree of difference between the angular scattering patterns for particles of different sizes. The second factor is the very low scattered light intensity for small particles.

### ***13.9.4 LDT Literature***

The laser diffraction theory is described in numerous books [6, 17, 136, 223] and papers [64, 161].

## **13.10 Photography and High-Speed Imaging**

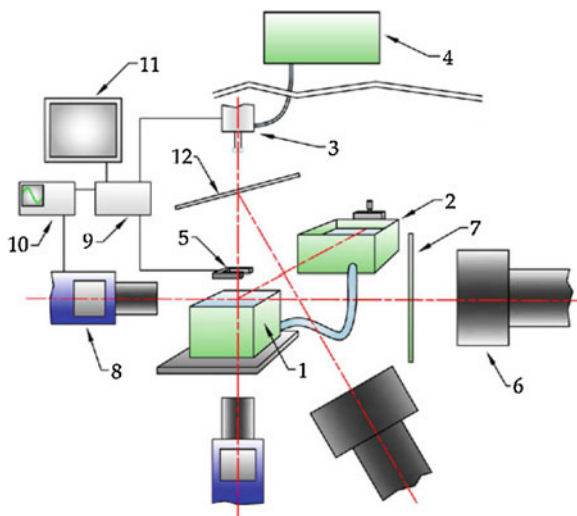

Photography and High-Speed Imaging (PHSI) is used for visualization of complex single—and multiphase flow phenomena. Both qualitative and quantitative visualization techniques are available. Typical investigations are focusing on droplet-droplet—and droplet-surface impact details for elucidating unknown phenomena, determination of interface model boundary conditions, validation of underlying models on single droplet breakage and binary droplet coalescence, and for model parameter fitting. Similar studies of single bubble breakage and binary bubble coalescence phenomena, and determination of free surface boundary conditions can be found in the literature.

### ***13.10.1 Basic Principles of PHSI Analysis***

To observe details of small scale phenomenon that evolves faster than the human eye can observe, we either need to freeze the motion using a flash or film it with a high-speed movie camera [198]. A high-speed camera is a device used for recording fast moving objects as a photographic image onto a storage medium. After recording, the images stored on the medium can be played back in slow-motion. Early high-speed cameras used film to record the high-speed events, but today high-speed cameras are entirely electronic using either a charge-coupled device (CCD) or a complementary metal-oxide semiconductor (CMOS) active pixel sensor, recording typically over 1000 frames per second and playing images back slowly to study the motion for scientific study of transient phenomena. A brief review of the existing high-speed camera types, pointing out the advantages of the new technology, was provided by Thoroddsen et al. [198]. The simplest way to construct movies of some transient flow phenomena is to acquire only one image per event and change the timing of each picture to get a sequence of images. When the frequency of the light pulses is synchronized with the motion of the drop and the camera, the drop appears to be stationary. Such time-delay imaging is only possible for highly repeatable events in which one impact is identical to the next. This technique relies on accurate triggering, such as the piezo-electric driver signal, because slight jitter between separate events will confuse the time history [198]. This technique is known as *Stroboscopic* imaging [68]. Another family of techniques, named *Stereoscopic* imaging, is based on the Lagrangian particle tracking idea. These techniques were originally designed for the characterization of fluid velocity fields. PIV is a well-established technique for obtaining quantitative velocity information over extended regions of a flow with high accuracy. Tracer particles, suspended in a flow-field, are illuminated with short-duration pulses of laser light, and their images are recorded on a CCD array. Conventional PIV uses a single camera whose axis is perpendicular to the illuminated plane in order to obtain the in-plane velocity components. Particle-tracking using two or more cameras allows the mapping of a finite volume in a flow, as opposed to a planar domain in PIV. The particle trajectories are reconstructed and velocity field information can be obtained. Prasad and Adrian [157] developed the first twin-camera stereoscopic system in order to extend the conventional PIV to 3D vectors in planar domains. The stereoscopic 3D reconstruction and the Lagrangian particle tracking idea can also be applied for individual droplets, where further information such as size, morphology, velocity and velocity and acceleration can be obtained as by use of traditional imaging techniques [56, 198, 231].

### ***13.10.2 Chemical Reactor Flow Characterization by PHSI Analysis***

Photography visualization was previously employed for qualitative visualization and quantitative determination of steady or slow transient multiphase flow phenomena,

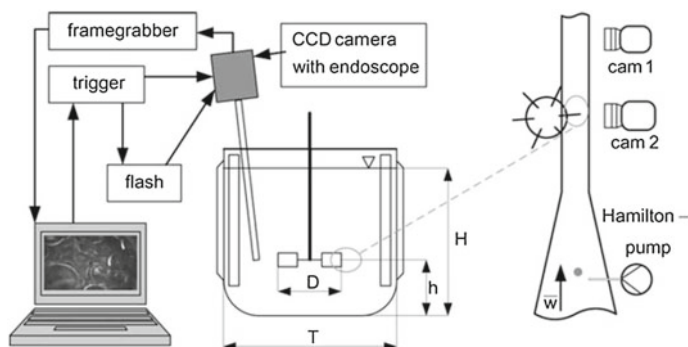

**Fig. 13.18** The target pool 1 is connected to a vertically moving level pool 2 to maintain the liquid in 1 at the wanted level. Drops generated with a dripper 3, fed by a reservoir 4, are detected by a light sensor 5. A lamp 6 generates the light, diffused by an etched glass 7, needed to record high-speed images on a high-speed camera 8. The components are controlled and synchronized with electronic cards 9, a wave generator 10 and a graphical user interface 11. When images are taken from below, light is reflected and diffused with an aluminium plate 12. Distilled water is mainly used as a working liquid and, in few cases, acetic acid. The impact velocity was varied by changing the fall height. All the experiments were performed under the atmospheric conditions. The figure is reproduced from Bisighini and Cossali [23] with permission from Springer

like size and shapes of solid- and fluid particles, wakes behind moving particles, wave phenomena in free surface flow, etc. High-speed visualization by imaging and imaging processing are currently frequently used for qualitative elucidation and quantitative determination of complex transient multiphase flow phenomena. Numerous drop impact mechanisms have been widely investigated, in relation to a wide range of technical applications and natural science research [231]. For example, Bisighini and Cossali [23] observed single and double drop impacts onto a deep pool with a high-speed camera. A sketch of their experimental setup for high-speed visualization of multiphase phenomena is shown in Fig. 13.18. In chemical reactor engineering, similar high-speed visualization techniques have been employed to study the fluid particle breakage and coalescence phenomena. The population balance modeling framework is frequently used to describe these phenomena. In order to experimentally validate the population balance equation (PBE) breakage rate models and for parameter fitting, the breakage probability, the breakage frequency (i.e., reciprocal of breakage time), the number of daughters and the daughter size distribution might be measured within specified ranges of mother particle sizes, flow characteristics and physical property values. Because fluid particle breakage and coalescence are simultaneous processes, there are experimental setups designed to investigate the

interactions in the system. Other setups designs allow separate investigation of the breakage process. This may be achieved by hindered coalescence obtained by addition of surfactants or by investigating dilute systems. There are researchers that look at the interaction directly and there are those who investigate breakage events generated in single fluid particle experiments in specialized vessels or channels. Another division can be made when taking the flow conditions into account, these being laminar and turbulent. Konno et al. [102] used high-speed photography to directly observe drop breakage events in stirred vessels. Chatzi and Lee [37] did investigate the drop interaction processes in liquid-liquid dispersions in agitated vessels. The experimental data obtained by use of a micro-photographic technique indicate that 2–7 daughter drops were produced in each breakage event in liquid-liquid dispersions. Prince et al. [158] did study two possible mechanisms causing bubble breakage in air-sparged bio-reactors. Hesketh et al. [86, 87] studied breakage of bubbles in turbulent liquid flow in a pipeline by use of a high-speed camera. Stewart [189] did perform a study investigating how freely rising ellipsoidal bubbles approach each other, make contact and coalesce or break up. Bubble interactions were recorded by an 8 mm video camera that traversed to follow the rising swarm. The video tapes were later studied in detail by viewing each run frame-by-frame and at reduced speeds. Bahmanyar and Slater [15] observed breakage of single drops in Liquid-Liquid systems in a rotating disk contactor. They investigated the breakage probability as well as the daughter size distribution and the number of initial daughter drops by use of a video technique. Kuriyama et al. [104] investigated liquid-liquid agitated systems to determine the average number of daughter drops formed by breakup of highly viscous parent drops in turbulent flow. They used a loop flow design with a stirred vessel imposing turbulent circulation flow in which the dispersed phase was injected to form single parent drops. Each single drop was then photographed from outside the vessel allowing them to investigate single drop breakage events. Galinat et al. [70] investigated the breakage probability, the number of daughter drops and the resulting daughter drop size distribution as a function of the flow velocity and mother drop diameter using high-speed video recording. Martinez-Bazan et al. [129] studied primary the evolution of the bubble size distribution in a turbulent liquid jet using phase Doppler particle sizing and image processing techniques using a CCD camera. They reported that the breakage events observed were mainly binary. Maaß et al. [123] performed experimental investigations in stirred liquid-liquid systems using high speed camera with 650 fps. In the experiments, breakage of a single organic droplet and the subsequent fragment formation were analyzed by image processing techniques. The single drop experiments had the aim of recording the number of daughter drops per breakage for different mother drop diameters. The set-up consisting of a single drop breakage cell where both the process of breakage (cam 2) and the daughter drop size distributions (cam 1) were analyzed, is sketched in Fig. 13.19. Maaß and Kraume [124] evaluated several breakage rate models from the literature comparing the model predictions with their own data on single drop experiments. The data was collected in the single drop breakage cell (Fig. 13.19) operated under turbulent conditions, comparable to those in a stirred tank. For a constant initial diameter and flow velocity at least 750 single drops were investigated to measure the breakage time and

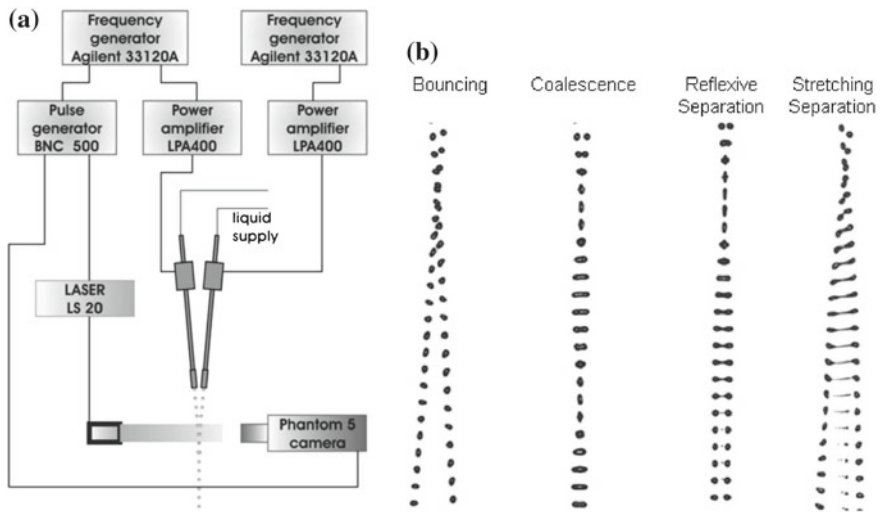

**Fig. 13.19** Experimental set-up: Endoscope technique (*left*); drop breakage cell (*right*). The figure is reproduced from Maaß et al. [123] with permission from Elsevier

probability, using high-speed imaging. These results were used for the determination of breakage rates constituting the product of the inverse of breakage time and the breakage probability. Zaccone et al. [237] studied drop breakage in liquid–liquid stirred dispersions. In the experiments, breakage of a single organic droplet and the subsequent fragment formation were analyzed in the breakage cell (Fig. 13.19) by image processing techniques. Sleicher [183] studied breakage of drops larger than the maximum stable drop size in turbulent water flows by taking photographs of a steady stream of drops generated with a suitable dispersed-phase nozzle. Walter and Blanch [205] studied bubble breakage in a turbulent pipe flow field assumed to be representative for gas–liquid bio-reactors. Bubbles were injected into the turbulent flowing liquid recirculation cell and photographed by a high speed cine camera as they passed down the tube within a photographic box. Both the viscous and surface tension stresses resist bubble elongation and stabilize the bubble surface. Risso and Fabre [167] studied the breakage of bubbles under micro-gravity conditions aboard an aircraft flying in parabolic trajectories to avoid any possible buoyancy driven breakage mechanism besides the turbulent breakage. A scalar parameter, characteristic of the eddy-bubble deformation, was obtained by video processing of high-speed movies. Andersson and Andersson [7, 8] investigated the dynamics of bubble and drop breakage with a high-speed camera technique.

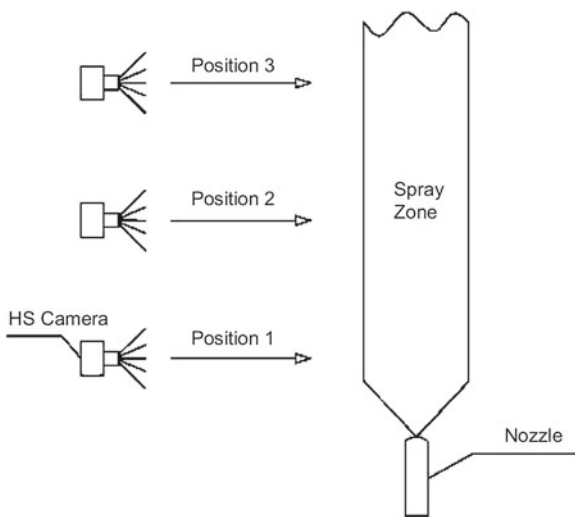

The breakage time, deformations, deformation velocities, number of fragments and daughter drop size distribution were measured with frame rates between 500 and 4000 frames per second (fps) under homogeneous turbulence and energy dissipation rates in a reactor, developed in their laboratory. Their main purpose was to compare the breakage process of bubbles and drops. Tcholakova et al. [197] and Vankova et al. [201] did study emulsification in turbulent flow. They performed an experimental study elucidating the effects of several characteristic system parameters on the breakage rate and the daughter drop-size distribution. These parameters were the parent drop size, surface tension, viscosity of the dispersed phase, and the rate of turbulent energy dissipation. The drop-size distribution was determined

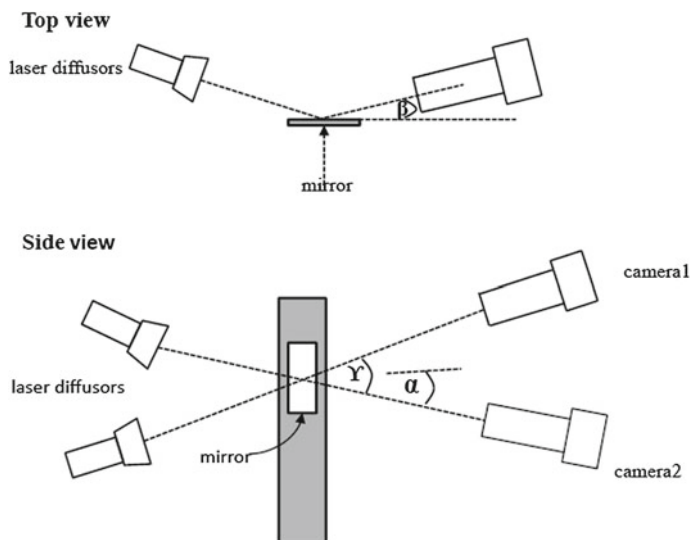

by optical microscopy. The drops were observed and video-recorded in transmitted light by means of microscope Axioplan, equipped with objective Epiplan and connected to a CCD camera and video recorder. The studies by Eastwood et al. [61] deal with drop breakage in a turbulent liquid jet. High-speed video images and digital image-processing techniques were employed. Gotaas et al. [75] studied the effect of the impact parameter in droplet-droplet impact experiments by the aliasing method. This method is based on a small frequency shift between the droplet generating nozzles. The laminar jets emerging from the nozzles are unstable against axisymmetric disturbances and will naturally disintegrate into droplets. However, the production of mono-disperse droplets was controlled by using a piezoelectric element, attached to the nozzle body. By applying a shaped signal to the piezoceramic element, the shape of the element change, which in turn make the orifice vibrate. This vibration subsequently introduced disturbances to the liquid jet. Regular jet breakage was enabled using single frequency disturbances (Fig. 13.20). The plane of the interacting droplet streams was visualized by back-lighting by a laser and the observed process was recorded using a high-speed video camera. A stroboscopic method was used, in which the light source (Oxford laser LS20), each of the nozzle piezoceramics, and the high-speed digital video camera (Phantom 5) were synchronized in order to get still images of the droplet streams (see Fig. 13.20). The droplet collision outcomes, for a fixed Weber number, was then visually followed continuously for the whole range of impact parameters during one collision experiment. In this way the borders between the various collision outcome regimes for droplet-droplet impact were determined. Patruno et al. [155] proposed a procedure to acquire and process droplet data in a liquid–gas two-phase system in order to obtain the evolution of the droplet size distribution. This work was performed in order to elucidate the physical phenomena determining the separation efficiency of natural gas scrubbers. In this study the authors used a high-speed camera to take a sequence of images during a certain period of time at three different positions from the nozzle along the droplet spray in order to obtain the evolution of the droplet size distribution. The system characterized consisted of distilled water droplets in air. The experimental setup of the measurements is sketched in Fig. 13.21. Dupuy et al. [56] investigated droplet-surface impacts at high pressures. Collisions of droplets towards dry and wet walls were studied for several model fluid systems. In order to run droplet experiments up to 100 bar, a high pressure cell was designed with two large glasses for optical access. A back-light illumination stereoscopic technique which requires two high-speed cameras, was employed. As sketched in Fig. 13.22, the objective of both cameras capture the same event but from different angles simultaneously. The simultaneity was guaranteed because the sharp laser pulses and the two cameras were synchronized by the same external clock signal. This technique did allow an in-depth study of droplet-surface collisions at high pressures.

### 13.10.3 PHSI Limitations

Azzopardi [11] did review the experimental techniques available in 1979 for the measurement of drops, solid particle and bubbles. It was concluded that the most generally applicable method is photography but this technique suffers from various difficulties especially for data reduction. Other difficulties that might lead to large errors in the data were related to illumination type, observation magnification, visual sizing and counting methods. The visualization techniques are, like the other laser based techniques, limited to dilute bubble, droplet and particulate flows, due to the requirement of visual accessibility. This puts severe limitations to the application of this method in reactor technology. However, the method is very useful for fundamental single particle breakage and binary particle coalescence analyzes within a transparent fluid. Another major drawback of the visualization methods are related to the accuracy reflected by manual or commercial software image interpretation. In the cases in which an edge of the body is diffuse, the information is normally disregarded.

### 13.10.4 PHSI Literature

Many methods of optical imaging is outlined in the books of Frohn and Roth [68] and Tanaka and Nakamura [191]. Several journal articles are informative [157, 198, 231].

## Mathematical Theorems

The mathematical theorems needed in order to derive the governing model equations are defined in this appendix.

### A.1 Transport Theorem for a Single Phase Region

The transport theorem is employed deriving the conservation equations in continuum mechanics.

The mathematical statement is sometimes attributed to, or named in honor of, the German Mathematician Gottfried Wilhelm Leibnitz (1646–1716) and the British fluid dynamics engineer Osborne Reynolds (1842–1912) due to their work and contributions related to the theorem. Hence it follows that the transport theorem, or alternate forms of the theorem, may be named the *Leibnitz theorem* in mathematics and *Reynolds transport theorem* in mechanics.

In a customary interpretation the Reynolds transport theorem provides the link between the system and control volume representations, while the Leibnitz's theorem is a three dimensional version of the integral rule for differentiation of an integral. There are several notations used for the transport theorem and there are numerous forms and corollaries.

#### A.1.1 Leibnitz's Rule

The *Leibnitz's integral rule* gives a formula for differentiation of an integral whose limits are functions of the differential variable [7, 8, 22, 23, 45, 55, 79, 94, 99]. The formula is also known as differentiation under the integral sign.

$$\frac{d}{dt} \int_{a(t)}^{b(t)} f(t, x) dx = \int_{a(t)}^{b(t)} \frac{\partial f(t, x)}{\partial t} dx + f(t, b) \frac{db}{dt} - f(t, a) \frac{da}{dt} \quad (\text{A.1})$$

The first term on the RHS gives the change in the integral because the function itself is changing with time, the second term accounts for the gain in area as the upper limit is moved in the positive axis direction, and the third term accounts for the loss in area as the lower limit is moved. The formal derivation of the Leibnitz's rule can be found elsewhere [8, 45].

### A.1.2 Leibnitz Theorem

A three dimensional extension of the Leibnitz rule for differentiating an integral is relevant for the derivation of the governing transport equations.<sup>1</sup>

In the material (Lagrangian) representation of continuum mechanics a representative particle of the continuum occupies a point in the initial configuration of the continuum at time  $t = 0$  and has the position vector  $\boldsymbol{\xi} = (\xi_1, \xi_2, \xi_3)$ . In this  $\xi$ -space the coordinates are called the material coordinates. In the Eulerian representation the particle position vector in  $r$ -space is defined by  $\mathbf{r} = (r_1, r_2, r_3)$ . The coordinates  $r_1, r_2, r_3$  which gives the current position of the particle are called the spatial coordinates. Let  $\psi(\mathbf{r}, t)$  be any scalar, vector or tensor function of time and position and  $V(t)$  a material volume. We may then define a variable  $\Psi(t)$  as the volume integral [2]:

$$\Psi(t) = \int_{V(t)} (\rho\psi) dv \quad (\text{A.2})$$

It is desired to find an expression for differentiating the integral  $\Psi(t)$  with time:

$$\frac{D\Psi(t)}{Dt} = \frac{D}{Dt} \int_{V(t)} (\rho\psi)(\mathbf{r}, t) dv \quad (\text{A.3})$$

The integral is over the material volume  $V(t)$  that is a function of  $t$ , hence we cannot take the differentiation through the integration sign.

However, if the integration were with respect to a volume in the material  $\xi$ -coordinates it would be possible to interchange the differentiation and integration, since  $D/Dt$  is defined as differentiation with respect to time keeping  $\boldsymbol{\xi}$  constant. A transformation of the volume from  $r$ -space to  $\xi$ -space allows us to do the desired

---

<sup>1</sup> The theory has been outlined by Truesdell and Toupin [98] (p. 347), Aris [2] (p. 84), Malvern [62] (p. 210), Slattery [87] (p. 17), Slattery [89] (p. 21), Bird et al. [7] (p. 732), Fan and Zhu [40] (p. 167), Kundu [55] (p. 75), Delhayé and Achard [22] (p. 9), Delhayé [23] (p. 42), Bouré and Delhayé [12] (pp. 1–37), Whitaker [99], Donea and Huerta [27] (Sects. 1.3–1.4), Donea et al. [28], and Collado [20].

operation. The position vector in  $r$ -space,  $\mathbf{r} = (r_1, r_2, r_3)$ , is transformed as  $\mathbf{r} = \mathbf{r}(\xi, t)$  in  $\xi$ -space. If the coordinate system is changed from  $r$ -space to  $\xi$ -space, the volume element changes according to:

$$dv = \frac{\partial(r_1, r_2, r_3)}{\partial(\xi_1, \xi_2, \xi_3)} d\xi_1 d\xi_2 d\xi_3 = J dv_0 \quad (\text{A.4})$$

in which  $d\xi_1 d\xi_2 d\xi_3$  denotes the material volume  $dv_0$  about a given point  $\xi$  at the initial instant.

The Jacobian determinant of transformation between the material and fixed coordinate systems, is defined by:

$$J = \frac{\partial(r_1, r_2, r_3)}{\partial(\xi_1, \xi_2, \xi_3)} = \frac{dv}{dv_0} \quad (\text{A.5})$$

The quantity  $J$  may be thought of as the ratio of an elementary material volume to its initial volume.

The differentiation of the integral  $\Psi(t)$  with respect to time can then be proven:

$$\begin{aligned} \frac{D\Psi}{Dt} &= \frac{D}{Dt} \int_{V(t)} (\rho\psi)(\mathbf{r}, t) dv = \frac{D}{Dt} \int_{V_0} (\rho\psi)(\mathbf{r}(\xi, t), t) J dv_0 \\ &= \int_{V_0} \left( \frac{D(\rho\psi)}{Dt} J + (\rho\psi) \frac{DJ}{Dt} \right) dv_0 \\ &= \int_{V_0} \left( \frac{D(\rho\psi)}{Dt} + (\rho\psi)(\nabla \cdot \mathbf{v}) \right) J dv_0 \quad (\text{A.6}) \\ &= \int_{V(t)} \left( \frac{D(\rho\psi)}{Dt} + (\rho\psi)(\nabla \cdot \mathbf{v}) \right) dv \\ &= \int_{V(t)} \left( \frac{\partial(\rho\psi)}{\partial t} + \nabla \cdot ((\rho\psi)\mathbf{v}) \right) dv \end{aligned}$$

in which we have adopted, without proof, the following Lemma<sup>2</sup>:

$$\frac{DJ}{Dt} = J(\nabla \cdot \mathbf{v}) \quad (\text{A.7})$$

Applying the divergence theorem (A.19) to the second integral on the RHS of (A.6) we get a particular three dimensional form of the Leibnitz theorem:

$$\frac{D\Psi}{Dt} = \frac{D}{Dt} \int_{V(t)} (\rho\psi)(\mathbf{r}, t) dv = \int_{V(t)} \frac{\partial(\rho\psi)}{\partial t} dv + \int_{A(t)} (\rho\psi)\mathbf{v} \cdot \mathbf{n} da \quad (\text{A.8})$$

---

<sup>2</sup> The proofs of the transport theorem are given by Slattery [90].

where  $A(t)$  is the surface of  $V(t)$ , and  $\mathbf{v}$  represents the velocity of the control surface with respect to the coordinate reference frame. This kinematical transport theorem is due to Reynolds [78]. For this reason it is sometimes referred to as the Reynolds theorem.

The given theorem can be extended to a general case considering an arbitrary geometric volume with a closed surface moving with an arbitrary velocity  $\mathbf{v}_S$ . Truesdell and Toupin [98] (p. 347) presented the corollary that the above relation remains valid if we replace the derivatives with respect to time while following material particles,  $D/Dt$ , by derivatives with respect to time while following fictitious system particles  $d/dt$ , and the velocity vector for a material particle  $\mathbf{v}$  by the velocity vector for a fictitious system particle  $\mathbf{v}_S$ . Let us thus consider a geometric volume  $V_S(t)$ , not necessarily a material volume, which is moving in space and bounded by a closed surface  $A_S(t)$ . At a given point belonging to this surface,  $\mathbf{n}$  is the unit normal vector outwardly directed. The speed of the displacement of the surface at that point is denoted by  $\mathbf{v}_S \cdot \mathbf{n}$ . The generalized *Leibnitz theorem* enables the time derivative of the volume integral to be transformed into the sum of a volume integral and a surface integral [12, 23, 55]:

$$\frac{d}{dt} \int_{V_S(t)} (\rho\psi)(\mathbf{r}, t) dv = \int_{V_S(t)} \frac{\partial(\rho\psi)}{\partial t} dv + \int_{A_S(t)} (\rho\psi) \mathbf{v}_S \cdot \mathbf{n} da \quad (\text{A.9})$$

in which  $\mathbf{v}_S$  is the velocity of the points on the control volume surface with respect to the coordinate reference frame. Slattery [90] named this mathematical statement the *generalized transport theorem*. This kinematical transport theorem was asserted, not proven, by Reynolds [78].

Comparing (A.8) and (A.9) we note that to make these relations coincide the total time derivative must be specified equal to the substantial time derivative. In this way the substantial derivative may be considered a special kind of the total time derivative [7, 79], and thus the Reynolds transport theorem is a special kind of the Leibnitz theorem.

In the case that the integral boundaries are fixed, the surface integral vanishes because the surface velocity is zero [22, 23, 38, 55]:

$$\frac{d}{dt} \int_V f dv = \int_V \frac{\partial f}{\partial t} dv \quad (\text{A.10})$$

### A.1.3 Reynolds Theorem

In fluid mechanics the laws governing the fluid motion are expressed using both system concepts in which we consider a given mass of the fluid, and control volume concepts in which we consider a given volume [45, 69, 96, 100]. Basically the

physical laws are defined for a system, thus we need a mathematical link between control volume and system concepts to convert the governing equations to apply to a specific region rather than to individual masses. The Reynolds transport theorem is precisely the analytical tool required to transform the laws from one representation to the other.

Let  $\Psi_{\text{sys}}(t)$  be an extensive property of the system at time  $t$ ,  $\psi(\mathbf{r}, t)$  is the corresponding intensive property. If  $V_{\text{sys}}(t)$  denotes a system material volume at time  $t$ ,  $CV$  a control volume, and  $CS$  the control volume surface, the extensive system property can be defined by:

$$\Psi_{\text{sys}}(t) = \int_{V_{\text{sys}}(t)} \rho \psi \, dv \quad (\text{A.11})$$

The corresponding extensive control volume property is defined by:

$$\Psi_{CV}(t) = \int_{CV} \rho \psi \, dv \quad (\text{A.12})$$

The system is defined by the fluid mass within the control volume at the initial time  $t$ . The values of the analogous extensive properties of the system and the fluid within control volume are thus equal at this time,  $\Psi_{\text{sys}}(t_0) = \Psi_{CV}(t_0)$ . A short time later a portion of the system fluid may have exited from the control volume and some of the surrounding fluid may have entered the control volume. Then we seek to determine how the rate of change of  $\Psi_{\text{sys}}$  within the system is related to the rate of change of  $\Psi_{CV}$  within the control volume at any instant. Based on a physical understanding of the concepts of the system and control volume motion, the kinematic Reynolds transport theorem relating system concepts to control volume concepts can be derived by geometrical analysis.

The most general form of the Reynolds transport theorem is defined for an arbitrary moving and deforming control volume [20]:

$$\frac{D\Psi_{\text{sys}}(t)}{Dt} = \frac{D}{Dt} \int_{V_{\text{sys}}(t)} \rho \psi \, dv = \frac{D}{Dt} \int_{CV(t)} \rho \psi \, dv + \int_{CS(t)} \rho \psi \mathbf{w} \cdot \mathbf{n} \, da \quad (\text{A.13})$$

in which  $\mathbf{w}$  is the velocity of the fluid at the control surface with respect to the control surface, and  $\rho$  is the fluid density.

For a fixed control volume, the integral limits are fixed thus the order of differentiation and integration may be interchanged, so the substantial derivative of the CV integral in (A.13) can be written in the equivalent form [100]:

$$\frac{D}{Dt} \int_{CV} \rho \psi \, dv = \int_{CV} \frac{\partial(\rho \psi)}{\partial t} \, dv \quad (\text{A.14})$$

Hence, for a fixed control volume, the Reynolds theorem (A.13) reduces to:

$$\frac{D\Psi_{\text{sys}}(t)}{Dt} = \frac{D}{Dt} \int_{V_{\text{sys}}(t)} \rho\psi \, dv = \int_{CV} \frac{\partial(\rho\psi)}{\partial t} \, dv + \int_{CS} \rho\psi \mathbf{v} \cdot \mathbf{n} \, da \quad (\text{A.15})$$

in which the velocity  $\mathbf{v}$  represents the velocity of the fluid at the control surface with respect to the control surface that coincides with the coordinate reference frame.

This form of the Reynolds transport theorem is a special version of the more general mathematical statement (A.13). However, the latter version is particularly important because fixed control volumes are commonly employed in fluid mechanics and reactor modeling.

In Chap. 1 the derivation of the governing Eulerian equations for single phase flow is performed employing (A.15).

Let us now consider the Leibnitz theorem (A.8) and the Reynolds theorem (A.13). The volume integral on the RHS of the Reynolds theorem is defined over a control volume  $CV(t)$  which coincides with the geometric volume on the LHS of Leibnitz theorem at the considered instant  $t$  in time. At that instant the integrals cover precisely the same space, so we can substitute the Leibnitz theorem (A.8) expression for differentiating the integral into the Reynolds theorem (A.13). The Reynolds theorem can then be written as [20]:

$$\frac{D\Psi_{\text{sys}}(t)}{Dt} = \int_{CV(t)} \frac{\partial}{\partial t} (\rho\psi) \, dv + \int_{CS(t)} (\rho\psi) \mathbf{v} \cdot \mathbf{n} \, da \quad (\text{A.16})$$

The vector quantity  $\mathbf{v} = \mathbf{w} + \mathbf{v}$  represents the velocity of the fluid at the control surface with respect to the coordinate reference frame. This is the conventional Reynolds transport theorem.

## A.2 Gauss Theorem

In general, consider a geometric volume,  $V(t)$ , bounded by a closed surface,  $A(t)$ , which may either be material or not, moving or not. At a given point belonging to this surface  $A(t)$ , the unit normal vector  $\mathbf{n}$  is outwardly directed. For any scalar ( $f$ ), vector or tensor fields ( $\mathbf{f}$ ), Gauss theorem<sup>3</sup> enable a surface integral to be transformed into a volume integral according to the following relation:

---

<sup>3</sup> The Gauss' theorem is also known as the divergence theorem, Green's theorem, and Ostrogradsky's theorem [99]. In particular, the vector form of Gauss's theorem is normally referred to as the divergence theorem [55].

**Gauss' theorem for a scalar**

For single phase flows:

$$\oint_{A(t)} f \mathbf{n} da = \int_{V(t)} \nabla f dv \quad (\text{A.17})$$

For two phase flows we need to consider the interface, and a modified form of the theorem is applied (e.g., [22, 23]). Now we may consider a geometric volume,  $V_k(t)$ , bounded by a closed surface,  $A_k(t) + A_I(t)$ , which may either be material or not, moving or not. At a given point belonging to this surface  $A_k(t) + A_I(t)$ , the unit normal vector  $\mathbf{n}$  is outwardly directed.

$$\int_{A_k(t)} f \mathbf{n} da + \int_{A_I(t)} f \mathbf{n} da = \int_{V_k(t)} \nabla f dv \quad (\text{A.18})$$

**Gauss' theorem for a vector or tensor**

For single phase flows:

$$\oint_{A(t)} \mathbf{f} \cdot \mathbf{n} da = \int_{V(t)} \nabla \cdot \mathbf{f} dv \quad (\text{A.19})$$

For two phase flows we need to consider the interface, and a modified form of the theorem is applied. Now we may consider a geometric volume,  $V_k(t)$ , bounded by a closed surface,  $A_k(t) + A_I(t)$ , which may either be material or not, moving or not. At a given point belonging to this surface  $A_k(t) + A_I(t)$ , the unit normal vector  $\mathbf{n}$  is outwardly directed.

$$\int_{A_k(t)} \mathbf{f} \cdot \mathbf{n} da + \int_{A_I(t)} \mathbf{f} \cdot \mathbf{n} da = \int_{V_k(t)} \nabla \cdot \mathbf{f} dv \quad (\text{A.20})$$

**A.3 Surface Theorems**

These theorems can be found in the books of [2, 67] [89] (p. 73) [33], pp. 48–52 and in the papers of [13, 24], pp. 428–432, and pp. 436–438.

***A.3.1 Leibnitz Transport Theorem for a Surface***

The surface transport theorem ([89], p. 73) can be used to reformulate the term:

$$\frac{d_I}{dt} \int_{A_I(t)} \rho_I \psi_I da \quad (\text{A.21})$$

where  $\psi_I$  is any scalar-, vector-, or tensor function of time and position on the dividing surface. The indicated integration is to be performed over the dividing surface in its current configuration  $A_I$ . We allow  $A_I$  or the limits of the this integration to be a function of time. Slattery ([89], p. 74) presents the surface transport theorem:

$$\frac{d_I}{dt} \int_{A_I(t)} (\rho_I \psi_I) da = \int_{A_I(t)} \left( \frac{d_I(\rho_I \psi_I)}{dt} + \rho_I \psi_I \nabla_I \cdot \mathbf{v}_I \right) da \quad (\text{A.22})$$

Note that this theorem can be reformulated into more generalized forms, but the formulation given here is used in most papers on reactor modeling.

### A.3.2 Gauss Theorem for a Surface

In a 3D space, the Gauss theorems enable the transformation of a surface integral into a volume integral. Similarly, in a 2D space, the Gauss theorems enable the transformation of a line integral into a surface integral. The surface divergence theorem can be expressed in a generic form as follows [33]:

$$\oint_{l_I(t)} \mathcal{R}_I \mathbf{N}_I dl = \int_{A_I(t)} \nabla_I \cdot (\mathbf{e}_I \mathcal{R}_I) da = \int_{A_I} (\nabla_I \mathcal{R}_I - (\nabla_I \cdot \mathbf{n}_I) \mathcal{R}_I \mathbf{n}_I) da \quad (\text{A.23})$$

where  $\mathcal{R}_I$  is a generic field of arbitrary tensorial order. The generic identity may be specialized by inserting a dot- or cross-product operational sign into identical tensorial positions on both sides of the equality sign. The scalar fields  $\mathcal{R}_I$  is defined by  $R_I \mathbf{N}_I$ .

The frequently used forms of the theorem are given as illustrative examples:

#### For interfacial vector fields

$$\oint_{l_I(t)} \mathbf{f}_I \cdot \mathbf{N}_I dl = \int_{A_I(t)} \nabla_I \cdot \mathbf{f}_I da \quad (\text{A.24})$$

where  $\mathbf{N}_I$  is the unit normal vector at a given point belonging to the curve  $l(t)$ , the boundary of  $A_I$ . The vector  $\mathbf{N}_I$  is directed outward the area  $A_I$  and located in the tangent plane.  $\nabla_I$  is the surface del operator.  $\mathbf{f}_I$  is a vector tangent to the surface  $A_I$ .

### For interfacial tensor fields

$$\oint_{l_I(t)} \mathbf{f}_I \cdot \mathbf{N}_I d\mathbf{l} = \int_{A_I(t)} \nabla_I \cdot \mathbf{f}_I da \quad (\text{A.25})$$

where  $\mathbf{f}_I$  is any interfacial tensor field.

### For interfacial scalar fields

$$\oint_{l_I} f_I d\mathbf{l} = \int_{A_I} \nabla_I \cdot (\mathbf{e}_I f_I) da = \int_{A_I} (\nabla_I f_I - (\nabla_I \cdot \mathbf{n}_I) f_I \mathbf{n}_I) da \quad (\text{A.26})$$

where  $f_I$  is any interfacial scalar field,  $\mathbf{e}_I$  is the dyadic idemfactor ([33], p. 46), and  $\nabla_I \cdot \mathbf{n}_I$  is the surface divergence (equal to twice the mean curvature).

### Static Force Balance at a Fluid Interface

Brenner ([13], pp. 428–432, and pp. 436–438), Middleman [66] (pp. 39–42) and Edwards et al. ([33], pp. 48–52) address the basic nature of macro-scale interfacial force balances at an arbitrary curved fluid in the state of hydrostatic equilibrium (a state that serves as a standard from which non-equilibrium interfacial transport processes depart).

Analogous to 3D fluid continua, applying Newton second law the macro-scale fluid interfaces are acted upon by two fundamental types of forces, surface body forces per unit area,  $\mathbf{f}_I$ , and surface contact stress component,  $\mathbf{T}_I \cdot \mathbf{N}_I$ , being a force per unit length. The apparent surface body force densities denote forces originating outside of the 2D interface itself, whereas the apparent surface stresses denote forces acting lineally by virtue of intimate contact between adjacent 2D interfacial fluid elements.

Considering an interface existing in a state of hydrostatic equilibrium, an integral force balance over an element of area,  $A_I$ , lying on a fluid interface may be expressed as :

$$\int_{A_I} \mathbf{F}_I da + \oint_{l_I} \mathbf{T}_I \cdot d\mathbf{l} = 0 \quad (\text{A.27})$$

where  $d\mathbf{l} = \mathbf{N}_I d\mathbf{l}$  is an outwardly directed, differential line element to the closed contour  $l_I$  of the area domain  $A_I$ .

To derive the differential counterpart of the integral balance, starting from (A.27) we need to express the second term (line integral) as an area integral. Thereafter, analogous to the 3D approach used in Chap. 1 deriving the governing conservation equations, the differential form emerges requiring that the resulting relation is valid for an arbitrary chosen surface domain so that the integrand itself must vanish.

To transform the line integral in (A.27) to a surface integral, the version of (A.23) that is defined inserting the dot product sign is relevant. Accordingly, introducing the

dot product and a tensor field into (A.23), a specific version of the surface divergence theorem can be derived:

$$\begin{aligned}
 \oint_{l_I} \mathcal{R}_I \cdot d\mathbf{l} &= \int_{A_I} \nabla_I \cdot (\mathbf{e}_I \cdot \mathcal{R}_I) da = \int_{A_I} \nabla_I \cdot \mathcal{R}_I da \\
 &= \int_{A_I} (\mathcal{R}_I \cdot \nabla_I \cdot \mathbf{e}_I + \mathbf{e}_I \cdot \nabla_I \cdot \mathcal{R}_I) da = \int_{A_I} (\mathcal{R}_I \cdot 2H_I \mathbf{n}_I + \nabla_I \cdot \mathcal{R}_I) da
 \end{aligned} \tag{A.28}$$

where the following relationships have been used:  $\mathbf{e}_I^T = \mathbf{e}_I$ ,  $\mathbf{e}_I \cdot \nabla_I = \nabla_I$ ,  $\nabla_I \cdot \mathbf{e}_I = 2H_I \mathbf{n}_I$ , and  $\mathbf{n}_I \cdot \mathbf{T}_I = 0$ .

To proceed we need to determine the nature of the interface defining the surface pressure- or stress tensor. For the general non-equilibrium circumstances  $\mathbf{T}_I$  is a non-isotropic and non-symmetric tensor, containing six independent components. Four of these components are analogous to the normal- and shear stresses in 3D fluids, while the so-called bending forces have no analog in ordinary 3D fluids. Fortunately, in practice most fluid interfaces are assumed to be inviscid and isotropic. For an isotropic interface existing in a state of hydrostatic equilibrium the surface-excess pressure tensor is given by  $\mathbf{T}_I = \sigma_I \mathbf{e}_I$ , where the scalar  $\sigma_I$  is the interfacial tension. This scalar quantity is an apparent macro-scale property of the physicochemical system, generally interpreted as the 2D analog of the thermodynamic pressure,  $p$ , for 3D continua. From thermodynamic analysis it is concluded that  $\sigma_I$  depends only upon macro-scale pressure, temperature and interfacial composition at the point  $\mathbf{r}_I$ .  $\mathbf{e}_I$  denotes the dyadic idem-factor ([33], p. 46), defined as  $\mathbf{e}_I = \mathbf{e} - \mathbf{n}_I \mathbf{n}_I$ , with the dyadic  $\mathbf{e}$  being the 3D spatial idem-factor.

For the special case of  $\mathcal{R}_I = \mathbf{T}_I$ , (A.28) reduces to:

$$\begin{aligned}
 \oint_{l_I} \mathbf{T}_I \cdot d\mathbf{l} &= \int_{A_I} \nabla_I \cdot (\mathbf{e}_I \cdot \mathbf{T}_I) da = \int_{A_I} \nabla_I \cdot \mathbf{T}_I da = \int_{A_I} \nabla_I \cdot (\sigma_I \mathbf{e}_I) da \\
 &= \int_{A_I} (\sigma_I \nabla_I \cdot \mathbf{e}_I + \mathbf{e}_I \cdot \nabla_I \sigma_I) da = \int_{A_I} (2H_I \sigma_I \mathbf{n}_I + \nabla_I \sigma_I) da
 \end{aligned} \tag{A.29}$$

Thereby, for an isotropic interfacial tensor existing in a state of hydrostatic equilibrium (A.27) yields,

$$\int_{A_I} (\mathbf{F}_I + \nabla_I \cdot \mathbf{T}_I) da = \int_{A_I} (\mathbf{F}_I + 2H_I \sigma_I \mathbf{n}_I + \nabla_I \sigma_I) da = 0 \tag{A.30}$$

As the choice of local surface domain,  $A_I$ , is arbitrary, and since the field variables  $\mathbf{F}_I(\mathbf{r}_I)$  and  $\mathbf{T}_I(\mathbf{r}_I)$  are independent of this choice, this requires at each point ( $\mathbf{r}_I$ ) that:

$$\mathbf{F}_I + \nabla_I \cdot \mathbf{T}_I = \mathbf{F}_I + \nabla_I \sigma_I + 2H_I \sigma_I \mathbf{n}_I = 0 \quad (\text{A.31})$$

which constitutes the local surface force balance at a static fluid interface.<sup>4</sup> Nevertheless, the net surface tension force on a closed surface equals zero [32, 70, 71, 77].

Finally, we note that the surface body force term constitutes the sum of the surface-excess body force and the bulk-phase body force vector densities. The surface-excess body force is the 2D analog of continuum body forces in 3D fluids (e.g., gravitational force, electromagnetic force, etc). This force is often neglected. The bulk-phase body force has no counterpart for 3D fluids, as it denotes the stresses applied intimately at the interface by the surrounding 3D bulk phases. The normal component of this force equals the pressure difference between the two bulk phases, a relationship often referred to as the Young–Laplace equation.

---

<sup>4</sup> This is the analog of the corresponding hydrostatic equation:

$$\rho \mathbf{g} - \nabla \cdot \mathbf{T} = 0 \quad (\text{A.32})$$

for a 3D fluid continuum, where the isotropic stresses are given by  $\mathbf{T} = p\mathbf{e}$ , with  $p = p(\mathbf{r})$  the thermodynamic pressure.

Note also that in typical textbooks on mechanical engineering this relation will be given as  $\mathbf{T} = -p\mathbf{e}$ , as the hydrostatic equation yields:

$$\rho \mathbf{g} + \nabla \cdot \mathbf{T} = 0 \quad (\text{A.33})$$

## Appendix B

# Equation of Change for Temperature for a Multicomponent System

The equation of change for temperature can be derived from the enthalpy equation. For completeness, in this appendix we outline the procedure described by Bird et al. ([8], Problem 19D.2., pp. 608–609) and *Instructor's resource CD-ROM* to accompany *TRANSPORT PHENOMENA*, Second Edition, pp. 15–19 and pp. 16–19.

### B.1 The Problem Definition

In this appendix we will derive the equation of change for temperature:

$$\rho C_P \frac{DT}{Dt} = -\nabla \cdot \mathbf{q} - \boldsymbol{\sigma} : \nabla \mathbf{v} + \sum_{c=1}^N \mathbf{J}_c \cdot \mathbf{g}_c - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega} \frac{Dp}{Dt} + \sum_{c=1}^N \bar{h}_c \left( \nabla \cdot \left( \frac{\mathbf{J}_c}{M_{\omega_c}} \right) - \left( \frac{R_c}{M_{\omega_c}} \right) \right) \quad (\text{B.1})$$

starting out from the enthalpy equation:

$$\rho \frac{Dh}{Dt} = -\nabla \cdot \mathbf{q} - \boldsymbol{\sigma} : \nabla \mathbf{v} + \sum_{c=1}^N \mathbf{J}_c \cdot \mathbf{g}_c + \frac{Dp}{Dt} \quad (\text{B.2})$$

In the next section the sequence of steps for the derivation of (B.1) from (B.2) will be described in detail.

### B.2 Deriving the Equation of Change for Temperature

For a closed system the enthalpy is given by  $\hat{H} = \hat{H}(P, T)$ , while for an open system that can exchange mass with its surroundings the total enthalpy depends also on the possible changes in masses  $M_c$  of each component  $c$ . This implies that for an open

system the enthalpy is written as  $\hat{H} = \hat{H}(T, p, M_1, M_2, M_3, \dots, M_N)$ , where  $N$  is the number of chemical components. An extensive quantity can be divided by the mass of the system constituting a new variable defining a specific quantity ([54], p. 103). The specific enthalpy (per unit mass) is then expressed as:

$$H = H(T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1}) = \sum_{c=1}^N \omega_c \check{H}_c \quad (\text{B.3})$$

where the partial specific enthalpy of species  $c$  is given by  $\check{H}_c = (\frac{\partial \hat{H}}{\partial M_c})_{M', p, T} = (\frac{\partial (MH)}{\partial M_c})_{M', p, T}$ . Note also that these intensive quantities may be computed both per unit mass, per unit volume, or per mole.

In the given notation the LHS of (B.2) can be reformulated in terms of a complete differential if we consider the enthalpy per unit mass to be a thermodynamic function of  $T, p$  and the first  $(N - 1)$  mass fractions:

$$dH = \left( \frac{\partial H}{\partial p} \right)_{T, \omega'} dp + \left( \frac{\partial H}{\partial T} \right)_{p, \omega'} dT + \sum_{c=1}^{N-1} \left( \frac{\partial H}{\partial \omega_c} \right)_{p, T, \omega'} d\omega_c \quad (\text{B.4})$$

and then apply the principle of local instantaneous equilibrium:

$$\frac{Dh}{Dt} = \left( \frac{\partial h}{\partial p} \right)_{T, \omega'} \frac{Dp}{Dt} + \left( \frac{\partial h}{\partial T} \right)_{p, \omega'} \frac{DT}{Dt} + \sum_{c=1}^{N-1} \left( \frac{\partial h}{\partial \omega_c} \right)_{p, T, \omega'} \frac{D\omega_c}{Dt} \quad (\text{B.5})$$

The capital letters for the quantities (e.g.,  $H = H(T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1})$ ) indicate that we are considering the variable as a thermodynamic function, whereas the corresponding variables used in continuum mechanics are defined by lower case letters (e.g.,  $h = h(t, \mathbf{r}, T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1})$ ).

Next, the term  $\frac{D\omega_c}{Dt}$  can be eliminated from (B.5) using the transport equation for the chemical species:

$$\rho \frac{D\omega_c}{Dt} = -\nabla \cdot \mathbf{J}_c + R_c \quad (\text{B.6})$$

The coefficient in front of  $\frac{D\omega_c}{Dt}$  in (B.5) is usually reformulated in terms of molar quantities known from thermodynamic theory. This is a rather complex task, thus a detailed description of this part of the model derivation is given shortly.

The theoretical basis for the model derivation used at this point originates from thermodynamics. The corresponding variables used in continuum mechanics are then defined in analogy to the thermodynamic quantities applying the principle of local instantaneous equilibrium, in line with the approach adopted above obtaining (B.5) from (B.4). Following the same approach, the thermodynamic quantities and relations needed in order to reformulate the coefficient in front of  $\frac{D\omega_c}{Dt}$  in (B.5) will be

described before we introduce the corresponding extensions approved in continuum mechanic theory.

If we first consider the enthalpy variable as a thermodynamic quantity, the total enthalpy,  $\hat{H} = \hat{H}(T, p, M_1, M_2, M_3, \dots, M_N)$ , and the specific enthalpy (per unit mass),  $H = H(T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1})$ , can be defined characterizing an open thermodynamic system. Since enthalpy is an extensive thermodynamic property, we may write:

$$\hat{H}(M_1, M_2, M_3, \dots, M_N) = MH(\omega_1, \omega_2, \omega_3, \dots, \omega_{N-1}) \quad (\text{B.7})$$

in which the  $M_\alpha$  are the masses of the various species,  $M$  is the sum of the  $M_\alpha$ 's, and  $\omega_\alpha = M_\alpha/M$  are the corresponding mass fractions. Both  $H$  and  $\hat{H}$  are understood to be functions of  $T, p$  and as well as of composition (i.e.,  $T$  and  $p$  have been left out for simplicity in the mathematical manipulation below).

By use of the chain rule of partial differentiation we find for  $\alpha \neq N$ :

$$\begin{aligned} \left( \frac{\partial \hat{H}}{\partial M_\alpha} \right)_{M_\gamma} &= \sum_{\beta=1}^{N-1} \left( \frac{\partial (MH)}{\partial \omega_\beta} \right)_{\omega_\gamma, M} \left( \frac{\partial \omega_\beta}{\partial M_\alpha} \right)_{M_\gamma} + \left( \frac{\partial (MH)}{\partial M} \right)_{\omega_\gamma} \left( \frac{\partial M}{\partial M_\alpha} \right)_{M_\gamma} \\ &= M \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \frac{\partial (M_\beta/M)}{\partial M_\alpha} \right)_{M_\gamma} + H \left( \frac{\partial M}{\partial M_\alpha} \right)_{\omega_\gamma} \cdot 1 \\ &= M \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \frac{1}{M} \frac{\partial M_\beta}{\partial M_\alpha} - \frac{M_\beta}{M^2} \frac{\partial M}{\partial M_\alpha} \right) + H \cdot 1 \cdot 1 \\ &= M \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \frac{\delta_{\alpha\beta}}{M} - \frac{M_\beta}{M^2} \right) + H \\ &= \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \delta_{\alpha\beta} - \frac{M_\beta}{M} \right) + H \end{aligned} \quad (\text{B.8})$$

The corresponding expression for  $\alpha = N$  can be found in a similar way:

$$\begin{aligned} \left( \frac{\partial \hat{H}}{\partial M_N} \right)_{M_\gamma} &= \sum_{\beta=1}^{N-1} \left( \frac{\partial (MH)}{\partial \omega_\beta} \right)_{\omega_\gamma, M} \left( \frac{\partial \omega_\beta}{\partial M_N} \right)_{M_\gamma} + \left( \frac{\partial (MH)}{\partial M} \right)_{\omega_\gamma} \left( \frac{\partial M}{\partial M_N} \right)_{M_\gamma} \\ &= M \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \frac{1}{M} \frac{\partial M_\beta}{\partial M_N} - \frac{M_\beta}{M^2} \frac{\partial M}{\partial M_N} \right) + H \cdot 1 \\ &= M \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( -\frac{M_\beta}{M^2} \right) + H \\ &= \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( -\frac{M_\beta}{M} \right) + H \end{aligned} \quad (\text{B.9})$$

The subscript  $\omega_\gamma$  means that all other mass fractions should be held constant.

Subtraction then gives for  $\alpha \neq N$ :

$$\begin{aligned}
 & \left( \frac{\partial \hat{H}}{\partial M_\alpha} \right)_{M_\gamma} - \left( \frac{\partial \hat{H}}{\partial M_N} \right)_{M_\gamma} \\
 &= \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \delta_{\alpha\beta} - \frac{M_\beta}{M} \right) + H - \left[ \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( -\frac{M_\beta}{M} \right) + H \right] \\
 &= \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \left( \delta_{\alpha\beta} - \frac{M_\beta}{M} + \frac{M_\beta}{M} \right) \\
 &= \sum_{\beta=1}^{N-1} \left( \frac{\partial H}{\partial \omega_\beta} \right)_{\omega_\gamma} \delta_{\alpha\beta} = \left( \frac{\partial H}{\partial \omega_\alpha} \right)_{\omega_\gamma}
 \end{aligned} \tag{B.10}$$

In the last paragraph the coefficient of  $d\omega_c$  in (B.4) has been expressed in terms of species masses rather than species mass fractions by use of thermodynamic theory and a complete differential regarding the specific enthalpy to be a function of  $T$ ,  $p$  and the first  $(N - 1)$  mass fractions. These species mass based functions may then more easily be converted to the appropriate molar quantities which we can obtain from thermodynamic models.

On the equivalent molar basis<sup>5</sup> the total enthalpy content (or the enthalpy)  $\hat{H}$  may be defined by  $\hat{H} = MH = n\bar{H}$ . This means that  $\hat{H}(T, p, M_1, M_2, M_3, \dots, M_N)$  may equivalently be written as  $\hat{H}(T, p, n_1, n_2, n_3, \dots, n_N)$ .

The specific molar enthalpy (per mole) is then expressed as:

$$\underline{H} = \underline{H}(T, p, x_1, x_2, x_3, \dots, x_{N-1}) = \sum_{c=1}^N x_c \bar{H}_c \tag{B.11}$$

where the partial (specific) molar enthalpy of species  $c$  is given by  $\bar{H}_c = \left( \frac{\partial \hat{H}}{\partial n_c} \right)_{n', p, T} = \left( \frac{\partial(n\bar{H})}{\partial n_c} \right)_{n', p, T}$ . Thus, we can easily see that  $\check{H}_c = \left( \frac{\partial \hat{H}}{\partial M_c} \right)_{M', p, T} = \frac{1}{M_{w_c}} \left( \frac{\partial \hat{H}}{\partial n_c} \right)_{n', p, T} = \frac{1}{M_{w_c}} \bar{H}_c$ . The specific molar enthalpy for an ideal gas is denoted by  $\underline{H}^*$ , and for ideal gases we have the following relations:  $\underline{H} = \underline{H}^* = \sum_{c=1}^N x_c \underline{H}_c^*$  and  $\bar{H}_c = \underline{H}_c^*$ .

The LHS of (B.2) can now be expressed as:

$$\begin{aligned}
 \rho \frac{Dh}{Dt} &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p, \omega} \right) \frac{Dp}{Dt} + C_P \frac{DT}{Dt} \\
 &+ \sum_{c=1}^{N-1} \left[ \left( \frac{\partial \hat{h}}{\partial M_c} \right)_{M'} - \left( \frac{\partial \hat{h}}{\partial M_N} \right)_{M'} \right] (-\nabla \cdot \mathbf{J}_c + R_c)
 \end{aligned} \tag{B.12}$$

<sup>5</sup> For further studies of these thermodynamic quantities the reader is referred to standard thermodynamic—and continuum mechanic textbooks [7, 8, 54, 56, 79, 81].

where we have applied the principle of local instantaneous equilibrium to obtain an expression for the coefficient in front of  $\frac{D\omega_c}{Dt}$  in (B.5) based on the result we obtained from thermodynamic theory as given in (B.10).

Because of the relations  $M_c = n_c M_{w_c}$  and  $\hat{h} = Mh = n\bar{h}$ , the differential quotients in the last term in (B.12) can be rewritten in terms of partial molar quantities:

$$\begin{aligned}
 \rho \frac{Dh}{Dt} &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p,\omega} \right) \frac{Dp}{Dt} + \rho C_P \frac{DT}{Dt} \\
 &+ \sum_{c=1}^{N-1} \left[ \frac{1}{M_{w_c}} \left( \frac{\partial \hat{h}}{\partial n_c} \right)_{n'} - \frac{1}{M_{w_N}} \left( \frac{\partial \hat{h}}{\partial n_N} \right)_{n'} \right] (-\nabla \cdot \mathbf{J}_c + R_c) \\
 &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p,\omega} \right) \frac{Dp}{Dt} + \rho C_P \frac{DT}{Dt} \\
 &+ \sum_{c=1}^{N-1} \left[ \frac{\bar{h}_c}{M_{w_c}} - \frac{\bar{h}_N}{M_{w_N}} \right] (-\nabla \cdot \mathbf{J}_c + R_c) \\
 &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p,\omega} \right) \frac{Dp}{Dt} + \rho C_P \frac{DT}{Dt} \\
 &+ \sum_{c=1}^{N-1} \frac{\bar{h}_c}{M_{w_c}} (-\nabla \cdot \mathbf{J}_c + R_c) - \sum_{c=1}^{N-1} (-\nabla \cdot \mathbf{J}_c + R_c) \frac{\bar{h}_N}{M_{w_N}} \\
 &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p,\omega} \right) \frac{Dp}{Dt} + \rho C_P \frac{DT}{Dt} \\
 &+ \sum_{c=1}^{N-1} \bar{h}_c \left( -\nabla \cdot \left( \frac{\mathbf{J}_c}{M_{w_c}} \right) + \left( \frac{R_c}{M_{w_c}} \right) \right) + (-\nabla \cdot \mathbf{J}_N + R_N) \frac{\bar{h}_N}{M_{w_N}} \\
 &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p,\omega} \right) \frac{Dp}{Dt} + \rho C_P \frac{DT}{Dt} \\
 &+ \sum_{c=1}^{N-1} \bar{h}_c \left( -\nabla \cdot \left( \frac{\mathbf{J}_c}{M_{w_c}} \right) + \left( \frac{R_c}{M_{w_c}} \right) \right) + \bar{h}_N \left( -\nabla \cdot \left( \frac{\mathbf{J}_N}{M_{w_N}} \right) + \left( \frac{R_N}{M_{w_N}} \right) \right) \\
 &= \rho \left( \frac{1}{\rho} - T \left( \frac{\partial \left( \frac{1}{\rho} \right)}{\partial T} \right)_{p,\omega} \right) \frac{Dp}{Dt} + \rho C_P \frac{DT}{Dt} + \sum_{c=1}^N \bar{h}_c \left( -\nabla \cdot \left( \frac{\mathbf{J}_c}{M_{w_c}} \right) + \left( \frac{R_c}{M_{w_c}} \right) \right)
 \end{aligned} \tag{B.13}$$

where we have used the relations that  $\sum_{c=1}^N \mathbf{J}_c = 0$  and  $\sum_{c=1}^N R_c = 0$ .

Inserted into (B.2) this result coincides with the temperature equation on the form (B.1).

#### C.2.1 The Viscous Stress Tensor for Newtonian Fluids

Vector notation

$$\boldsymbol{\sigma} = -\mu \left( \nabla \mathbf{v} + (\nabla \mathbf{v})^T \right) + \frac{2}{3} \mu \nabla \cdot \mathbf{v} \mathbf{e}, \quad \text{where } \mathbf{e} = \sum_i \sum_j \mathbf{e}_i \mathbf{e}_j \delta_{ij} \quad (\text{C.15})$$

**C.2.2 Cartesian Coordinates (x, y, z):**

---

$$\sigma_{xx} = -\mu \left[ 2 \frac{\partial v_x}{\partial x} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.16})$$

---

---

$$\sigma_{yy} = -\mu \left[ 2 \frac{\partial v_y}{\partial y} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.17})$$

---

---

$$\sigma_{zz} = -\mu \left[ 2 \frac{\partial v_z}{\partial z} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.18})$$

---

---

$$\sigma_{xy} = \sigma_{yx} = -\mu \left[ \frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x} \right] \quad (\text{C.19})$$

---

---

$$\sigma_{yz} = \sigma_{zy} = -\mu \left[ \frac{\partial v_y}{\partial z} + \frac{\partial v_z}{\partial y} \right] \quad (\text{C.20})$$

---

---

$$\sigma_{zx} = \sigma_{xz} = -\mu \left[ \frac{\partial v_z}{\partial x} + \frac{\partial v_x}{\partial z} \right] \quad (\text{C.21})$$

---

---

$$\nabla \cdot \mathbf{v} = \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z} \quad (\text{C.22})$$

---

### C.2.3 Cylindrical Coordinates ( $r, \theta, z$ ):

---

$$\sigma_{rr} = -\mu \left[ 2 \frac{\partial v_r}{\partial r} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.23})$$

---

$$\sigma_{\theta\theta} = -\mu \left[ 2 \left( \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right) - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.24})$$

---

$$\sigma_{zz} = -\mu \left[ 2 \frac{\partial v_z}{\partial z} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.25})$$

---

$$\sigma_{r\theta} = \sigma_{\theta r} = -\mu \left[ r \frac{\partial}{\partial r} \left( \frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right] \quad (\text{C.26})$$

---

$$\sigma_{\theta z} = \sigma_{z\theta} = -\mu \left[ \frac{\partial v_\theta}{\partial z} + \frac{1}{r} \frac{\partial v_z}{\partial \theta} \right] \quad (\text{C.27})$$

---

$$\sigma_{zr} = \sigma_{rz} = -\mu \left[ \frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z} \right] \quad (\text{C.28})$$

---

$$\nabla \cdot \mathbf{v} = \frac{1}{r} \frac{\partial}{\partial r} (r v_r) + \frac{1}{r} \frac{\partial}{\partial \theta} (v_\theta) + \frac{\partial v_z}{\partial z} = 0 \quad (\text{C.29})$$

---

### C.2.4 Spherical Coordinates ( $r, \theta, \phi$ ):

---

$$\sigma_{rr} = -\mu \left[ 2 \frac{\partial v_r}{\partial r} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.30})$$

---

$$\sigma_{\theta\theta} = -\mu \left[ 2 \left( \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right) - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.31})$$

---

$$\sigma_{\phi\phi} = -\mu \left[ 2 \left( \frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_r}{r} + \frac{v_\theta \cot \theta}{r} \right) - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (\text{C.32})$$

---

$$\sigma_{r\theta} = \sigma_{\theta r} = -\mu \left[ r \frac{\partial}{\partial r} \left( \frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right] \quad (\text{C.33})$$

---

$$\sigma_{\theta\phi} = \sigma_{\phi\theta} = -\mu \left[ \frac{\sin \theta}{r} \frac{\partial}{\partial \theta} \left( \frac{v_\phi}{\sin \theta} \right) + \frac{1}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} \right] \quad (\text{C.34})$$

---

$$\sigma_{\phi r} = \sigma_{r\phi} = -\mu \left[ \frac{1}{\sin \theta} \frac{\partial v_r}{\partial \phi} + r \frac{\partial}{\partial r} \left( \frac{v_\phi}{r} \right) \right] \quad (\text{C.35})$$

---

$$\nabla \cdot \mathbf{v} = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 v_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (v_\theta \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} \quad (\text{C.36})$$

---

### C.3 The Equation of Heat in Terms of T and Flux q

#### Vector notation

$$\begin{aligned} \rho C_p \left( \frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla T \right) = & -\nabla \cdot \mathbf{q} - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega} \frac{Dp}{Dt} - \boldsymbol{\sigma} : \nabla \mathbf{v} \\ & + \sum_{s=1}^N \frac{\bar{h}_s}{M_{\omega_s}} \nabla \cdot \mathbf{j}_s + \sum_{r=1}^Q \frac{R_{ref,r}}{M_{w_{ref}}} (-\Delta H_{R_{ref},r}) \end{aligned} \quad (\text{C.37})$$

---

#### Cartesian Coordinates (x, y, z)

$$\begin{aligned} \rho C_p \left( \frac{\partial T}{\partial t} + v_x \frac{\partial T}{\partial x} + v_y \frac{\partial T}{\partial y} + v_z \frac{\partial T}{\partial z} \right) = & - \left[ \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} + \frac{\partial q_z}{\partial z} \right] \\ & - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega} \frac{Dp}{Dt} - \boldsymbol{\sigma} : \nabla \mathbf{v} + \sum_{s=1}^N \frac{\bar{h}_s}{M_{\omega_s}} \left( \frac{\partial j_{sx}}{\partial x} + \frac{\partial j_{sy}}{\partial y} + \frac{\partial j_{sz}}{\partial z} \right) \\ & + \sum_{r=1}^Q \frac{R_{ref,r}}{M_{w_{ref}}} (-\Delta H_{R_{ref},r}) \end{aligned} \quad (\text{C.38})$$

---

#### Cylindrical Coordinates (r, $\theta$ , z)

$$\begin{aligned} \rho C_p \left( \frac{\partial T}{\partial t} + v_r \frac{\partial T}{\partial r} + \frac{v_\theta}{r} \frac{\partial T}{\partial \theta} + v_z \frac{\partial T}{\partial z} \right) = & - \left[ \frac{1}{r} \frac{\partial}{\partial r} (r q_r) + \frac{1}{r} \frac{\partial q_\theta}{\partial \theta} + \frac{\partial q_z}{\partial z} \right] \\ & - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega} \frac{Dp}{Dt} - \boldsymbol{\sigma} : \nabla \mathbf{v} + \sum_{s=1}^N \frac{\bar{h}_s}{M_{\omega_s}} \left[ \frac{1}{r} \frac{\partial}{\partial r} (r j_{r,s}) + \frac{1}{r} \frac{\partial j_{\theta,s}}{\partial \theta} + \frac{\partial j_{z,s}}{\partial z} \right] \\ & + \sum_{r=1}^Q \frac{R_{ref,r}}{M_{w_{ref}}} (-\Delta H_{R_{ref},r}) \end{aligned} \quad (\text{C.39})$$

---

### Spherical Coordinates ( $r, \theta, \phi$ )

---

$$\begin{aligned}
 & \rho C_p \left( \frac{\partial T}{\partial t} + v_r \frac{\partial T}{\partial r} + \frac{v_\theta}{r} \frac{\partial T}{\partial \theta} + \frac{v_\phi}{r \sin \phi} \frac{\partial T}{\partial \phi} \right) \\
 &= -\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 q_r) - \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (q_\theta \sin \theta) - \frac{1}{r \sin \theta} \frac{\partial q_\phi}{\partial \phi} - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega} \frac{Dp}{Dt} - \boldsymbol{\sigma} : \nabla \mathbf{v} \\

## Appendix D

# Alternative Two-Fluid Model Granular Material Kinetic Theory Closures

Two families of two-fluid model closures have emerged from the kinetic theory of granular flow (KTGF). The first family of closures is based on the modeling work of Gidaspow [42] and the second family of closures is based on the modeling work of Simonin et al. [3–6, 25, 47, 48, 68, 82, 83, 86]. The kinetic theory of granular flow (KTGF) derived by Gidaspow [42] for dense beds has been reviewed in Chap. 4. The KTGF derived by Simonin et al. is outlined in this appendix. This theory might be viewed as an extension of the Chapman-Enskog theory presented by Gidaspow [42].

With these two families of closure models at hand, numerous models for fluidized bed reactor flows have been established based on solving the average continuity, momentum and granular temperature or turbulent kinetic energy equations. However, the majority of the papers published on this topic still focus on cold flow gas-particle flows, intending to develop closures that are able to predict the important flow phenomena observed analyzing experimental data. Very few attempts have been made to predict the performance of chemical reactive processes using this type of models.

### Alternative Two-Fluid Model Closures

According to Enwald and Almstedt [36], the existing ensemble averaged two-fluid model closures for bubbling beds, developed by Simonin et al. (e.g., [3–6, 25, 47, 48, 68, 82, 83, 86]), Drew [31], Drew and Lahey [30], and the group at Chalmers University of Technology (e.g., [35–37, 74–76]), are frequently divided into four different model classes.

With increasing model complexity, these model versions are:

- Constant Particle Viscosity (CPV) models.
- Particle Turbulence (PT) models.
- Particle and Gas Turbulence (PGT) models.
- Particle and Gas Turbulence with Drift Velocity (PGTDV) models.

The continuity and momentum equations that are common for these model versions are listed below. The model equations adopted for non-reactive mixtures can be deduced from the more general formulations (3.297) and (3.300), respectively.

The continuity equation used is expressed as:

$$\frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle^{X_k} \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \right) = 0 \quad (\text{D.1})$$

The momentum equation employed is given by:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \right) \\ = -\nabla \cdot \left( \alpha_k \langle \mathbf{T}_k \rangle^{X_k} + \alpha_k \mathbf{T}_k^{Re, X_k} \right) + \alpha_k \langle \rho_k \rangle^{X_k} \mathbf{g} + \langle \mathbf{M}_{kI} \rangle \end{aligned} \quad (\text{D.2})$$

In order to separate the average of products into products of average, weighted averaged values are commonly introduced. The phasic—and mass averages have been defined by (3.281) and (3.282), respectively. Hence, the instantaneous velocity is decomposed into a weighted mean component and a fluctuation component in accordance with (3.283).

The Reynolds stress tensor of phase  $k$  is given by:

$$\mathbf{T}_k^{Re, X_k} = \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k'' \mathbf{v}_k'' \rangle^{X_k \rho_k} \quad (\text{D.3})$$

The total stress tensor is conventionally decomposed into a pressure term and a viscous stress term. The average total stress term in the momentum equations may thus be re-written as:

$$\begin{aligned} -\nabla \cdot (\alpha_k \langle \mathbf{T}_k \rangle^{X_k}) &= -\nabla \cdot [\alpha_k (\langle p_k \rangle^{X_k} \mathbf{e} + \langle \boldsymbol{\sigma}_k \rangle^{X_k})] \\ &= -\nabla (\alpha_k \langle p_k \rangle^{X_k}) - \nabla \cdot (\alpha_k \langle \boldsymbol{\sigma}_k \rangle^{X_k}) \end{aligned} \quad (\text{D.4})$$

The viscous stress tensor of both phases can be modeled using the rigorous Newtonian strain-stress relation:

$$\langle \boldsymbol{\sigma}_k \rangle^{X_k} = -\mu_{B,k} \nabla \cdot \langle \mathbf{v}_k \rangle^{X_k \rho_k} \mathbf{e} - 2\mu_k (\langle \mathbf{S}_k \rangle^{X_k \rho_k} - \frac{1}{3} \nabla \cdot \langle \mathbf{v}_k \rangle^{X_k \rho_k} \mathbf{e}) \quad (\text{D.5})$$

where  $\mu_{B,k}$  represents the bulk viscosity of phase  $k$  (kg/ms).

The average strain rate tensor is defined by:

$$\langle \mathbf{S}_k \rangle^{X_k \rho_k} = \frac{1}{2} (\nabla \langle \mathbf{v}_k \rangle^{X_k \rho_k} + (\nabla \langle \mathbf{v}_k \rangle^{X_k \rho_k})^T) \quad (\text{D.6})$$

It was explained in Chap. 4 that the particulate phase pressure,  $\langle p_p \rangle^{X_p}$ , consists of three effects, one kinetic contribution corresponding to momentum transport caused by particle velocity fluctuation correlations,  $\langle p_{p,kin} \rangle^{X_p}$ , one collisional contribution

caused by particle interaction,  $\langle p_{p,coll} \rangle^{X_p}$ , and one being a contribution from the gas phase pressure,  $\langle p_g \rangle^{X_p}$ . The pressure in the particulate phase is thus given by:

$$\alpha_p \langle p_p \rangle^{X_p} = \alpha_p \langle p_{p,kin} \rangle^{X_p} + \alpha_p \langle p_{p,coll} \rangle^{X_p} + \alpha_p \langle p_g \rangle^{X_p} \quad (D.7)$$

The particulate phase total stress tensor can then be written as:

$$\begin{aligned} -\nabla \cdot (\alpha_p \langle \mathbf{T}_p \rangle^{X_p}) &= -\nabla (\alpha_p \langle p_{p,kin} \rangle^{X_p}) - \nabla (\alpha_p \langle p_{p,coll} \rangle^{X_p}) \\ &\quad - \langle p_g \rangle^{X_p} \nabla \alpha_p - \alpha_p \nabla \langle p_g \rangle^{X_p} - \nabla \cdot (\alpha_p \langle \boldsymbol{\alpha} \mathbf{e} \rangle^{X_p}) \end{aligned} \quad (D.8)$$

The interfacial momentum transfer to phase  $k$  is defined by [30, 35]:

$$\langle \mathbf{M}_{kl} \rangle = \langle \mathbf{T}_k \cdot \nabla X_k \rangle \quad (D.9)$$

This relation can be reformulated adopting one out of several possible modeling approaches. The conventional continuum mechanical approach for re-writing the interfacial momentum transfer terms for dispersed flows was outlined in Sect. 3.4.3. Hence, an alternative approach for calculating the interfacial momentum transfer terms based on kinetic or probabilistic theories, as proposed by Simonin et al. is examined in this section.

The gradient of the phase indicator function, which appears in (D.9), was defined by (3.292). The expression for  $\mathbf{M}_{kl}$  then becomes [30, 35]:

$$\langle \mathbf{M}_{kl} \rangle = \langle \mathbf{T}_k \cdot \nabla X_k \rangle = -\langle \mathbf{T}_k \cdot \mathbf{n}_k \delta_k \rangle \quad (D.10)$$

as we recall that  $\nabla X_k = (\partial X_k / \partial n) \mathbf{n}_k$ , where  $(\partial X_k / \partial n) = -\delta_k$ .

He and Simonin [48] argued that to find a relation for the drag force acting on a single sphere in a suspension, the velocity field of the undisturbed flow is needed. They derived a momentum equation for an undisturbed flow based on probabilistic arguments. Based on the momentum equations for the disturbed and undisturbed flow, they derived an expression for the interfacial momentum transfer. The interfacial momentum transfer term was thus decomposed as follows:

$$\begin{aligned} \langle \mathbf{T}_p \cdot \mathbf{n}_p \delta_p \rangle &= -\langle \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle = -\langle \tilde{\mathbf{T}}_g \cdot \mathbf{n}_g \delta_g \rangle - \langle \delta \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle \\ &= \langle \tilde{\mathbf{T}}_g \cdot \nabla X_g \rangle - \langle \delta \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle \approx \langle \tilde{p}_g \mathbf{e} \cdot \nabla X_g \rangle - \langle \delta \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle \\ &= \langle \tilde{p}_g \nabla X_g \rangle - \langle \delta \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle \\ &= \langle \tilde{p}_g \rangle \nabla \alpha_g + \langle \tilde{p}'_g \nabla X_g \rangle - \langle \delta \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle \approx \langle p_g \rangle \nabla \alpha_g + \mathbf{F}_g \end{aligned} \quad (D.11)$$

where  $\tilde{\mathbf{T}}_g$  denotes the total stress tensor of the undisturbed flow.

The undisturbed pressure is decomposed in accordance with the Reynolds procedure  $\tilde{p}_g = \langle \tilde{p}_g \rangle + \tilde{p}'_g$ .

The interfacial momentum transfer terms for the disturbed flow are approximated by the steady drag force:

$$\begin{aligned}\mathbf{F}_g &\approx -\langle \delta \mathbf{T}_g \cdot \mathbf{n}_g \delta_g \rangle \approx \langle X_p \rho_p \mathbf{v}_r / \tau_{gp} \rangle \approx \langle X_p \rho_p \rangle \langle \mathbf{v}_r \rangle^{X_p \rho_p} / \langle \tau_{gp} \rangle^{X_p \rho_p} \\ &\approx \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_r \rangle^{X_p \rho_p} / \langle \tau_{gp} \rangle^{X_p \rho_p}\end{aligned}\quad (\text{D.12})$$

where  $\tau_{gp}$  is the particle relaxation time.

We reiterate that for a dispersed flow  $\mathbf{F}_p$  the macroscopic generalized drag force normally contains numerous contributions, as outlined in Chap. 5. However, for gas-solid flows the lift force  $\mathbf{f}_L$ , the virtual mass force  $\mathbf{f}_V$ , and the Basset history force  $\mathbf{f}_B$  components are usually neglected [35]. The conventional generalized drag force given by (5.7) thus reduces to:

$$\mathbf{F}_p \approx N_p (\mathbf{f}_D + \mathbf{f}_L + \mathbf{f}_V + \mathbf{f}_B) \approx N_p \mathbf{f}_D \quad (\text{D.13})$$

where the forces in the brackets on the right hand side are the forces acting on a single particle in a suspension and  $N_p$  is the number of particles per unit volume.

The generalized drag force is then expressed as:

$$\mathbf{F}_g = -\mathbf{F}_p = -\frac{X_p \rho_p}{\tau_{gp}} (\mathbf{v}_g - \mathbf{v}_p) \quad (\text{D.14})$$

in which the particle relaxation time  $\tau_{gp}$  is defined by:

$$\frac{1}{\tau_{gp}} = \frac{3}{4d_p} \frac{\rho_g}{\rho_p} C_D |\mathbf{v}_g - \mathbf{v}_p| \quad (\text{D.15})$$

The averaged drag force was approximated by [3]:

$$\begin{aligned}\langle \mathbf{F}_g \rangle &= -\langle \mathbf{F}_p \rangle = \left\langle -\frac{X_p \rho_p}{\tau_{gp}} (\mathbf{v}_g - \mathbf{v}_p) \right\rangle \\ &\approx -\frac{3}{4d_p} \alpha_p \langle C_D \rangle^{X_p \rho_p} \langle \rho_g \rangle^{X_p} \langle |\mathbf{v}_r| \rangle^{X_p \rho_p} \langle \mathbf{v}_r \rangle^{X_p \rho_p}\end{aligned}\quad (\text{D.16})$$

The average drag coefficient used is [41]:

$$\langle C_D \rangle^{X_p \rho_p} = \left( \frac{17.3}{\langle Re_p \rangle^{X_p \rho_p}} + 0.336 \right) \alpha_g^{-1.8} \quad (\text{D.17})$$

An alternative parameterization for the drag coefficient is given by [26, 42].

The particle Reynolds number is given by:

$$\langle Re_p \rangle^{X_p \rho_p} = \frac{\langle \rho_g \rangle^{X_p} \langle |\mathbf{v}_r| \rangle^{X_p \rho_p} d_p}{\mu_g} \quad (\text{D.18})$$

The average particle relaxation time is given by:

$$\langle \tau_{gp} \rangle^{X_p \rho_p} = \frac{4}{3} \frac{\langle \rho_p \rangle^{X_p} d_p}{\langle \rho_g \rangle^{X_g} \langle C_D \rangle^{X_p \rho_p} \langle |\mathbf{v}_r| \rangle^{X_p \rho_p}} \quad (\text{D.19})$$

The resulting decomposition of the interfacial momentum transfer term is equivalent to the conventional closure outlined in Sect. 3.4.3, and adopted by several investigations on gas solids flow [35, 47, 48, 74]. Nevertheless, as for the conventional formulation, several simplifying assumptions are invoked in this model closure as well. Most important, the viscous terms in the undisturbed flow were neglected, the average undisturbed pressure is approximated by the mean pressure of the bulk phase, and the terms involving correlations of the pressure fluctuations are negligible in gas-solid flows. Moreover, additional closures are needed for the stress tensors, the fluctuating terms and the mean relative velocity.

According to Bel F'dhila and Simonin [6], the average of the relative velocity between each particle and the surrounding fluid  $\mathbf{v}_r$  can be expressed as a function of the mean relative velocity and a drift velocity due to the correlation between the instantaneous distribution of the particles and the large scale turbulent fluid motion with respect to the particle diameter:

$$\langle X_p \rho_p \mathbf{v}_r \rangle = \langle X_p \rho_p \mathbf{v}_p \rangle - \langle X_p \rho_p \mathbf{v}_g \rangle \quad (\text{D.20})$$

Introducing weighted velocity variables in the first and second term in this equation, while decomposing the instantaneous velocity in the third term into its weighted and fluctuating components, we obtain:

$$\langle X_p \rho_p \rangle \langle \mathbf{v}_r \rangle^{X_p \rho_p} = \langle X_p \rho_p \rangle \langle \mathbf{v}_p \rangle^{X_p \rho_p} - \langle X_p \rho_p \rangle \langle \mathbf{v}_g \rangle^{X_p \rho_p} - \langle X_p \rho_p \mathbf{v}_g'' \rangle \quad (\text{D.21})$$

Dividing all terms by the factor  $\langle X_p \rho_p \rangle$ , we get:

$$\langle \mathbf{v}_r \rangle^{X_p \rho_p} = \langle \mathbf{v}_p \rangle^{X_p \rho_p} - \langle \mathbf{v}_g \rangle^{X_p \rho_p} - \langle X_p \rho_p \mathbf{v}_g'' \rangle / \langle X_p \rho_p \rangle \quad (\text{D.22})$$

The last term on the right hand side of (D.22) is defined as the drift velocity:

$$\mathbf{v}_{\text{drift}} = \langle \mathbf{v}_g'' \rangle^{X_p \rho_p} = \langle X_p \rho_p \mathbf{v}_g'' \rangle / \langle X_p \rho_p \rangle \quad (\text{D.23})$$

where  $\mathbf{v}_g''$  is the gas fluctuating velocity.

The term  $\langle |\mathbf{v}_r| \rangle^{X_p \rho_p}$  is the average relative velocity length that is approximated by [47, 48]:

$$\langle |\mathbf{v}_r| \rangle^{X_p \rho_p} \approx \sqrt{\langle \mathbf{v}_r \rangle^{X_p \rho_p} \cdot \langle \mathbf{v}_r \rangle^{X_p \rho_p} + \langle \mathbf{v}_r'' \cdot \mathbf{v}_r'' \rangle^{X_p \rho_p}} \quad (\text{D.24})$$

where  $\mathbf{v}_r''$  is the fluctuating relative velocity.

The term  $\langle \mathbf{v}_r'' \cdot \mathbf{v}_r'' \rangle^{X_p \rho_p}$  is determined by:

$$\langle \mathbf{v}_r'' \cdot \mathbf{v}_r'' \rangle^{X_p \rho_p} = 2(k_p + k_g - k_{gp}) \quad (\text{D.25})$$

where  $k_g$  represents the turbulent kinetic energy of the gas phase ( $\text{m}^2/\text{s}^2$ ),  $k_{gp}$  the gas-particle fluctuation covariance ( $\text{m}^2/\text{s}^2$ ),  $k_p = 3\theta_p/2$  the turbulent kinetic energy

analogue of the particulate phase ( $\text{m}^2/\text{s}^2$ ), and  $\theta_p$  the granular temperature of the particle phase ( $\text{m}^2/\text{s}^2$ ).

### The Constant Particle Viscosity (CPV) model

The first attempts at describing the gas-particle flows in fluidized beds were performed using rather simple models neglecting both the Reynolds stresses,  $\mathbf{T}_k^{Re, X_k}$  in (D.3), and the kinetic pressure-gradient term,  $\alpha_p \langle p_{p, kin} \rangle^{X_p}$ , in (D.8). No turbulence models are thus used for any of the phases.

The momentum equation for the gas phase is thus given by:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \alpha_g \langle \rho_g \rangle^{X_g} \langle \mathbf{v}_g \rangle^{X_g \rho_g} \right) + \nabla \cdot \left( \alpha_g \langle \rho_g \rangle^{X_g} \langle \mathbf{v}_g \rangle^{X_g \rho_g} \langle \mathbf{v}_g \rangle^{X_g \rho_g} \right) \\ = -\alpha_g \nabla \langle p_g \rangle^{X_g} - \nabla \cdot \left( \alpha_g \langle \boldsymbol{\sigma}_g \rangle^{X_g} \right) + \alpha_g \langle \rho_g \rangle^{X_g} \mathbf{g} + \langle \mathbf{F}_g \rangle \end{aligned} \quad (\text{D.26})$$

The viscous stress tensor of the gas phase is modeled using a reduced form of the Newtonian strain-stress relation (D.5):

$$\langle \boldsymbol{\sigma}_g \rangle^{X_g} = -2\mu_g \left( \langle \mathbf{S}_g \rangle^{X_g \rho_g} - \frac{1}{3} \nabla \cdot \langle \mathbf{v}_g \rangle^{X_g \rho_g} \mathbf{e} \right) \quad (\text{D.27})$$

The bulk viscosity is set to zero for the continuous gas phase, in line with what is common practice for single phase flows.

The momentum equation for the particulate phase is written as:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} \right) + \nabla \cdot \left( \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} \right) \\ = -\nabla \cdot \left( \alpha_g \langle \mathbf{T}_p \rangle^{X_p} \right) + \alpha_p \langle \rho_p \rangle^{X_p} \mathbf{g} + \langle \mathbf{M}_{pI} \rangle \\ = -\nabla \left( \alpha_p \langle p_p \rangle^{X_p} \right) - \nabla \cdot \left( \alpha_p \langle \boldsymbol{\sigma}_p \rangle^{X_p} \right) + \alpha_p \langle \rho_p \rangle^{X_p} \mathbf{g} + \langle \mathbf{M}_{pI} \rangle \\ = -\nabla \left( \alpha_p \langle p_{p, coll} \rangle^{X_p} \right) - \alpha_p \nabla \langle p_g \rangle^{X_p} - \nabla \cdot \left( \alpha_p \langle \boldsymbol{\sigma}_p \rangle^{X_p} \right) + \alpha_p \langle \rho_p \rangle^{X_p} \mathbf{g} + \langle \mathbf{F}_p \rangle \end{aligned} \quad (\text{D.28})$$

where  $\langle \mathbf{F}_p \rangle$  is given by (D.16) to (D.25). Since no turbulence closure is employed in the CPV model, (D.24) is approximated as:

$$\langle |\mathbf{v}_r| \rangle^{X_p \rho_p} \approx \sqrt{\langle \mathbf{v}_r \rangle^{X_p \rho_p} \cdot \langle \mathbf{v}_r \rangle^{X_p \rho_p}}, \quad (\text{D.29})$$

and the average relative velocity vector (D.22) is approximated by:

$$\langle \mathbf{v}_r \rangle^{X_p \rho_p} = \langle \mathbf{v}_p \rangle^{X_p \rho_p} - \langle \mathbf{v}_g \rangle^{X_p \rho_p} \quad (\text{D.30})$$

The particle collisional pressure-gradient term in (D.8) is approximated by [42]:

$$\nabla(\alpha_p \langle p_{p,coll} \rangle^{X_p}) \approx -G(\alpha_g) \nabla \alpha_g \quad (\text{D.31})$$

This term is often referred to as a particle–particle interaction force and has the effect of keeping the particles apart above a maximum possible particle packing. The particle–particle interaction coefficient  $G(\alpha_g)$  is named the modulus of elasticity. A survey of different particle–particle interaction force models are given by Massoudiet et al. [65].

Enwald and Almstedt [36] adopted a relation for the particle–particle interaction force proposed by Bouillard et al. [11]:

$$\nabla(\alpha_p \langle p_{p,coll} \rangle^{X_p}) \approx -G_0 \exp(-c(\alpha_g - \alpha^*)) \nabla \alpha_g \quad (\text{D.32})$$

where  $G_0$ ,  $c$  and  $\alpha^*$  are empirical constants. Enwald and Almstedt [36] set  $\alpha^* = 0.46$  to limit the voidage from decreasing below this value. The other two constants were chosen as  $G_0 = 1.0$  (kg/m s<sup>2</sup>) and  $c = 500$ .

In the CPV model the viscous stress tensor for the particulate phase is modeled using a simplified version of the Newtonian strain-stress relation (D.5), similar to that employed for the gas phase:

$$\langle \sigma_p \rangle^{X_p} = -2\mu_p \left( \langle \mathbf{S}_p \rangle^{X_p \rho_p} - \frac{1}{3} \nabla \cdot \langle \mathbf{v}_p \rangle^{X_p \rho_p} \mathbf{e} \right) \quad (\text{D.33})$$

In this particular model version, the bulk viscosity is set to zero for the particulate phase. The particle viscosity variable,  $\mu_p$ , is set to a constant value. Enwald and Almstedt [36] used a particle viscosity value of  $\mu_p \approx 1.0$  (kg/m s), being representative for the experimental data presented by Clift and Grace [19] (p. 77).

## The Particle Turbulence (PT) models

Over the years the CPV model has been shown not to be appropriate to represent important details of certain gas-particle flows. For this reason more rigorous closures have been developed for the total stress tensor of the particulate phase, intending to obtain better representations of the physical phenomena involved.

The PT model represents an extension of the basic CPV model and contains extended closures for the particle collisional pressure and the particle–particle velocity correlation terms, as well as simple attempts to account for some of the gas-particle interaction phenomena. For the gas phase, on the other hand, the same set of transport equations as for the CPV model are employed. The particulate phase continuity equation is also the same, but the momentum equation for the particulate phase is modified.

To model the particle velocity fluctuation covariances caused by particle–particle collisions and particle interactions with the interstitial gas phase, the concept of

kinetic theory of granular flows is adapted (see Chap. 4). This theory is based on an analogy between the particles and the molecules of dense gases. The particulate phase is thus represented as a population of identical, smooth and inelastic spheres. In order to predict the form of the transport equations for a granular material the classical framework from the kinetic theory of dense gases is used [17]. However, as explained by Peirano and Leckner [75], to derive the closure laws for the fluxes that occur in these equations the method of Grad [44] was preferred to that of Chapman-Enskog [17]. It is thus emphasized that the work of Simonin et al. is based on the results of Jenkins and Richman [52] that derived the necessary closure laws using the Grad's 13 moment system for a dense gas of inelastic spheres. It follows that the transport equations discussed in this section are derived from the classical results of the kinetic theory for dense gases [17], in combination with Grad's theory [44]. Bear in mind that in Chap. 4 the Chapman-Enskog method was used, so the closure laws obtained by Simonin et al. are similar but not completely identical to those given earlier.

Moreover, He and Simonin [47, 48] considered the early models developed by Jenkins and Richman [52] appropriate for granular flows in vacuum, but inaccurate in the dilute zones of the bed where the interstitial gas phase fluctuations may affect the particles. He and Simonin [47, 48] thus extended the kinetic theory of granular materials in vacuum to take into account the influence of the interstitial gas.

In the PT model the extended momentum balance for the particle phase yields:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} \right) + \nabla \cdot \left( \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} \right) \\ &= -\alpha_p \nabla \left( \langle p_g \rangle^{X_p} \right) - \nabla \left( \alpha_p [\langle p_{p,kin} \rangle^{X_p} + \langle p_{p,coll} \rangle^{X_p}] \right) \\ & \quad - \nabla \cdot \left( \alpha_p \langle \boldsymbol{\sigma}_p \rangle^{X_p} + \alpha_p \mathbf{T}_p^{Re, X_p} \right) + \alpha_p \langle \rho_p \rangle^{X_p} \mathbf{g} + \langle \mathbf{F}_p \rangle \end{aligned} \quad (\text{D.34})$$

where  $\langle \mathbf{F}_p \rangle$  is given by (D.16) to (D.25). However, in accordance with the turbulence closure employed in the PT model, the relative velocity covariance term (D.25) therein is approximated by:

$$\langle \mathbf{v}_r'' \cdot \mathbf{v}_r'' \rangle^{X_p \rho_p} = 2k_p \quad (\text{D.35})$$

Moreover, the average relative velocity vector (D.22) is approximated by (D.30), as for the CPV model, because the drift velocity is neglected.

The effective stress tensor of the particulate phase can be expressed by an analogy to Newton's law of viscosity for viscous fluids (D.5), adopting the well known gradient and Boussinesq hypotheses modeling the Reynolds stresses (D.3):

$$\begin{aligned} -\alpha_p \langle \boldsymbol{\sigma}_p \rangle^{X_p} - \alpha_p \mathbf{T}_p^{Re, X_p} &= \alpha_p \mu_{B,p} \nabla \cdot \langle \mathbf{v}_p \rangle^{X_p \rho_p} \mathbf{e} \\ & \quad + 2\alpha_p \mu_{p,eff} \left( \langle \mathbf{S}_p \rangle^{X_p \rho_p} - \frac{1}{3} \nabla \cdot \langle \mathbf{v}_p \rangle^{X_p \rho_p} \mathbf{e} \right) \end{aligned} \quad (\text{D.36})$$

In the PT model the particle pressure terms in (D.8) are modeled by:

$$-\nabla \left( \alpha_p [\langle p_{p,kin} \rangle^{X_p} + \langle p_{p,coll} \rangle^{X_p}] \right) = -\nabla \left( \alpha_p \langle \rho_p \rangle^{X_p} (1 + 2\alpha_p g_0 (1 + e)) \theta_p \right) \quad (D.37)$$

The transport equation for the granular temperature  $\theta_p$ , written in terms of the turbulent kinetic energy analogue of the particulate phase  $k_p$ , is given by [47, 48, 75]:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \alpha_p \langle \rho_p \rangle^{X_p} k_p \right) + \nabla \cdot \left( \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} k_p \right) \\ &= \nabla \cdot \left( \alpha_p \langle \rho_p \rangle^{X_p} (K_p^{coll} + K_p^t) \nabla k_p \right) - \left( \alpha_p \langle \sigma_p \rangle^{X_p} + \alpha_p \langle \mathbf{T}_p^{Re} \rangle^{X_p} \right) : \nabla \langle \mathbf{v}_p \rangle^{X_p \rho_p} \\ & - \frac{\alpha_p \langle \rho_p \rangle^{X_p}}{\langle \tau_{gp} \rangle^{X_p \rho_p}} (2k_p - k_{gp}) + \alpha_p \langle \rho_p \rangle^{X_p} \frac{e^2 - 1}{3\tau_p^c} k_p \end{aligned} \quad (D.38)$$

where  $k_p = \frac{3}{2}\theta_p$  represents the turbulent kinetic energy analogue of the particulate phase ( $\text{m}^2/\text{s}^2$ ),  $K_p^{coll}$  the collisional diffusion coefficient ( $\text{m}^2/\text{s}$ ),  $K_p^t$  the turbulent diffusion coefficient ( $\text{m}^2/\text{s}$ ),  $e$  the restitution coefficient, and  $\tau_p^c$  the particle–particle collision time (s). Furthermore, it is emphasized that the gas–particle covariance  $k_{gp}$  is set to zero in the PT-model.

The bulk viscosity  $\mu_{B,p}$  and the effective dynamic viscosity of the particulate phase  $\mu_{p,eff}$  are given by:

$$\mu_{B,p} = \frac{4}{3} d_p \alpha_p \langle \rho_p \rangle^{X_p} g_0 (1 + e) \sqrt{\frac{\theta_p}{\pi}} \quad (D.39)$$

$$\mu_{p,eff} = \langle \rho_p \rangle^{X_p} (\nu_p^{coll} + \nu_p^t) \quad (D.40)$$

in which  $\nu_p^{coll}$  and  $\nu_p^t$  are the collisional and turbulent viscosities of the particulate phase.

The collisional and turbulent viscosity values were calculated from [47, 48, 75]:

$$\nu_p^{coll} = \frac{4}{5} g_0 (1 + e) (\nu_p^t + d_p \sqrt{\frac{\theta_p}{\pi}}) \quad (D.41)$$

$$\nu_p^t = \left( \frac{2}{3} \frac{\tau_{gp}^t}{\langle \tau_{gp} \rangle} k_{gp} + \theta_p (1 + \alpha_p g_0 A) \right) / \left( \frac{2}{\langle \tau_{gp} \rangle^{X_p \rho_p}} + \frac{B}{\tau_p^c} \right) \quad (D.42)$$

where  $A = 2(1 + e)(3e - 1)/5$  and  $B = (1 + e)(3 - e)/5$ . The average particle relaxation time  $\langle \tau_{gp} \rangle^{X_p \rho_p}$  is obtained from (D.19). Moreover, it is emphasized that

the gas-particle covariance  $k_{gp}$  and the interaction time between the particle motion and the gas phase velocity fluctuations  $\tau_{gp}^t$  are set to zero in the PT-model.

In the formulation of the transport equations, several characteristic time scales are defined. In this framework these time scales are considered fundamental in the classification and the understanding of the dominant mechanisms in the suspension flow. The particle relaxation time  $\tau_{gp}$  was already defined in (D.15). The particle-particle collision time  $\tau_p^c$ , is defined by:

$$\tau_p^c = \frac{d_p}{24\alpha_p g_0} \sqrt{\frac{\pi}{\theta_p}} \quad (\text{D.43})$$

The radial distribution function  $g_0$  accounts for the probability of particle contact. A possible parameterization is given by [60]:

$$g_0 = (1 - \alpha_p/\alpha_{p,max})^{-2.5\alpha_{p,max}} \quad (\text{D.44})$$

where  $\alpha_{p,max}$  is the maximum packing of the particulate phase ( $\approx 0.64$ ). Alternative parameterizations for  $g_0$  can be found in [14, 26, 42, 61, 72, 75].

The collisional and turbulent diffusion coefficients are modeled by [75, 83]:

$$K_p^t = \frac{\theta_p(1 + \alpha_p g_0 C)}{\left( \frac{9}{5\langle\tau_{gp}\rangle^{\chi_{pp}}} + \frac{D}{\tau_p^c} \right)} \quad (\text{D.45})$$

$$K_p^{coll} = \alpha_p g_0 (1 + e) \left( \frac{6}{5} K_p^t + \frac{4}{3} d_p \sqrt{\frac{\theta_p}{\pi}} \right) \quad (\text{D.46})$$

where  $C = 3(1 + e)^2(2e - 1)/5$  and  $D = (1 + e)(49 - 33e)/100$ .

### The Particle and Gas Turbulence (PGT) model

The PGT model represents an extension of the PT models in that the gas turbulence is taken into account by including the Reynolds stress tensor in the momentum equation for the gas phase. The turbulence model used for the gas phase is similar to the standard single phase  $k$ - $\epsilon$  turbulence model presented in Sect. 1.3.5, although additional generation and dissipation terms may be added to consider the presence of particles. In the PGT model the drift velocity is neglected.

In the PGT momentum equations the average drag force  $\langle \mathbf{F}_p \rangle$  is given by (D.16) to (D.25). Moreover, the average relative velocity vector (D.22) is approximated by (D.30), as for the CPV and PT models, because the drift velocity is neglected in the PGT model too.

In the momentum equation for the gas phase the Reynolds stress tensor is approximated by the gradient and Boussinesq hypotheses and given by:

$$\begin{aligned} \mathbf{T}_g^{Re, X_g} &= \langle \rho_g \rangle^{X_g} \langle \mathbf{v}_g'' \mathbf{v}_g'' \rangle^{X_g \rho_g} \\ &= \frac{2}{3} \langle \rho_g \rangle^{X_g} k_g \mathbf{e} - 2\mu_g^t \left( \langle \mathbf{S}_g \rangle - \frac{1}{3} \nabla \cdot \langle \mathbf{v}_g \rangle^{X_g \rho_g} \mathbf{e} \right) \end{aligned} \quad (\text{D.47})$$

where  $\mu_g^t$  is the dynamic turbulent viscosity of the gas phase. The viscous stress tensor used is given by (D.27).

Simonin and Viollet [86] calculated the dynamic viscosity for the gas phase from a modified  $k - \varepsilon$  model. The time scale of the large eddies of the gas phase flow was given by:

$$\tau_g^t = 3C_\mu k_g / (2\varepsilon_g) \quad (\text{D.48})$$

The dynamic turbulent viscosity of the gas phase flow was given by  $\mu_g^t = 2\langle \rho_g \rangle^{X_g} k_g \tau_g^t / 3$ , in accordance with the standard single phase turbulence theory presented in Sect. 1.3.5.

The transport equation that was used for the turbulent kinetic energy of the gas phase is written as [3, 83, 86]:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \alpha_g \langle \rho_g \rangle^{X_g} k_g \right) + \nabla \cdot \left( \alpha_g \langle \rho_g \rangle^{X_g} \langle \mathbf{v}_g \rangle^{X_g \rho_g} k_g \right) &= \nabla \cdot \left( \alpha_g \frac{\mu_g^t}{\sigma_k} \nabla k_g \right) \\ &\quad - \alpha_g \mathbf{T}_g^{Re, X_g} : \nabla \langle \mathbf{v}_g \rangle^{X_g \rho_g} - \alpha_g \langle \rho_g \rangle^{X_g} \varepsilon_g + \Pi_{kg} \end{aligned} \quad (\text{D.49})$$

where  $\Pi_{kg}$  represents the gas-particle interaction phenomena ( $\text{kg/m s}^3$ ). This interaction term is modeled by:

$$\Pi_{kg} = \frac{\alpha_p \langle \rho_p \rangle^{X_p}}{\langle \tau_{gp}^x \rangle^{X_p \rho_p}} \left( -2k_g + k_{gp} + \mathbf{v}_{\text{drift}} \cdot \langle \mathbf{v}_r \rangle^{X_p \rho_p} \right) \quad (\text{D.50})$$

However, in the PGT model the drift velocity  $\mathbf{v}_{\text{drift}}$  is neglected and set to zero. The average particle relaxation time  $\langle \tau_{gp}^x \rangle^{X_p \rho_p}$  is obtained from (D.19).

The transport equation for the dissipation rate of the gas-phase turbulent kinetic energy is given by [3, 83, 86]:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \alpha_g \langle \rho_g \rangle^{X_g} \varepsilon_g \right) + \nabla \cdot \left( \alpha_g \langle \rho_g \rangle^{X_g} \langle \mathbf{v}_g \rangle^{X_g} \varepsilon_g \right) &= \nabla \cdot \left( \alpha_g \frac{\mu_g^t}{\sigma_\varepsilon} \nabla \varepsilon_g \right) \\ &\quad - \alpha_g \frac{\varepsilon_g}{k_g} \left( C_{\varepsilon 1} \alpha_g \mathbf{T}_g^{Re, X_g} : \nabla \langle \mathbf{v}_g \rangle^{X_g \rho_g} + C_{\varepsilon 2} \langle \rho_g \rangle^{X_g} \varepsilon_g \right) + \Pi_{\varepsilon g} \end{aligned} \quad (\text{D.51})$$

where  $\Pi_{\varepsilon g}$  denotes the interaction term in the  $\varepsilon_g$  equation ( $\text{kg/m s}^4$ ). This interaction term is modeled by:

$$\Pi_{\varepsilon g} = C_{\varepsilon 3} \frac{\varepsilon_g}{k_g} \Pi_{kg} \quad (\text{D.52})$$

The parameter values chosen in the gas phase turbulence model are the same as those used for the standard single phase  $k$ - $\epsilon$  model (see Sect. 1.3.5). The additional interaction term parameter is set at a fixed value,  $C_{\epsilon 3} = 1.3$ , as suggested by Elghobashi and Abou-Arab [34].

For the particulate phase, the PT-model equations that were described in Appendix D are used with minor extensions. That is, in the PGT-model the transport equation for  $k_p$  (D.38) contains the gas-particle fluctuation covariance,  $k_{gp}$ , to take into account the effect of the gas phase turbulence.

The effective particle phase viscosity is still obtained from (D.40). In addition, the turbulent viscosity of the particulate phase is calculated from (D.42) in which  $k_{gp}$  is obtained from a separate balance equation. The interaction time between the particle motion and the gas velocity fluctuations  $\tau_{gp}^t$ , is modeled as suggested by Csanady [21]:

$$\tau_{gp}^t = \frac{\tau_g^t}{\sqrt{1 + 1.45 \left( 3 \langle \mathbf{v}_r \rangle^{X_p \rho_p} \cdot \langle \mathbf{v}_r \rangle^{X_p \rho_p} / 2k_g \right)}} \quad (\text{D.53})$$

The transport equation for the gas-particle fluctuation covariance is given by [83]:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \alpha_p \langle \rho_p \rangle^{X_p} k_{gp} \right) + \nabla \cdot \left( \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_p \rangle^{X_p \rho_p} k_{gp} \right) \\ = \nabla \cdot \left( \alpha_p \langle \rho_p \rangle^{X_p} \frac{\nu_{gp}^t}{\sigma_k} \nabla k_{gp} \right) - \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_g'' \mathbf{v}_p'' \rangle : \nabla \langle \mathbf{v}_p \rangle^{X_p \rho_p} \\ - \alpha_p \langle \rho_p \rangle^{X_p} \langle \mathbf{v}_g' \mathbf{v}_p' \rangle : \nabla \langle \mathbf{v}_g \rangle^{X_g \rho_g} - \alpha_p \langle \rho_p \rangle^{X_p} \epsilon_{gp} + \Pi_{gp} \end{aligned} \quad (\text{D.54})$$

where  $\nu_{gp}^t$  denotes the gas-particle turbulent viscosity ( $\text{m}^2/\text{s}$ ),  $\epsilon_{gp}$  the dissipation rate of the gas-particle fluctuation covariance ( $\text{m}^2/\text{s}^3$ ), and  $\Pi_{gp}$  the interaction term in the  $k_{gp}$  model ( $\text{kg}/\text{m s}^3$ ).

The dissipation rate of the gas-particle fluctuation covariance  $\epsilon_{gp}$  and the gas-particle turbulent viscosity  $\nu_{gp}^t$  are defined by:

$$\epsilon_{gp} = k_{gp} / \tau_{gp}^t \quad (\text{D.55})$$

$$\nu_{gp}^t = k_{gp} \tau_{gp}^t / 3 \quad (\text{D.56})$$

The gas-particle fluctuation correlation tensor  $\langle \mathbf{v}_g'' \mathbf{v}_p'' \rangle$  is expressed by:

$$\langle \mathbf{v}_g'' \mathbf{v}_p'' \rangle = \frac{1}{3} k_{gp} \mathbf{e} - \nu_{gp}^t \left( \langle \mathbf{S}_{gp} \rangle - \frac{1}{3} \text{tr}(\langle \mathbf{S}_{gp} \rangle) \mathbf{e} \right) \quad (\text{D.57})$$

The average gas-particle strain rate tensor is given by:

$$\langle \mathbf{S}_{gp} \rangle = \frac{1}{2} \left( \nabla \langle \mathbf{v}_g \rangle^{X_g \rho_g} + (\nabla \langle \mathbf{v}_p \rangle^{X_p \rho_p})^T \right) \quad (\text{D.58})$$

The interaction term in (D.54) is modeled by:

$$\Pi_{gp} = -\frac{\alpha_p \langle \rho_p \rangle^{X_p}}{\langle \tau_{gp}^x \rangle^{X_p \rho_p}} \left( \left( 1 + \frac{\alpha_p \langle \rho_p \rangle^{X_p}}{\alpha_g \langle \rho_g \rangle^{X_g}} \right) k_{gp} - 2k_g - 2 \frac{\alpha_p \langle \rho_p \rangle^{X_p}}{\alpha_g \langle \rho_g \rangle^{X_g}} k_p \right). \quad (\text{D.59})$$

### The Particle and Gas Turbulence Model with Drift Velocity (PGTVD) model

The PGTVD model consists of the same equations as the PGT model described in Appendix D, the only difference being that the drift velocity is considered in the PGTVD model. The drift velocity  $\mathbf{v}_{\text{drift}}$  is included in (D.22) and (D.50).

The drift velocity takes into account the dispersion effect due to the particle transport by the fluid turbulence. From the limiting case of particles with diameter tending towards zero, for which the drift velocity reduces to single turbulence correlation between the volumetric fraction of the dispersed phase and the turbulent velocity fluctuations of the continuous phase. The drift velocity:  $\mathbf{v}_{\text{drift}}$  is modeled as [25]:

$$\mathbf{v}_{\text{drift}} = D_{gp}^t \left( \frac{1}{\alpha_g} \nabla \alpha_g - \frac{1}{\alpha_p} \nabla \alpha_p \right) \quad (\text{D.60})$$

Based on semi-empirical analysis, the fluid-particle turbulent dispersion tensor,  $D_{gp}^t$ , is expressed in terms of the covariance between the turbulent velocity fluctuations of the two phases and a fluid particle turbulent characteristic time:

$$D_{gp}^t = \tau_{gp}^t k_{gp} / 3 \quad (\text{D.61})$$

The model assumes that the particles are suspended in a homogeneous field of gas turbulence.

It is mentioned, although not used in the model evaluation by Enwald and Almstedt [36], that a much simpler closure for the binary turbulent diffusion coefficient  $D_{gp}^t$  has been derived by Simonin [82] by an extension of Tchen's theory. This simple closure has been used by Simonin and Viollet [84], Simonin and Flour [85] and Mudde and Simonin [68] simulating several dispersed two-phase flows.

### Initial and Boundary Conditions

To simulate a rectangular fluidized bed reactor the bed vessel dimensions have to be specified first. The vessel used for validation has a rectangular cross section [36]. The bed vessel was 0.3 (m) wide, 2.22 (m) high and 0.2 (m) deep.

Proper boundary conditions are generally required for the primary variables like the gas and particle velocities, pressures and volume fractions at all the vessel boundaries as these model equations are elliptic. Moreover, boundary conditions for the granular temperature of the particulate phase is required for the PT, PGT and PGTDV models. For the models including gas phase turbulence, i.e., PGT and PGTDV, additional boundary conditions for the turbulent kinetic energy of the gas phase, as well as the dissipation rate of the gas phase and the gas-particle fluctuation covariance are required. The boundary conditions for the primary variables are normally specified adopting the standard single phase flow approaches. For some of the variables like the turbulence properties and the volume fractions one has to use empirical or semi-empirical information obtained from experiments to approximate the boundary values. The specification of the velocities at the inlet may require special attention to consider the different geometries of the gas distributors.

The initial conditions are generally specified in correspondence with the state of a fluidized bed operating at minimum fluidization conditions. The bed height at minimum fluidization conditions is then set to  $L_{mf}$ , and the gas volume fraction is set to  $\alpha_{mf}$  at the bed levels below  $L_{mf}$  and unity in the freeboard. The pressure profile in the bed is initialized using the Ergun [39] equation, whereas the pressure in the freeboard is set to the operational pressure at the outlet. The horizontal velocity components of both phases and the vertical particle velocity component are set to zero. The vertical interstitial gas velocity in the bed is normally initiated as  $U_{mf}^S / \alpha_{mf}$ , and  $U_{mf}^S$  in the freeboard.

The gas density is initiated by use of the ideal gas law requiring that the gas pressure, species composition and temperature are known. When turbulence is considered,  $k_g$ ,  $k_p$  and  $\epsilon_g$  are frequently set to small but non-zero values.  $k_{gp}$  is set to zero.

To obtain an asymmetrical flow, as observed for real cases, particular flow perturbations are generally introduced for a short time period as the flow develops in time from the start. Small jets at the bottom are often used for this purpose.

## Model Evaluations

Enwald and Almstedt [36] assessed the four different two-fluid model closures given above to investigate the effect of the gas phase turbulence, drift velocity and three dimensionality on the fluid dynamics of a bubbling fluidized bed. A few characteristics features of the different models were observed. The CPV model results generally deviated from those obtained by the more rigorous model versions. Nevertheless, the CPV model results were often in better agreement with the experimental data than the other model predictions. Comparing the PGT and PT model results it was observed that at atmospheric conditions the gas phase turbulence did not have any significant effect on the bed behavior. However, at higher pressures significant changes in the results were observed. Moreover, the drift velocity included in the most advanced model version PGTDV did not have any noticeable effect on the results at any pressure. Furthermore, strictly grid independent solutions were not obtained, and the three-dimensional effects were considered considerable.

## Appendix E

# Integral and Constitutive Equations

In this appendix, the integral theorems needed in order to solve particular integrals in the derivation of the three-fluid model with a KTGF stress closure are defined. All of these integrals can be evaluated using procedures given by Chapman and Cowling [16]. Most of the necessary integral theorems are provided in their book [16], but the third and fourth integral theorems are not given by Chapman and Cowling [16]. For this reason, a brief summary of the derivation of these two theorems is given after the list of theorems.

### E.1 Integral Equations

The first integral corresponds to Chapman and Cowling [16] Eq. (1.42, 4):

$$\int F(C) \mathbf{C} \mathbf{C} d\mathbf{C} = \frac{1}{3} \mathbf{e} \int F(C) C^2 dC \quad (\text{E.1})$$

The second integral corresponds to Chapman and Cowling [16] Eq. (16.8, 3):

$$\int \mathbf{k} \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k})^2 d\mathbf{k} = \frac{2\pi}{15} (2\mathbf{g}_{ij} \mathbf{g}_{ij} + g_{ij}^2 \mathbf{e}) \quad (\text{E.2})$$

The third integral is derived based on the procedure given by Chapman and Cowling [16] (see derivation at the end of this subsection):

$$\int (\mathbf{g}_{ij} \cdot \mathbf{k})^n \mathbf{k} d\mathbf{k} = \frac{2\pi}{n+2} g_{ij}^{n-1} \mathbf{g}_{ij} \quad (\text{E.3})$$

The fourth integral is derived based on the procedure given by Chapman and Cowling [16] (see derivation at the end of this subsection):

$$\int (\mathbf{g}_{ij} \cdot \mathbf{k})^n d\mathbf{k} = \frac{2\pi}{n+1} g_{ij}^n \quad (\text{E.4})$$

The fifth integral corresponds to Chapman and Cowling [16] Eq. (16.8,4):

$$\int \mathbf{k} \mathbf{k} (\boldsymbol{\nu} \cdot \mathbf{k}) (\mathbf{g}_{ij} \cdot \mathbf{k})^2 d\mathbf{k} = \frac{\pi}{12} \left[ \frac{\boldsymbol{\nu} \cdot \mathbf{g}_{ij}}{g_{ij}} (\mathbf{g}_{ij} \mathbf{g}_{ij} + g_{ij}^2 \boldsymbol{\Theta}) + g_{ij} (\mathbf{g}_{ij} \boldsymbol{\nu} + \boldsymbol{\nu} \mathbf{g}_{ij}) \right] \quad (\text{E.5})$$

where  $\boldsymbol{\nu}$  is any vector independent of  $\psi$  and  $\psi$ .

The sixth integral of type (a) corresponds to Chapman and Cowling [16] Eq. (1.4, 2):

$$\int_0^\infty e^{-\alpha C^2} C^r dC = \frac{\sqrt{\pi}}{2} \cdot \frac{1}{2} \cdot \frac{3}{2} \cdot \frac{5}{2} \cdots \frac{r-1}{2} \alpha^{-(r+1)/2} \quad (\text{E.6a})$$

where  $r$  is a positive even integer. The sixth integral of type (b) corresponds to Chapman and Cowling [16] Eq. (1.4, 3):

$$\int_0^\infty e^{-\alpha C^2} C^r dC = \frac{1}{2} \alpha^{-(r+1)/2} \left( \frac{r-1}{2} \right)! \quad (\text{E.6b})$$

where  $r$  is an odd integer greater than  $-1$ .

### On the Derivation of Integral Theorems for the Collision Integrals

Several integrals with respect to  $\mathbf{k}$ , i.e., the unit vector pointing from the centre of particle one to the centre of particle two at collision, must be solved evaluating the collision integrals. The integrals can be evaluated using the approach of Chapman and Cowling [16] at p.319.

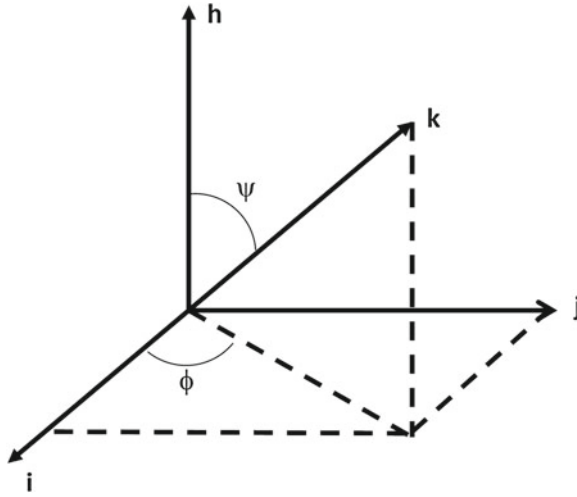

Consider the three mutually perpendicular unit vectors  $\mathbf{h}$ ,  $\mathbf{i}$  and  $\mathbf{j}$ , and let  $\mathbf{h}$  be the unit vector in the direction of  $\mathbf{g}_{12}$ . Define the polar angles  $\psi$  and  $\phi$  of  $\mathbf{k}$  with respect to  $\mathbf{h}$  as axis and the plane of  $\mathbf{i}$  and  $\mathbf{j}$  as the initial plane, illustrated in Fig. E.1. The unit vector  $\mathbf{k}$  can then be defined by:

$$\mathbf{k} = \mathbf{h} \cos \psi + \mathbf{i} \sin \psi \cos \phi + \mathbf{j} \sin \psi \sin \phi \quad (\text{E.7})$$

This unit vector definition implies that:

$$\mathbf{g}_{12} \cdot \mathbf{k} = g_{12} \cos \psi \quad (\text{E.8})$$

where the relative velocity is defined by (2.111) and the element of solid angle is expressed on the form (2.650).

**Fig. E.1** The coordinate system

### Scalar integrals

The fourth type of scalar integrals transform as:

$$\begin{aligned}
 \int (\mathbf{k} \cdot \mathbf{g}_{12})^n d\mathbf{k} &= \int_0^{2\pi} \int_0^{\pi/2} (g_{12} \cos \psi)^n \sin \psi d\psi d\phi \\
 &= 2\pi g_{21} \int_0^{\pi/2} (\cos \psi)^n \sin \psi d\psi \\
 &= \frac{2\pi}{n+1}
 \end{aligned} \tag{E.9}$$

The remaining integral can simply be solved by the integration by parts theorem. The integration limits for  $\psi$  and  $\phi$  are respectively  $[0, \pi/2]$  and  $[0, 2\pi]$  since the integration should be done only where  $(\mathbf{g}_{21} \cdot \mathbf{k})$  is positive. Thus, integrals involving odd powers in  $\sin \phi$  or  $\cos \phi$  might be neglected.

### Vector integrals

The third type of scalar integrals transform as:

$$\begin{aligned}
 \int (\mathbf{k} \cdot \mathbf{g}_{12})^n \mathbf{k} d\mathbf{k} &= \int_0^{2\pi} \int_0^{\pi/2} \mathbf{h} \cos \psi (g_{12} \cos \psi)^n \sin \psi d\psi d\phi \\
 &= 2\pi g_{21}^n \int_0^{\pi/2} \mathbf{h} (\cos \psi)^{n+1} \sin \psi d\psi = \frac{2\pi}{n+2} g_{12}^n \mathbf{h}
 \end{aligned}$$

$$= \frac{2\pi}{n+2} g_{12}^{n-1} \mathbf{g}_{12} \quad (\text{E.10})$$

The remaining integral can simply be solved by the integration by parts theorem. The integration limits for  $\psi$  and  $\phi$  are respectively  $[0, \pi/2]$  and  $[0, 2\pi]$  since the integration should be done only where  $(\mathbf{g}_{21} \cdot \mathbf{k})$  is positive. Thus, integrals involving odd powers in  $\sin \phi$  or  $\cos \phi$  might be neglected.

## E.2 Constitutive Equation Calculation and Approximations

### E.2.1 Calculation of Collisional Pressure Tensor, $\mathbf{p}_i^{\text{coll}}$

The collisional pressure tensor naturally divides into two separate integrals when expanding the pair distribution function by truncated Taylor series. From Eq. (4.349), the integral could thus be separated into two parts  $\mathbf{p}_i^{\text{coll}} = \mathbf{p}_i^{\text{coll},1} + \mathbf{p}_i^{\text{coll},2}$ . The pressure tensors  $\mathbf{p}_i^{\text{coll},1}$  and  $\mathbf{p}_i^{\text{coll},2}$  are defined by:

$$\mathbf{p}_i^{\text{coll},1} = \sum_{j=1}^N \frac{1}{2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j \mathbf{k} \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k})^2 d\mathbf{V} \quad (\text{E.11})$$

$$\mathbf{p}_i^{\text{coll},2} = \sum_{j=1}^N \frac{1}{4} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i^{(0)} f_j^{(0)} \mathbf{k} \cdot \nabla \frac{f_i^{(0)}}{f_j^{(0)}} \mathbf{k} \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k})^2 d\mathbf{v} \quad (\text{E.12})$$

Using Eqs. (4.345) and (E.2), Eq. (E.11) becomes:

$$\begin{aligned} \mathbf{p}_i^{\text{coll},1} &= \sum_{j=1}^N \frac{1}{120\pi^2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} \left( \frac{1}{\Theta_i \Theta_j} \right)^{\frac{3}{2}} (1 + e_{ij}) \\ &\times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left[-\frac{1}{2\Theta_i} C_i^2 - \frac{1}{2\Theta_j} C_j^2\right] (2\mathbf{g}_{ij} \mathbf{g}_{ij} + g_{ij}^2 \mathbf{e}) d\mathbf{c}_i d\mathbf{c}_j d\mathbf{V}_{ij} \end{aligned} \quad (\text{E.13})$$

where  $d\mathbf{V}_{ij} = \delta(m_i - \bar{m}_i) \delta(T_i - \langle T_i \rangle) \delta(\omega_{1,i} - \langle \omega_{1,i} \rangle) \delta(\omega_{2,i} - \langle \omega_{2,i} \rangle) \cdots \delta(\omega_{N_\xi,i} - \langle \omega_{N_\xi,i} \rangle) \delta(m_j - \bar{m}_j) \delta(T_j - \langle T_j \rangle) \delta(\omega_{1,j} - \langle \omega_{1,j} \rangle) \delta(\omega_{2,j} - \langle \omega_{2,j} \rangle) \cdots \delta(\omega_{N_\xi,j} - \langle \omega_{N_\xi,j} \rangle) dm_i dm_j dT_i dT_j d\omega_{1,i} d\omega_{1,j} d\omega_{2,i} d\omega_{2,j} \cdots d\omega_{N_\xi,i} d\omega_{N_\xi,j}$ , and  $\int d\mathbf{V}_{ij} = 1$  [15, 57, 59].

It is noted that  $\mathbf{g}_{ij} = \mathbf{C}_{ij} + \mathbf{v}_{ij}$ , and  $\mathbf{v}_{ij}$  lead to the binary particle momentum coupling terms. To approximate these terms, Chao [15] assumed that the binary particle momentum coupling is mainly determined by the particle–particle drag, thus  $\mathbf{v}_{ij}$  was neglected when calculating the collisional pressure tensor, i.e.  $\mathbf{g}_{ij} \approx \mathbf{C}_{ij}$ .

Equation (E.13) was thus written as:

$$\begin{aligned} p_i^{\text{coll},1} = & \sum_{j=1}^N \frac{1}{120\pi^2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} \left( \frac{1}{\Theta_i \Theta_j} \right)^{\frac{3}{2}} (1 + e_{ij}) \\ & \times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left[-\frac{1}{2\Theta_i} C_i^2 - \frac{1}{2\Theta_j} C_j^2\right] (2\mathbf{C}_{ij} \mathbf{C}_{ij} + C_{ij}^2 \mathbf{e}) d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij} \quad (\text{E.14}) \end{aligned}$$

Manipulations the terms in the last parenthesis using dyadic products:

$\mathbf{C}_{ij} \mathbf{C}_{ij} = \mathbf{C}_i \mathbf{C}_i + \mathbf{C}_j \mathbf{C}_j - \mathbf{C}_i \mathbf{C}_j - \mathbf{C}_j \mathbf{C}_i$  and scalar products:  $C_{ij}^2 = \mathbf{C}_{ij} \cdot \mathbf{C}_{ij} = C_i^2 + C_j^2 - 2\mathbf{C}_i \cdot \mathbf{C}_j$ , Eq. (E.14) becomes:

$$\begin{aligned} p_i^{\text{coll},1} = & \sum_{j=1}^N \frac{1+e_{ij}}{120\pi^2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} \left( \frac{1}{\Theta_i \Theta_j} \right)^{\frac{3}{2}} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left(-\frac{1}{2\Theta_i} C_i^2 - \frac{1}{2\Theta_j} C_j^2\right) \\ & \times (2\mathbf{C}_i \mathbf{C}_i + 2\mathbf{C}_j \mathbf{C}_j + C_i^2 \mathbf{e} + C_j^2 \mathbf{e}) d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij} \quad (\text{E.15}) \end{aligned}$$

Applying Eq. (E.1), Eq. (E.15) becomes:

$$\begin{aligned} p_i^{\text{coll},1} = & \sum_{j=1}^N \frac{1+e_{ij}}{120\pi^2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} \left( \frac{1}{\Theta_i \Theta_j} \right)^{\frac{3}{2}} \\ & \times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left(-\frac{1}{2\Theta_i} C_i^2 - \frac{1}{2\Theta_j} C_j^2\right) \left( \frac{5}{3} C_i^2 \mathbf{e} + \frac{5}{3} C_j^2 \mathbf{e} \right) d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij} \quad (\text{E.16}) \end{aligned}$$

By assuming spherical symmetry, the integral can be carried out in parts using (4.139):

$$\begin{aligned} p_i^{\text{coll},1} = & \sum_{j=1}^N \frac{1+e_{ij}}{120\pi^2} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} \left( \frac{1}{\Theta_i \Theta_j} \right)^{\frac{3}{2}} \times \frac{80\pi^2}{3} \mathbf{e} \\ & \times \left[ \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left(-\frac{1}{2\Theta_i} C_i^2\right) C_i^4 d\mathbf{C}_i \exp\left(-\frac{1}{2\Theta_j} C_j^2\right) C_j^2 d\mathbf{C}_j d\mathbf{v}_{ij} \right. \\ & \left. + \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left(-\frac{1}{2\Theta_i} C_i^2\right) C_i^2 d\mathbf{C}_i \exp\left(-\frac{1}{2\Theta_j} C_j^2\right) C_j^4 d\mathbf{C}_j d\mathbf{v}_{ij} \right] \quad (\text{E.17}) \end{aligned}$$

The two integrals in this relation can be written on the form that can be solved by (E.6a) with  $r = 2$  and  $r = 4$ , respectively.

The integrals in (E.17) can thus be computed as exemplified below:

$$\int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left(-\frac{1}{2\Theta_i} C_i^2\right) C_i^4 d\mathbf{C}_i = \frac{3(2\pi)^{1/2}}{4} \Theta_i^{5/2}, \quad \text{with } r = 4 \quad (\text{E.18})$$

$$\int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \exp\left(-\frac{1}{2\Theta_j} C_j^2\right) C_j^2 dC_j = \frac{(2\pi)^{1/2}}{2} \Theta_j^{3/2}, \quad \text{with } r = 2 \quad (\text{E.19})$$

$$\int d\mathbf{v}_{ij} = 1 \quad (\text{E.20})$$

It is seen that by using the same modeling approach as employed in Sect. 4.1.5 for the mono particle counterparts (4.127), the integral approximations yield [15]:

$$\mathbf{p}_i^{\text{coll},1} = \sum_{j=1}^N \frac{\pi}{3} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} (1 + e_{ij}) (\Theta_i + \Theta_j) \mathbf{e} \quad (\text{E.21})$$

Applying (E.5), the second part of the collisional pressure tensor,  $\mathbf{p}_i^{\text{coll},2}$ , (E.12) can be expressed as:

$$\begin{aligned} \mathbf{p}_i^{\text{coll},2} = \sum_{j=1}^N \frac{\pi}{48} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j \left[ \mathbf{g}_{ij} \cdot \nabla \ln \frac{f_j}{f_i} (\mathbf{g}_{ij} \mathbf{g}_{ij} + g_{ij}^2 \mathbf{e}) / g_{ij} \right. \\ \left. + g_{ij} (\mathbf{g}_{ij} \nabla \ln \frac{f_j}{f_i} + \nabla \ln \frac{f_j}{f_i} \mathbf{g}_{ij}) \right] d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.22})$$

in which  $\nabla \ln \frac{f_j}{f_i}$  is defined by Eq. (A.6) from [64]:

$$\begin{aligned} \nabla \ln \frac{f_j}{f_i} \approx \nabla \ln \frac{n_j}{n_i} + \frac{1}{2} \left( \frac{1}{\Theta_j^2} C_j^2 - \frac{3}{\Theta_j} \right) \nabla \Theta_j - \frac{1}{2} \left( \frac{1}{\Theta_i^2} C_i^2 - \frac{3}{\Theta_i} \right) \nabla \Theta_i \\ + \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \end{aligned} \quad (\text{E.23})$$

In the study of Chao [15], only the last terms in (E.23) related to  $\nabla \mathbf{v}_i$  and  $\nabla \mathbf{v}_j$  were taken into account, thus Eq. (E.22) becomes:

$$\begin{aligned} \mathbf{p}_i^{\text{coll},2} = \sum_{j=1}^N \frac{\pi}{48} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \\ \times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j \left[ \mathbf{g}_{ij} \cdot \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) (\mathbf{g}_{ij} \mathbf{g}_{ij} + g_{ij}^2 \mathbf{e}) / g_{ij} \right. \\ \left. + g_{ij} \left( \mathbf{g}_{ij} \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) + \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) \mathbf{g}_{ij} \right) \right] \\ \times d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.24})$$

Using the relations  $\mathbf{g}_{ij} \cdot \nabla \mathbf{v}_j \cdot \mathbf{C}_j = \mathbf{g}_{ij} \mathbf{C}_j : \nabla \mathbf{v}_j$  and  $\mathbf{g}_{ij} \cdot \nabla \mathbf{v}_i \cdot \mathbf{C}_i = \mathbf{g}_{ij} \mathbf{C}_i : \nabla \mathbf{v}_i$  from Chapman and Cowling [16], Eq. (E.24) becomes:

$$\begin{aligned}
\mathbf{p}_i^{\text{coll},2} = & \sum_{j=1}^N \frac{\pi}{48} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \\
& \times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_{ij} \left[ \left( \frac{1}{\Theta_j} \mathbf{g}_{ij} \mathbf{C}_j : \nabla \mathbf{v}_j - \frac{1}{\Theta_i} \mathbf{g}_{ij} \mathbf{C}_i : \nabla \mathbf{v}_i \right) (\mathbf{g}_{ij} \mathbf{g}_{ij} + g_{ij}^2 \mathbf{e}) / g_{ij} \right. \\
& + g_{ij} \left( \mathbf{g}_{ij} \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) + \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) \mathbf{g}_{ij} \right) \Big] \\
& \times d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij}
\end{aligned} \tag{E.25}$$

Invoking the simplifying approximation  $\mathbf{g}_{ij} \approx \mathbf{C}_{ij}$ , Eq. (E.25) becomes:

$$\begin{aligned}
\mathbf{p}_i^{\text{coll},2} = & \sum_{j=1}^N \frac{\pi}{48} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \\
& \times \int_{\mathbf{C}_{ij} \cdot \mathbf{k} > 0} f_{ij} \left[ \left( \frac{1}{\Theta_j} \mathbf{C}_{ij} \mathbf{C}_j : \nabla \mathbf{v}_j - \frac{1}{\Theta_i} \mathbf{C}_{ij} \mathbf{C}_i : \nabla \mathbf{v}_i \right) (\mathbf{C}_{ij} \mathbf{C}_{ij} + C_{ij}^2 \mathbf{e}) / C_{ij} \right. \\
& + C_{ij} \left( \mathbf{C}_{ij} \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) + \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) \mathbf{C}_{ij} \right) \Big] \\
& \times d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij}
\end{aligned} \tag{E.26}$$

Using  $\mathbf{W} \cdot \mathbf{a} = \mathbf{a} \cdot \mathbf{W}^T$ , a relation corresponding to Eq. (1.32, 2) in the book of Chapman and Cowling [16] (in which  $\mathbf{W}$  is a tensor,  $\mathbf{a}$  is a vector, and  $\mathbf{W}^T$  denotes the tensor conjugate to  $\mathbf{W}$ ), Eq. (E.26) becomes:

$$\begin{aligned}
\mathbf{p}_i^{\text{coll},2} = & \sum_{j=1}^N \frac{\pi}{48} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \\
& \times \int_{\mathbf{C}_{ij} \cdot \mathbf{k} > 0} f_{ij} \left[ \left( \frac{1}{\Theta_j} \mathbf{C}_{ij} \mathbf{C}_j : \nabla \mathbf{v}_j - \frac{1}{\Theta_i} \mathbf{C}_{ij} \mathbf{C}_i : \nabla \mathbf{v}_i \right) (\mathbf{C}_{ij} \mathbf{C}_{ij} + C_{ij}^2 \mathbf{e}) / C_{ij} \right. \\
& + C_{ij} \left( \mathbf{C}_{ij} \left( \frac{1}{\Theta_j} \mathbf{C}_j \cdot (\nabla \mathbf{v}_j)^T - \frac{1}{\Theta_i} \mathbf{C}_i \cdot (\nabla \mathbf{v}_i)^T \right) + \left( \frac{1}{\Theta_j} \nabla \mathbf{v}_j \cdot \mathbf{C}_j - \frac{1}{\Theta_i} \nabla \mathbf{v}_i \cdot \mathbf{C}_i \right) \mathbf{C}_{ij} \right) \Big] \\
& \times d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij}
\end{aligned} \tag{E.27}$$

Applying  $\mathbf{C}_{ij} = \mathbf{C}_i - \mathbf{C}_j$  and (E.1), relation (E.27) can be written as:

$$\begin{aligned}
\mathbf{p}_i^{\text{coll},2} = & - \sum_{j=1}^N \frac{\pi}{48} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \\
& \times \int_{\mathbf{C}_{ij} \cdot \mathbf{k} > 0} f_{ij} \left[ \frac{4}{9} \left( \frac{1}{\Theta_j} C_j^2 \nabla \cdot \mathbf{v}_j + \frac{1}{\Theta_i} C_i^2 \nabla \cdot \mathbf{v}_i \right) C_{ij} \mathbf{e} \right. \\
& + \frac{1}{3} C_{ij} \frac{C_j^2}{\Theta_j} (\nabla \mathbf{v}_j + (\nabla \mathbf{v}_j)^T) + \frac{1}{3} C_{ij} \frac{C_i^2}{\Theta_i} (\nabla \mathbf{v}_i + (\nabla \mathbf{v}_i)^T) \Big] d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij}
\end{aligned} \tag{E.28}$$

To proceed we need to approximate the unknown function  $C_{ij}$  in some appropriate manner. A truncated series expansion might be sufficient. Following the approach proposed by Chao [15], a zero order truncated series expansion is deduced based on the binomial theorem [80] as follows. The unknown function  $C_{ij}$  was first expressed in an alternative form:

$$C_{ij} = [(\mathbf{C}_i - \mathbf{C}_j) \cdot (\mathbf{C}_i - \mathbf{C}_j)]^{1/2} = [C_i^2 + C_j^2 - 2\mathbf{C}_i \cdot \mathbf{C}_j]^{1/2} \quad (\text{E.29})$$

Noticing that with statistical collisional symmetry (i.e.,  $\mathbf{C}_i \cdot \mathbf{C}_j = 0$ ), the last term in the bracket will approach zero. Hence, a zero order truncated series expansion was proposed on the form:

$$C_{ij} \approx [C_i^2 + C_j^2]^{1/2} \approx C_i + C_j + \alpha_1 C_i^{1/2} C_j^{1/2} \quad (\text{E.30})$$

The value of the parameter  $\alpha_1$  was approximated by the value obtained with  $\mathbf{C}_i \approx \mathbf{C}_j$ , giving  $\alpha_1 \approx -0.586$ . The advantage of using this approximate modeling approach is that it provides a relatively simple relation with a limited number of terms. A higher order series expansion would be more computational expensive.

Employing the resulting approximate relation  $C_{ij} \approx C_i + C_j - 0.586 C_i^{0.5} C_j^{0.5}$  as given by Chao [15], and the integral theorem (E.6a), the second collisional pressure tensor part (E.28) might be expressed as:

$$\begin{aligned} \mathbf{p}_i^{\text{coll},2} = & - \sum_{j=1}^N \frac{\sqrt{2\pi}}{72} d_{ij}^4 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} (1 + e_{ij}) \\ & \times \left[ (\nabla \mathbf{v}_j + \overline{\nabla \mathbf{v}_j} + \frac{4}{3} \nabla \cdot \mathbf{v}_j \mathbf{e}) (3\Theta_i^{0.5} + 4\Theta_j^{0.5} - 1.955\Theta_i^{0.25}\Theta_j^{0.25}) \right. \\ & \left. \times (\nabla \mathbf{v}_i + \overline{\nabla \mathbf{v}_i} + \frac{4}{3} \nabla \cdot \mathbf{v}_i \mathbf{e}) (3\Theta_j^{0.5} + 4\Theta_i^{0.5} - 1.955\Theta_i^{0.25}\Theta_j^{0.25}) \right] \end{aligned} \quad (\text{E.31})$$

The sum of the first part of the collisional pressure tensor (E.21) and the second part (E.31) can be casted into the standard form of the total collisional pressure tensor closure relation (4.350).

It is noticed that when  $N = 1$ , the proposed constitutive equations for the collisional pressure tensor reduce to those for a mono-particle bed. In particular, relation (E.21) reduces to:

$$\mathbf{p}_i^{\text{coll},1} = 2(1 + e_i) g_i \alpha_i^2 \rho_i \Theta_i \mathbf{e} \quad (\text{E.32})$$

The resulting relation for the first tensor part,  $\mathbf{p}_i^{\text{coll},1}$ , is identical to Eq. (9.229) in the book of Gidaspow [42].

It is further noted that Manger [64] did use a different series expansion approach (of higher order) approximating the collisional pressure tensor components for binary mixtures based on the work of Gidaspow [42]. Their modeling approach was outlined in the thesis by Manger [64], Sects. 7.4.2 and 7.2.

### E.2.2 Calculating the Collisional Particle–Particle Drag, $F_{ij}$

Neglecting the second part, the momentum source term Eq. (4.356) becomes:

$$\sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{c}_i) = - \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j}{\bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) g_{0,ij} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{ij})^2 \mathbf{k} f_i f_k d\mathbf{v} \quad (\text{E.33})$$

Using the integral Eq. (E.3), Eq. (E.33) becomes:

$$\sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{c}_i) = - \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j}{2 \bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) g_{0,ij} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} \mathbf{g}_{ij} g_{ij} d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \quad (\text{E.34})$$

Following the approach of Manger [64], and by use of  $\mathbf{g}_{ij} = \mathbf{C}_{ij} + \mathbf{v}_{ij}$ , the part related to  $\mathbf{C}_{ij}$  cancel out. The remaining part of the term (E.34) becomes:

$$\sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{c}_i) = - \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j}{2 \bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) g_{0,ij} \mathbf{v}_{ij} \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} g_{ij} d\mathbf{c}_i d\mathbf{c}_j d\mathbf{V}_{ij} \quad (\text{E.35})$$

To approximate the unknown function  $g_{ij} = C_{ij} + v_{ij}$  in some appropriate manner a truncated series expansion might be applicable. Following the approach proposed by Chao [15], a zero order truncated series expansion is deduced based on the binomial theorem [80]. The unknown function  $g_{ij}$  was first expressed in an alternative form:

$$g_{ij} = (\mathbf{g}_{ij} \cdot \mathbf{g}_{ij})^{1/2} = [(\mathbf{C}_{ij} + \mathbf{v}_{ij}) \cdot (\mathbf{C}_{ij} + \mathbf{v}_{ij})]^{1/2} = [C_{ij}^2 + v_{ij}^2 + 2\mathbf{v}_{ij} \cdot \mathbf{C}_{ij}]^{1/2} \quad (\text{E.36})$$

Noticing that with statistical collisional symmetry (i.e.,  $\mathbf{v}_{ij} \cdot \mathbf{C}_{ij} = 0$ ), the last term in the bracket will approach zero.

Hence, a zero order truncated series expansion was proposed on the form:

$$g_{ij} \approx [C_{ij}^2 + v_{ij}^2]^{1/2} \approx C_{ij} + v_{ij} + \alpha_2 C_{ij}^{1/2} v_{ij}^{1/2} \quad (\text{E.37})$$

The value of the parameter  $\alpha_2$  was approximated by the value obtained with  $\mathbf{C}_i \approx \mathbf{C}_j$ , giving  $\alpha_1 \approx -0.586$ .

Moreover, an approximation of  $C_{ij}^{1/2}$  is required (whereas  $v_{ij}^{1/2}$  is known from the solution of the governing equations). Following the same approximation method as outlined above, Chao [15] deduced the necessary relation considering that:

$$C_{ij}^{1/2} = (\mathbf{C}_{ij} \cdot \mathbf{C}_{ij})^{1/4} \quad (\text{E.38})$$

$$= [(\mathbf{C}_i - \mathbf{C}_j) \cdot (\mathbf{C}_i - \mathbf{C}_j)]^{1/4} = [C_i^2 + C_j^2 - 2\mathbf{C}_i \cdot \mathbf{C}_j]^{1/4} \quad (\text{E.39})$$

Noticing that with statistical collisional symmetry (i.e.,  $\mathbf{C}_i \cdot \mathbf{C}_j = 0$ ), the last term in the bracket will approach zero. Hence, a zero order truncated series expansion was proposed on the form:

$$C_{ij}^{1/2} \approx [C_i^2 + C_j^2]^{1/4} \approx C_i^{1/2} + C_j^{1/2} + \alpha_3 C_i^{1/4} C_j^{1/4} \quad (\text{E.40})$$

The value of the parameter  $\alpha_3$  was approximated by the value obtained with  $\mathbf{C}_i \approx \mathbf{C}_j$ , giving  $\alpha_3 \approx -0.811$ .

By employing the resulting approximate relation given by Chao [15]:

$$g_{ij} \approx v_{ij} + C_i + C_j - 0.586 C_i^{0.5} C_j^{0.5} - 0.586 v_{12}^{0.5} (C_i^{0.5} + C_j^{0.5} - 0.811 C_i^{0.25} C_j^{0.25}), \quad (\text{E.41})$$

and the integral theorem (E.6a) and (E.6b), the source term integration (E.35) result is:

$$\begin{aligned} \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}(\mathbf{c}_i) = & - \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_{c,ij}} d_{ij}^2 (1 + e_{ij}) g_{0,ij} \mathbf{v}_{ij} \\ & \times (\sqrt{2\pi\Theta_i} + \sqrt{2\pi\Theta_j} - \sqrt{2}\Theta_i^{0.25}\Theta_j^{0.25} \\ & + \frac{\pi}{2}v_{ij} - 1.135v_{ij}^{0.5}(\Theta_i^{0.25} + \Theta_j^{0.25} - 0.8\Theta_i^{0.125}\Theta_j^{0.125})). \quad (\text{E.42}) \end{aligned}$$

### E.2.3 Calculation of the Collisional Source Term of Granular Temperature Equation

Equation (4.363) can be divided into two separate integrals:

$$\begin{aligned} \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}}\left(\frac{1}{2}c_i^2\right) = & \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j d_{ij}^2}{4\bar{m}_{c,ij}} g_{0,ij}(e_{ij}^2 - 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{ij})^3 f_{if_j} d\mathbf{k} d\mathbf{c}_i d\mathbf{c}_j d\mathbf{V}_{ij} \\ & + \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j d_{ij}^3}{8\bar{m}_{c,ij}} g_{0,ij}(e_{ij}^2 - 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{ij})^3 f_{if_j} \mathbf{k} \cdot \nabla \ln \frac{f_j}{f_i} d\mathbf{k} d\mathbf{c}_i d\mathbf{c}_j d\mathbf{V}_{ij} \quad (\text{E.43}) \end{aligned}$$

For the first integral part, the inner integral over  $\mathbf{k}$  is determined by use of (E.4),

$$\int (\mathbf{k} \cdot \mathbf{g}_{ij})^3 d\mathbf{k} = \frac{\pi}{2} g_{ij}^3 \quad (\text{E.44})$$

For the second integral part, the inner integral over  $\mathbf{k}$  is determined by use of (E.3),

$$\int (\mathbf{k} \cdot \mathbf{g}_{ij})^3 \mathbf{k} d\mathbf{k} = \frac{2\pi}{5} g_{ij}^2 \mathbf{g}_{ij} \quad (\text{E.45})$$

Hence, by use of these two integral results, Eq. (4.363) becomes:

$$\begin{aligned} \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) &= \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^2}{8 \bar{m}_{c,ij}} g_{0,ij} (e_{ij}^2 - 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} g_{ij}^3 f_i f_j d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \\ &+ \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^3}{20 \bar{m}_{c,ij}} g_{0,ij} (e_{ij}^2 - 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j \nabla \ln \frac{f_j}{f_i} \cdot \mathbf{g}_{ij} g_{ij}^2 d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.46})$$

By use of Eq. (E.23), but only taking into account the terms related to  $\nabla \mathbf{v}_i$  and  $\nabla \mathbf{v}_j$ , Eq. (E.46) is reduced to:

$$\begin{aligned} \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) &= \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^2}{8 \bar{m}_{c,ij}} g_{0,ij} (e_{ij}^2 - 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} g_{ij}^3 f_i f_j d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \\ &+ \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j}{20 \bar{m}_{c,ij}} d_{ij}^3 g_{0,ij} (e_{ij}^2 - 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j g_{ij}^2 \left( \frac{1}{\Theta_j} \mathbf{C}_j \cdot \nabla \mathbf{v}_j - \frac{1}{\Theta_i} \mathbf{C}_i \cdot \nabla \mathbf{v}_i \right) \cdot \mathbf{g}_{ij} \\ &\times d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.47})$$

Moreover, by application of  $\mathbf{C}_j \cdot \nabla \mathbf{v}_j \cdot \mathbf{g}_{ij} = \mathbf{C}_j \mathbf{g}_{ij} : \nabla \mathbf{v}_j$  from Chapman and Cowling [16], the simplifying approximation  $\mathbf{g}_{ij} \approx \mathbf{C}_{ij}$ , the relative peculiar velocity definition  $\mathbf{C}_{ij} = \mathbf{C}_i - \mathbf{C}_j$  and (E.1), relation (E.47) can be expressed as:

$$\begin{aligned} \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} C_i^2 \right) &= \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^2}{8 \bar{m}_{c,ij}} g_{0,ij} (e_{ij}^2 - 1) \int_{\mathbf{C}_{ij} \cdot \mathbf{k} > 0} C_{ij}^3 f_i f_j d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij} \\ &- \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j}{60 \bar{m}_{c,ij}} d_{ij}^3 g_{0,ij} (e_{ij}^2 - 1) \int_{\mathbf{C}_{ij} \cdot \mathbf{k} > 0} f_i f_j C_{ij}^2 \\ &\times \left( \frac{C_j^2}{\Theta_j} \nabla \cdot \mathbf{v}_j - \frac{C_i^2}{\Theta_i} \nabla \cdot \mathbf{v}_i \right) d\mathbf{C}_i d\mathbf{C}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.48})$$

An appropriate approximation of the unknown function  $C_{ij}^3$  is required. Following the approach proposed by Chao [15], a zero order truncated series expansion was deduced based on the binomial theorem [80] as follows. The unknown function  $C_{ij}^3$  was first expressed in an alternative form:

$$C_{ij}^3 = (\mathbf{C}_{ij} \cdot \mathbf{C}_{ij})^{3/2} = [C_i^2 + C_j^2 - 2\mathbf{C}_i \cdot \mathbf{C}_j]^{3/2} \quad (\text{E.49})$$

Noticing that with statistical collisional symmetry, the last term in the bracket vanishes. A truncated series expansion based on the binomial theorem was thus employed:

$$C_{ij}^3 \approx [C_i^2 + C_j^2]^{3/2} \approx C_i^3 + C_j^3 + \alpha_4(C_i^2 C_j + C_i C_j^2) \quad (\text{E.50})$$

The value of the parameter  $\alpha_4$  was approximated by the value obtained with  $\mathbf{C}_i \approx \mathbf{C}_j$ , giving  $\alpha_4 \approx 0.414$ .

By applying the approximate relation  $C_{ij}^3 \approx C_i^3 + C_j^3 + 0.414(C_i C_j^2 + C_i^2 C_j)$  from Chao [15], and by employing the integral theorem (E.6a) and (E.6b), the source term (E.48) can be expressed as:

$$\begin{aligned} & \sum_{j=1}^N \Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) \\ &= \sum_{j=1}^N \frac{\pi (e_{ij}^2 - 1) d_{ij}^2 g_{0,ij} \bar{m}_i \bar{m}_j n_i n_j}{8(\bar{m}_i + \bar{m}_j)} (6.4(\Theta_i^{1.5} + \Theta_j^{1.5}) + 2.(\Theta_i \Theta_j^{0.5} + \Theta_i^{0.5} \Theta_j)) \quad (\text{E.51}) \\ &+ \sum_{j=1}^N \frac{\pi}{60} d_{ij}^3 g_{0,ij} \frac{\bar{m}_i \bar{m}_j n_i n_j}{\bar{m}_i + \bar{m}_j} (1 - e_{ij}^2) (\nabla \cdot \mathbf{v}_i (15\Theta_i + 9\Theta_j) + \nabla \cdot \mathbf{v}_j (15\Theta_j + 9\Theta_i)) \end{aligned}$$

It is noted that when  $N = 1$ , the source term closure (E.51) reduces to the following relation:

$$\Omega_{\mathbf{g}_{ij}} \left( \frac{1}{2} c_i^2 \right) = 3(e_i^2 - 1) \alpha_i^2 \rho_i g_{0,i} \Theta_i \left( \frac{3.72}{d_i} \left( \frac{\Theta_i}{\pi} \right)^{0.5} - 0.8 \nabla \cdot \mathbf{v}_i \right). \quad (\text{E.52})$$

This result is similar to Eq. (9.213) in the book of Gidaspow [42]. The latter relation was approximated as (4.179):

$$\Omega \left( \frac{1}{2} c_i^2 \right) = 3(e_i^2 - 1) \alpha_i^2 \rho_i g_{0,i} \Theta_i \left( \frac{4}{d_i} \left( \frac{\Theta_i}{\pi} \right)^{0.5} - \nabla \cdot \mathbf{v}_i \right). \quad (4.179)$$

### ***E.2.4 Calculation of the Granular Heat Conduction in the Granular Temperature Equation***

Following the approach of Manger [64], the collisional dynamics relation (4.366) is inserted into the collisional heat flux relation (4.365), and by separating the integrals four flux contributions are obtained (i.e., corresponding to Eqs. (A.55)–(A.58) in the thesis of Manger [64]). Moreover, the terms (A.55)–(A.57) are neglected, thus only

Eq. (A.58) is taken into account. The term (A.58) is written as:

$$\begin{aligned} \mathbf{q}_i^{col} = & \sum_{j=1}^N \frac{\bar{m}_i \bar{m}_j d_{ij}^4}{4\bar{m}_{c,ij}} g_{0,ij} (e_{ij} + 1) \\ & \times \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j \mathbf{k} \cdot \nabla \ln \frac{f_j}{f_i} \mathbf{k} (\mathbf{g}_{ij} \cdot \mathbf{k})^2 (\mathbf{k} \cdot \mathbf{C}_i) d\mathbf{k} d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.53})$$

Applying the integral theorem (E.5), the closure (E.53) can be expressed as:

$$\begin{aligned} \mathbf{q}_i^{col} = & \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^4}{48\bar{m}_{c,ij}} g_{0,ij} (e_{ij} + 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j g_{ij} \\ & \times \left[ 2\nabla \ln \frac{f_j}{f_i} \cdot \mathbf{C}_i \mathbf{g}_{ij} + \nabla \ln \frac{f_j}{f_i} \cdot \mathbf{g}_{ij} \mathbf{C}_i + \mathbf{C}_i \cdot \mathbf{g}_{ij} \nabla \ln \frac{f_j}{f_i} \right] d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.54})$$

Invoking the simplifying approximation  $\mathbf{g}_{ij} \approx \mathbf{C}_{ij}$  and the definition of the relative peculiar velocity  $\mathbf{C}_{ij} = \mathbf{C}_i - \mathbf{C}_j$ , and applying the theorem (E.1), relation (E.54) can be expressed as:

$$\mathbf{q}_i^{col} = \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^4}{24\bar{m}_{c,ij}} g_{0,ij} (e_{ij} + 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j g_{ij} C_i^2 \nabla \ln \frac{f_j}{f_i} d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \quad (\text{E.55})$$

Employing (E.23), considering the terms related to  $\nabla \Theta_i$  and  $\nabla \Theta_j$  only, (E.55) can be expressed as:

$$\begin{aligned} \mathbf{q}_i^{col} = & \sum_{j=1}^N \frac{\pi \bar{m}_i \bar{m}_j d_{ij}^4}{48\bar{m}_{c,ij}} g_{0,ij} (e_{ij} + 1) \int_{\mathbf{g}_{ij} \cdot \mathbf{k} > 0} f_i f_j g_{ij} C_i^2 \left[ \left( \frac{C_j^2}{\Theta_j^2} - \frac{3}{\Theta_j} \right) \nabla \Theta_j \right. \\ & \left. - \left( \frac{C_i^2}{\Theta_i^2} - \frac{3}{\Theta_i} \right) \nabla \Theta_i \right] d\mathbf{c}_i d\mathbf{c}_j d\mathbf{v}_{ij} \end{aligned} \quad (\text{E.56})$$

Application of the following approximations for the relative particle velocity  $g_{ij} \approx C_{ij}$  and the relative peculiar velocity  $C_{ij} \approx C_i + C_j - 0.586 C_i^{0.5} C_j^{0.5}$  obtained from Chao [15], and by use of the integral theorem (E.6a), the final form of (E.56) can be written as:

$$\mathbf{q}_i^{col} = - \sum_{j=1}^N \frac{2\pi \bar{m}_i \bar{m}_j n_i n_j}{5(\bar{m}_i + \bar{m}_j)} (1 + e_{ij}) g_{0,ij} d_{ij}^4 \sqrt{\Theta_i} \nabla \Theta_i \quad (\text{E.57})$$

It is further noted that when  $N = 1$ , the closure relation (E.57) reduces to:

$$\mathbf{q}_i^{col} = -2.13\alpha_i^2\rho_i(1 + e_i)g_id_i\sqrt{\frac{\Theta_i}{\pi}}\nabla\Theta_i \quad (\text{E.58})$$

which is very similar to the mono-particle relation (9.217) in the book of Gidaspow [42]:

$$\mathbf{q}_i^{col} = -2\alpha_i^2\rho_i(1 + e_i)g_id_i\sqrt{\frac{\Theta_i}{\pi}}\nabla\Theta_i. \quad (4.174)$$

## Appendix F

# Trondheim Bubble Column Model

The 2D steady-state two-fluid model presented in this section is based on the early work by Torvik and Svendsen [97], Svendsen et al. [95], and Jakobsen [51]. The two-fluid model was derived based on the time-after volume averaging procedure, described in Sect. 3.4.4.

The model was later implemented in a commercial code PHOENICS. The input files specifying the calculations have been deposited in the PHOENICS library of two-phase flow examples [9]. This early bubble column model is included in this book because it is considered particularly useful for educational purposes.

The model derivation is outlined in Cartesian coordinates. The governing equations are then more conveniently written in vector notation (vector symbolism). For practical applications and simulations these vector equations are converted into cylindrical coordinates and finally reduced to the 2D axi-symmetric bubble column problem. The axi-symmetric model is discretized by use of the IPSA-SIMPLEC solution algorithm in Sect. F.4.1.

### F.1 Model Formulation

The elementary Two-fluid model derivation is outlined in this section.

#### Conservation of mass

The instantaneous volume averaged conservation of mass of the continuous liquid and dispersed gas phases were expressed as:

$$\frac{\partial}{\partial t}(\alpha_l \rho_l) + \nabla \cdot (\alpha_l \rho_l \mathbf{v}_l) = \Gamma_l \quad (\text{F.1})$$

$$\frac{\partial}{\partial t}(\alpha_g \rho_g) + \nabla \cdot (\alpha_g \rho_g \mathbf{v}_g) = \Gamma_g \quad (\text{F.2})$$

The void fractions must fulfill the compatibility condition:

$$\alpha_l + \alpha_g = 1 \quad (\text{F.3})$$

The mass exchange terms must satisfy the constraint:

$$\Gamma_l + \Gamma_g = 0. \quad (\text{F.4})$$

### Conservation of momentum

The instantaneous volume averaged Navier-Stokes equations for the two phases are:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_l \rho_l v_{l,i}) + \frac{\partial}{\partial x_j}(\alpha_l \rho_l v_{l,j} v_{l,i}) = & -\alpha_l \frac{\partial p_l}{\partial x_i} + \frac{\partial}{\partial x_j} \left( \alpha_l \mu_l \left( \frac{\partial v_{l,i}}{\partial x_j} + \frac{\partial v_{l,j}}{\partial x_i} \right) \right) \\ & - \frac{\partial}{\partial x_j} \left( \delta_{ij} \alpha_l \left( \frac{2}{3} \mu_l - \mu_{bl} \right) \frac{\partial v_{l,k}}{\partial x_k} \right) \\ & + \rho_l \alpha_l g_i + F_{l,i}^C \end{aligned} \quad (\text{F.5})$$

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_g \rho_g v_{g,i}) + \frac{\partial}{\partial x_j}(\alpha_g \rho_g v_{g,j} v_{g,i}) = & -\alpha_g \frac{\partial p_g}{\partial x_i} + \frac{\partial}{\partial x_j} \left( \alpha_g \mu_g \left( \frac{\partial v_{g,i}}{\partial x_j} + \frac{\partial v_{g,j}}{\partial x_i} \right) \right) \\ & - \frac{\partial}{\partial x_j} \left( \delta_{ij} \alpha_g \left( \frac{2}{3} \mu_g - \mu_{bg} \right) \frac{\partial v_{g,k}}{\partial x_k} \right) \\ & + \rho_g \alpha_g g_i + F_{g,i}^C \end{aligned} \quad (\text{F.6})$$

where  $\mu_{bl}$  is the bulk viscosity of the liquid, and  $\mu_{bg}$  is the bulk viscosity of the gas.

The surface tension force was neglected so the interfacial momentum transfer terms satisfy:

$$\mathbf{F}_l^C + \mathbf{F}_g^C = 0 \quad (\text{F.7})$$

The pressure inside individual bubbles may vary, but this was assumed to have no relation to the flow of the continuous phase. The volume averaged pressure of the two phases were assumed to be equal,  $p_l = p_g$ . The dispersed phase approximation neglects internal flow inside the dispersed phases. The viscous terms of the gas equation were thus neglected. The bulk viscosity terms were also neglected since they are generally small, as discussed in Chap. 2. These assumptions and approximations simplify the momentum equations.

The instantaneous volume averaged liquid phase equation was written:

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_l \rho_l v_{l,i}) + \frac{\partial}{\partial x_j}(\alpha_l \rho_l v_{l,j} v_{l,i}) = & -\alpha_l \frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \left( \alpha_l \mu_l \left( \frac{\partial v_{l,i}}{\partial x_j} + \frac{\partial v_{l,j}}{\partial x_i} \right) \right) \\ & - \frac{\partial}{\partial x_j} \left( \frac{2}{3} \delta_{ij} \alpha_l \mu_l \frac{\partial v_{l,k}}{\partial x_k} \right) + \rho_l \alpha_l g_i + F_{l,i}^C \end{aligned} \quad (\text{F.8})$$

The corresponding gas phase equation was written:

$$\frac{\partial}{\partial t}(\alpha_g \rho_g v_{g,i}) + \frac{\partial}{\partial x_j}(\alpha_g \rho_g v_{g,j} v_{g,i}) = -\alpha_g \frac{\partial p}{\partial x_i} + \rho_g \alpha_g g_i + F_{g,i}^C. \quad (\text{F.9})$$

### Turbulence Modeling

Reynolds decomposition and time averaging were then applied to the instantaneous variables in the volume average model equations. However, it was assumed that none of the densities fluctuate. The terms of fluctuating quantities with order higher than two were considered small compared to those of first and second order and thus neglected.

Developed versions of the gradient and Boussinesq hypotheses were employed to model the second-order covariance terms. The liquid phase volume fraction-velocity covariance and the Reynolds stresses, for example, were approximated by:

$$\overline{\alpha'_l v'_{l,j}} = -\frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \quad (\text{F.10})$$

and

$$\begin{aligned} \overline{v'_{l,j} v'_{l,i}} &= \sigma_{l,ij}^t + \frac{2}{3} k \delta_{ij} \\ &= -\frac{\nu_{l,t}}{\sigma_{l,t}} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} - \frac{2}{3} \delta_{ij} \frac{\partial \bar{v}_{l,k}}{\partial x_k} \right) + \frac{2}{3} k \delta_{ij} \\ &= -\frac{\nu_{l,t}}{\sigma_{l,t}} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) + \frac{2}{3} \delta_{ij} \left( \frac{\nu_{l,t}}{\sigma_{l,t}} \frac{\partial \bar{v}_{l,k}}{\partial x_k} + k \right) \end{aligned} \quad (\text{F.11})$$

The turbulent Schmidt numbers ( $\sigma_\psi^t$ ) were included for all variables that are modeled via the gradient and Boussinesq hypotheses. These Schmidt numbers were set to 1.0. The only exception was  $\sigma_\epsilon = 1.3$ .

### Turbulence Modeling of the Liquid Phase Continuity Equation

Time averaging the volume averaged liquid mass balance (F.1) gives for the transient term:

$$\frac{\partial}{\partial t}(\rho_l \bar{\alpha}_l) = \frac{\partial}{\partial t}(\rho_l (\alpha_l + \alpha'_l)) = \frac{\partial}{\partial t}(\rho_l \bar{\alpha}_l) \quad (\text{F.12})$$

For the convective terms yield:

$$\begin{aligned}\overline{\frac{\partial}{\partial x_i}(\rho_l \tilde{\alpha}_l \tilde{v}_{l,i})} &= \frac{\partial}{\partial x_i}(\overline{\rho_l(\alpha_l + \alpha'_l)(v_{l,i} + v'_{l,i})}) = \frac{\partial}{\partial x_i}(\overline{\rho_l(\bar{\alpha}_l \bar{v}_{l,i} + \alpha'_l v'_{l,i})}) \\ &= \frac{\partial}{\partial x_i} \left( \rho_l \bar{\alpha}_l \bar{v}_{l,i} - \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \right).\end{aligned}\quad (\text{F.13})$$

### The Modeled Liquid Phase Continuity Equation

For none reactive flow calculations there are no mass exchange between the phases, the continuity equation was reduced to:

$$\frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l) + \frac{\partial}{\partial x_i}(\bar{\alpha}_l \rho_l \bar{v}_{l,i}) = \frac{\partial}{\partial x_i} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \right) \quad (\text{F.14})$$

In vector notation:

$$\frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l) + \nabla \cdot (\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l) = \nabla \cdot \left( \frac{\mu_{l,t}}{\sigma_{\alpha_l,t}} \nabla \bar{\alpha}_l \right). \quad (\text{F.15})$$

### Turbulence Modeling of the Liquid Phase Momentum Equation

Time averaging the volume averaged momentum balance (F.8) gives for the transient term:

$$\begin{aligned}\overline{\frac{\partial}{\partial t}(\tilde{\alpha}_l \rho_l \tilde{v}_{l,i})} &= \frac{\partial}{\partial t}(\overline{\rho_l(\alpha_l + \alpha'_l)(v_{l,i} + v'_{l,i})}) = \frac{\partial}{\partial t}(\overline{\rho_l(\bar{\alpha}_l \bar{v}_{l,i} + \alpha'_l v'_{l,i})}) \\ &\approx \frac{\partial}{\partial t}(\rho_l \bar{\alpha}_l \bar{v}_{l,i})\end{aligned}\quad (\text{F.16})$$

The turbulent covariance terms were neglected. The transient term did serve as a means of under-relaxation.

Modeling the convection terms:

$$\begin{aligned}\overline{\frac{\partial}{\partial x_j}(\tilde{\alpha}_l \rho_l \tilde{v}_{l,j} \tilde{v}_{l,i})} &= \frac{\partial}{\partial x_j}(\overline{\rho_l(\alpha_l + \alpha'_l)(v_{l,j} + v'_{l,j})(v_{l,i} + v'_{l,i})}) \\ &= \frac{\partial}{\partial x_j}(\overline{\rho_l(\bar{\alpha}_l \bar{v}_{l,j} \bar{v}_{l,i} + \alpha'_l v'_{l,j} \bar{v}_{l,i} + \alpha'_l v'_{l,i} \bar{v}_{l,j} + \bar{\alpha}_l v'_{l,j} v'_{l,i})}) \\ &= \frac{\partial}{\partial x_j} \left[ \bar{\alpha}_l \rho_l \bar{v}_{l,j} \bar{v}_{l,i} - \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \bar{v}_{l,i} \right]\end{aligned}$$

$$\begin{aligned}
& -\rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \bar{v}_{l,j} - \bar{\alpha}_l \rho_l \frac{\nu_{l,t}}{\sigma_{l,t}} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) \\
& + \frac{2}{3} \delta_{ij} \bar{\alpha}_l \rho_l \left( \frac{\nu_{l,t}}{\sigma_{l,t}} \frac{\partial \bar{v}_{l,k}}{\partial x_k} + k \right) \Big] \quad (F.17)
\end{aligned}$$

The time after volume averaged pressure-volume fraction term was modeled as:

$$\begin{aligned}
\overline{\tilde{\alpha}_l \frac{\partial \bar{p}}{\partial x_i}} &= \overline{(\alpha_l + \alpha'_l) \frac{\partial}{\partial x_i} (p + p')} = \bar{\alpha}_l \frac{\partial \bar{p}}{\partial x_i} + \overline{\alpha'_l \frac{\partial p'}{\partial x_i}} \\
&= \bar{\alpha}_l \frac{\partial \bar{p}}{\partial x_i} + \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \rho_l \bar{v}_{l,j} \frac{\partial}{\partial x_j} \left( \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \right) \quad (F.18)
\end{aligned}$$

The pressure-volume fraction covariance terms were deduced from the instantaneous steady state equations for conservation of mass and momentum of the continuous phase [51]. The instantaneous steady state continuity was written as:

$$\frac{\partial}{\partial x_i} \left( \rho_l (\bar{\alpha}_l \bar{v}_{l,i} + \bar{\alpha}_l v'_{l,i} + \alpha'_l \bar{v}_{l,i} + \alpha'_l v'_{l,i}) \right) = 0 \quad (F.19)$$

The time after volume averaged continuity equation became:

$$\frac{\partial}{\partial x_i} \left( \rho_l (\bar{\alpha}_l \bar{v}_{l,i} + \overline{\alpha'_l v'_{l,i}}) \right) = 0 \quad (F.20)$$

The steady state equation for the instantaneous mass fluctuations was found by subtracting (F.20) from (F.19) giving:

$$\frac{\partial}{\partial x_i} \left( \rho_l (\bar{\alpha}_l v'_{l,i} + \alpha'_l \bar{v}_{l,i} + \alpha'_l v'_{l,i} - \overline{\alpha'_l v'_{l,i}}) \right) = 0 \quad (F.21)$$

The instantaneous void fractions always satisfy (F.3), hence:

$$\bar{\alpha}_l + \alpha'_l + \bar{\alpha}_g + \alpha'_g = 1 \quad (F.22)$$

Time averaging the instantaneous volume averaged compatibility relation gives:

$$\bar{\alpha}_l + \bar{\alpha}_g = 1 \quad (F.23)$$

By subtracting the time averaged compatibility relation (F.23) from (F.22), the fluctuations were shown to satisfy:

$$\alpha'_l + \alpha'_g = 0 \quad (F.24)$$

Since the two phases share the same pressure, the phasic pressure–volume fraction covariance terms were related through:

$$\overline{\alpha'_l \frac{\partial p'}{\partial x_i}} = -\overline{\alpha'_g \frac{\partial p'}{\partial x_i}} \quad (\text{F.25})$$

The pressure-volume fraction covariance terms appear with opposite signs in the equations for the gas and liquid phases. The pressure-volume fraction covariance terms thus describe momentum transfer fluxes between the phases.

A steady state equation for the instantaneous momentum fluctuations was found by subtracting the time averaged steady state equation from the instantaneous steady state equation. The resulting steady state relations were then simplified by the use of (F.22) and (F.24). The resulting equation was then multiplied through with  $\alpha'_l/\alpha_l$  and time averaged. Covariances of fluctuating quantities with order larger than two were assumed small compared to the other terms and thus neglected. The fluctuating interphase forces and viscous interaction terms were also neglected. The factor:

$$\frac{\overline{\alpha'^2_l}}{\overline{\alpha_l^2}} \quad (\text{F.26})$$

is now a common factor for three of the remaining terms in the equation for the pressure–volume fraction covariance terms. By assuming that this pre-factor term was close to zero, all the terms with this prefactor were neglected. The pressure–volume fraction covariance terms were then approximated by:

$$\overline{\alpha'_l \frac{\partial p'}{\partial x_i}} = -\overline{\rho_l \alpha'_l v'_{l,j}} \frac{\partial \overline{v_{l,i}}}{\partial x_j} - \overline{\rho_l \overline{v_{l,j}} \alpha'_l} \frac{\partial v'_{l,i}}{\partial x_j} \quad (\text{F.27})$$

The first term on the RHS can be modeled using the gradient and Boussinesq hypotheses. The covariance within the second term was written as:

$$\overline{\alpha'_l \frac{\partial v_{l,i}}{\partial x_j}} = \frac{\partial}{\partial x_j} (\overline{\alpha'_l v'_{l,i}}) - \overline{v'_{l,i}} \frac{\partial \alpha'_l}{\partial x_j} \quad (\text{F.28})$$

A weakly justified approximation was then introduced [51]:

$$\overline{\alpha'_l \frac{\partial v'_{l,i}}{\partial x_j}} \approx \frac{\partial}{\partial x_j} (\overline{\alpha'_l v'_{l,i}}) \quad (\text{F.29})$$

The final equation for the turbulent pressure–volume fraction covariance terms was then obtained:

$$\overline{\alpha'_l \frac{\partial p'}{\partial x_i}} = -\overline{\rho_l \alpha'_l v'_{l,j}} \frac{\partial \overline{v_{l,i}}}{\partial x_j} - \overline{\rho_l \overline{v_{l,j}} \frac{\partial}{\partial x_j} (\overline{\alpha'_l v'_{l,i}})} \quad (\text{F.30})$$

The closure is completed by use of the gradient and Boussinesq hypotheses on the form (F.10).

Time averaging the volume averaged gravity force yield:

$$\overline{\tilde{\alpha}_l \rho_l g_i} = \overline{(\alpha_l + \alpha'_l) \rho_l g_i} = \bar{\alpha}_l \rho_l g_i \quad (\text{F.31})$$

The time after volume averaged viscous shear terms became:

$$\begin{aligned} & \overline{\frac{\partial}{\partial x_j} (\tilde{\alpha}_l \mu_l (\frac{\partial \tilde{v}_{l,i}}{\partial x_j} + \frac{\partial \tilde{v}_{l,j}}{\partial x_i}))} \\ &= \frac{\partial}{\partial x_j} \left( \overline{\mu_l (\alpha_l + \alpha'_l) (\frac{\partial (v_{l,i} + v'_{l,i})}{\partial x_j} + \frac{\partial (v_{l,j} + v'_{l,j})}{\partial x_i})} \right) \\ &= \frac{\partial}{\partial x_j} \left( \mu_l \bar{\alpha}_l (\frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i}) + \mu_l \alpha'_l (\frac{\partial v'_{l,i}}{\partial x_j} + \frac{\partial v'_{l,j}}{\partial x_i}) \right) \\ &\approx \frac{\partial}{\partial x_j} (\mu_l \bar{\alpha}_l (\frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i})) \end{aligned} \quad (\text{F.32})$$

and

$$\begin{aligned} -\overline{\frac{\partial}{\partial x_j} \left( \frac{2}{3} \delta_{ij} \tilde{\alpha}_l \mu_l \frac{\partial \tilde{v}_{l,k}}{\partial x_k} \right)} &= -\frac{2}{3} \frac{\partial}{\partial x_i} \left( \overline{\mu_l (\alpha_l + \alpha'_l) \frac{\partial (v_{l,k} + v'_{l,k})}{\partial x_k}} \right) \\ &= -\frac{2}{3} \frac{\partial}{\partial x_i} \left( \mu_l \bar{\alpha}_l \frac{\partial \bar{v}_{l,k}}{\partial x_k} + \mu_l \alpha'_l \frac{\partial v'_{l,k}}{\partial x_k} \right) \\ &\approx -\frac{2}{3} \frac{\partial}{\partial x_i} \left( \mu_l \bar{\alpha}_l \frac{\partial \bar{v}_{l,k}}{\partial x_k} \right) \end{aligned} \quad (\text{F.33})$$

To make the notation used for the latter term consistent with the other equations, index  $j$  is substituted for  $k$  :

$$-\overline{\frac{\partial}{\partial x_j} \left( \frac{2}{3} \delta_{ij} \tilde{\alpha}_l \mu_l \frac{\partial \tilde{v}_{l,j}}{\partial x_j} \right)} \approx -\frac{2}{3} \frac{\partial}{\partial x_i} \left( \mu_l \bar{\alpha}_l \frac{\partial \bar{v}_{l,j}}{\partial x_j} \right) \quad (\text{F.34})$$

In abbreviated form the viscous shear can thus be written as:

$$\overline{\tilde{F}_{l,i}^V} = \overline{F_{l,i}^V} + \overline{F_{l,i}^{V'}} \quad (\text{F.35})$$

in which the  $\overline{F_{l,i}^{V'}}$  terms are ignored.

The modeled viscous term was thus approximated as:

$$\tilde{F}_{l,i}^V \approx \overline{F}_{l,i}^V \approx \frac{\partial}{\partial x_j} \left( \mu_l \bar{\alpha}_l \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) \right) - \frac{2}{3} \frac{\partial}{\partial x_i} \left( \mu_l \bar{\alpha}_l \frac{\partial \bar{v}_{l,j}}{\partial x_j} \right) \quad (\text{F.36})$$

The time averaged interphase forces were modeled as:

$$\tilde{F}_{l,i}^C = \overline{F}_{l,i}^C + \overline{F}_{l,i}^{C'} \quad (\text{F.37})$$

It is noted that  $\overline{F}_{l,i}^{C'}$  is made up of terms which are of order higher than one in the fluctuating quantities, so by time averaging they are not zero. The interphase forces and the turbulence modeling of the drag force are described shortly in this section.

### The Modeled Liquid Phase Momentum Equation

After all the modeled terms were substituted into the averaged conservation equation for momentum, the balance equation became:

$$\begin{aligned} & \underbrace{\frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l \bar{v}_{l,i})}_{\text{Transient term}} + \underbrace{\frac{\partial}{\partial x_j} (\bar{\alpha}_l \rho_l \bar{v}_{l,j} \bar{v}_{l,i})}_{\text{Convection term}} \\ &= \underbrace{\frac{\partial}{\partial x_j} \left( \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \bar{v}_{l,i} + \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \bar{v}_{l,j} + \bar{\alpha}_l \rho_l \frac{\nu_{l,t}}{\sigma_{l,t}} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) \right)}_{\text{From convection term}} \\ & \quad - \underbrace{\frac{\partial}{\partial x_j} \left( \frac{2}{3} \delta_{ij} \bar{\alpha}_l \rho_l \left( k + \frac{\nu_{l,t}}{\sigma_{l,t}} \frac{\partial \bar{v}_{l,k}}{\partial x_k} \right) \right)}_{\text{From convection term}} - \underbrace{\bar{\alpha}_l \frac{\partial \bar{p}}{\partial x_i} - \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \frac{\partial \bar{v}_{l,i}}{\partial x_j}}_{\text{From pressure term}} \\ & \quad - \underbrace{\rho_l \bar{v}_{l,j} \frac{\partial}{\partial x_j} \left( \frac{\nu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \right)}_{\text{From pressure term}} + \underbrace{\rho_l \bar{\alpha}_l g_i}_{\text{Gravity term}} \\ & \quad + \underbrace{\frac{\partial}{\partial x_j} (\bar{\alpha}_l \mu_l \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right)) - \frac{\partial}{\partial x_i} \left( \frac{2}{3} \bar{\alpha}_l \mu_l \frac{\partial \bar{v}_{l,k}}{\partial x_k} \right)}_{\text{Viscous terms}} + \underbrace{\overline{F}_{l,i}^C + \overline{F}_{l,i}^{C'}}_{\text{Interphasial forces term}} \quad (\text{F.38}) \end{aligned}$$

The viscous terms were joined with the turbulent diffusion terms that come from the modeling of the convection terms. The notations  $\mu_{l,\text{eff}} = \mu_l + \frac{\mu_{l,t}}{\sigma_{l,t}}$  and  $\nu_{l,\text{eff}} = \nu_l + \frac{\nu_{l,t}}{\sigma_{l,t}}$  are used, giving:

$$\begin{aligned}
& \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l \bar{v}_{l,i}) + \frac{\partial}{\partial x_j}(\bar{\alpha}_l \rho_l \bar{v}_{l,j} \bar{v}_{l,i}) \\
&= \frac{\partial}{\partial x_j} \left( \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \bar{v}_{l,i} + \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \bar{v}_{l,j} + \bar{\alpha}_l \rho_l \nu_{l,\text{eff}} \left( \frac{\partial \bar{v}_{l,i}}{\partial x_j} + \frac{\partial \bar{v}_{l,j}}{\partial x_i} \right) \right) \\
&\quad - \frac{\partial}{\partial x_i} \left( \frac{2}{3} \bar{\alpha}_l \rho_l (k + \nu_{l,\text{eff}} \frac{\partial \bar{v}_{l,k}}{\partial x_k}) \right) - \bar{\alpha}_l \frac{\partial \bar{p}}{\partial x_i} - \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_j} \frac{\partial \bar{v}_{l,i}}{\partial x_j} \\
&\quad - \rho_l \bar{v}_{l,j} \frac{\partial}{\partial x_j} \left( \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \bar{\alpha}_l}{\partial x_i} \right) + \rho_l \bar{\alpha}_l g_i + \bar{F}_{l,i}^C + \bar{F}_{l,i}^{C'}
\end{aligned} \tag{F.39}$$

These equations can be written in vector notation giving:

$$\begin{aligned}
& \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l) + \nabla \cdot (\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l \bar{\mathbf{v}}_l) \\
&= \nabla \cdot \left( \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \nabla \bar{\alpha}_l \bar{\mathbf{v}}_l + \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \bar{\mathbf{v}}_l \nabla \bar{\alpha}_l + \bar{\alpha}_l \rho_l \nu_{l,\text{eff}} (\nabla \bar{\mathbf{v}}_l + (\nabla \bar{\mathbf{v}}_l)^T) \right) \\
&\quad - \nabla \left( \frac{2}{3} \bar{\alpha}_l \rho_l (k + \nu_{l,\text{eff}} \nabla \cdot \bar{\mathbf{v}}_l) \right) - \bar{\alpha}_l \nabla \bar{p} - \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \nabla \bar{\alpha}_l \cdot \nabla \bar{\mathbf{v}}_l \\
&\quad - \rho_l \bar{\mathbf{v}}_l \cdot \nabla \left( \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \nabla \bar{\alpha}_l \right) + \rho_l \bar{\alpha}_l \mathbf{g} + \bar{\mathbf{F}}_l^C + \bar{\mathbf{F}}_l^{C'}
\end{aligned} \tag{F.40}$$

This equation can be transformed into cylindrical coordinates as shown shortly in this appendix. The resulting equations in 2D cylindrical are listed in Sect. F.4.

### The Modeled Gas Phase Continuity Equation

The continuity equation was modeled in an identical manner to that of the liquid phase. The result is:

$$\frac{\partial}{\partial t}(\bar{\alpha}_g \rho_g) + \frac{\partial}{\partial x_i}(\bar{\alpha}_g \rho_g \bar{v}_{g,i}) = \frac{\partial}{\partial x_i} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_g,t}} \frac{\partial \bar{\alpha}_g}{\partial x_i} \right) \tag{F.41}$$

In vector notation this is:

$$\frac{\partial}{\partial t}(\bar{\alpha}_g \rho_g) + \nabla \cdot (\bar{\alpha}_g \rho_g \bar{\mathbf{v}}_g) = \nabla \cdot \left( \frac{\mu_{g,t}}{\sigma_{\alpha_g,t}} \nabla \bar{\alpha}_g \right). \tag{F.42}$$

### The Modeled Gas Phase Momentum Equation

The turbulence modeling of the transient and convective terms of the momentum balance (F.9) gives analogous results to that of the liquid phase. The pressure term is determined from [51]:

$$\overline{\alpha'_g \frac{\partial p'}{\partial x_i}} = -\overline{\alpha'_l \frac{\partial p'}{\partial x_i}} \quad (\text{F.43})$$

The gravitational and interphase forces are also analogous to those of the liquid phase.

The momentum balance was thus be written as:

$$\begin{aligned} & \underbrace{\frac{\partial}{\partial t}(\overline{\alpha_g \rho_g \bar{v}_{g,i}})}_{\text{Transient term}} + \underbrace{\frac{\partial}{\partial x_j}(\overline{\alpha_g \rho_g \bar{v}_{g,j} \bar{v}_{g,i}})}_{\text{Convection term}} \\ &= \underbrace{\frac{\partial}{\partial x_j}(\rho_g \frac{\nu_{g,t}}{\sigma_{\alpha_g,t}} \frac{\partial \overline{\alpha_g}}{\partial x_j} \bar{v}_{g,i} + \rho_g \frac{\nu_{g,t}}{\sigma_{\alpha_g,t}} \frac{\partial \overline{\alpha_g}}{\partial x_i} \bar{v}_{g,j} + \overline{\alpha_g} \rho_g \frac{\nu_{g,t}}{\sigma_{g,t}} (\frac{\partial \bar{v}_{g,i}}{\partial x_j} + \frac{\partial \bar{v}_{g,j}}{\partial x_i}))}_{\text{From convection term}} \\ & - \underbrace{\frac{\partial}{\partial x_j}(\frac{2}{3} \delta_{ij} \overline{\alpha_g \rho_g} (k + \frac{\nu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,k}}{\partial x_k}))}_{\text{From convection term}} - \underbrace{\overline{\alpha_g} \frac{\partial \bar{p}}{\partial x_i}}_{\text{From pressure term}} + \underbrace{\rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \overline{\alpha_l}}{\partial x_j} \frac{\partial \bar{v}_{l,i}}{\partial x_j}}_{\text{From pressure term}} \\ & + \underbrace{\rho_l \bar{v}_{l,j} \frac{\partial}{\partial x_j}(\frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \frac{\partial \overline{\alpha_l}}{\partial x_i})}_{\text{From pressure term}} + \underbrace{\rho_g \overline{\alpha_g} g_i}_{\text{Gravity term}} + \underbrace{\overline{F_{g,i}^C} + \overline{F_{g,i}^{C'}}}_{\text{Interphasial forces term}} \end{aligned} \quad (\text{F.44})$$

In vector notation this equation becomes:

$$\begin{aligned} & \frac{\partial}{\partial t}(\overline{\alpha_g \rho_g \bar{\mathbf{v}}_g}) + \nabla \cdot (\overline{\alpha_g \rho_g \bar{\mathbf{v}}_g \bar{\mathbf{v}}_g}) \\ &= \nabla \cdot \left( \rho_g \frac{\nu_{g,t}}{\sigma_{\alpha_g,t}} \nabla \overline{\alpha_g} \bar{\mathbf{v}}_g + \rho_g \frac{\nu_{g,t}}{\sigma_{\alpha_g,t}} \bar{\mathbf{v}}_g \nabla \overline{\alpha_g} + \overline{\alpha_g} \rho_g \frac{\nu_{g,t}}{\sigma_{\alpha_g,t}} (\nabla \bar{\mathbf{v}}_g + (\nabla \bar{\mathbf{v}}_g)^T) \right) \\ & - \nabla \cdot \left( \frac{2}{3} \overline{\alpha_g \rho_g} \left( k + \frac{\nu_{g,t}}{\sigma_{\alpha_g,t}} \nabla \cdot \bar{\mathbf{v}}_g \right) \right) - \overline{\alpha_g} \nabla \bar{p} + \rho_l \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \nabla \overline{\alpha_l} \cdot \nabla \bar{\mathbf{v}}_l \\ & + \rho_l \bar{\mathbf{v}}_l \cdot \nabla \left( \frac{\nu_{l,t}}{\sigma_{\alpha_l,t}} \nabla \overline{\alpha_l} \right) + \rho_g \overline{\alpha_g} \mathbf{g} + \overline{\mathbf{F}_g^C} + \overline{\mathbf{F}_g^{C'}} \end{aligned} \quad (\text{F.45})$$

The mass and momentum conservation equations are written in cylindrical coordinates in a later section in this appendix.

## The Liquid Phase Turbulence Model

The  $k - \epsilon$  model is chosen as the turbulence model [58]. It is assumed that the turbulence inside the dispersed phase (gas bubbles) does not affect the liquid phase turbulence. Both  $k$  and  $\epsilon$  are determined from transport equations, as described in Sect. 8.4.4.

In vector notation the equations are:

$$\frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l k) + \nabla \cdot (\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l k) = \nabla \cdot (\bar{\alpha}_l \frac{\mu_{l,t}}{\sigma_k} \nabla k) + \bar{\alpha}_l (P_k + P_b - \rho_l \varepsilon) \quad (\text{F.46})$$

and

$$\frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l \varepsilon) + \nabla \cdot (\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l \varepsilon) = \nabla \cdot (\bar{\alpha}_l \frac{\mu_{l,t}}{\sigma_\varepsilon} \nabla \varepsilon) + \bar{\alpha}_l \frac{\varepsilon}{k} (C_{\varepsilon 1} (P_k + P_b) - C_{\varepsilon 2} \rho_l \varepsilon) \quad (\text{F.47})$$

The turbulent production terms due to fluid shear and bubble movement are expressed as:

$$P_k = \mu_{l,t} (\nabla \bar{\mathbf{v}}_l + (\nabla \bar{\mathbf{v}}_l)^T) : \nabla \bar{\mathbf{v}}_l \quad (\text{F.48})$$

and

$$P_b = C_b \bar{\mathbf{F}}_{D,l} \cdot (\bar{\mathbf{v}}_l - \bar{\mathbf{v}}_g) \quad (\text{F.49})$$

The  $C_b$  parameter takes values between 0 and 1, and generally depends on bubble size and shape, and on the turbulent length scale. The empirical coefficients in the turbulence model were kept equal to the standard values for the original single phase model.

## Interphase Forces

The interphase forces considered were steady drag, added (virtual) mass and lift. The steady drag force on a collection of dispersed bubbles with a given average diameter was described by (5.28) and (5.14). The transversal lift force was determined by the conventional model (5.45), whereas the added mass force was approximated by (5.92).

Jakobsen [51] used a drag coefficient formulation for the bubbles formulated by Johansen and Boysan [53] based on the terminal velocities for ellipsoidal bubbles given by Clift et al. [18]:

$$C_D = \frac{0.622}{\frac{1.0}{E_0} + 0.235} \quad (\text{F.50})$$

By applying turbulence modeling to the drag force, negative transversal forces arise. The resulting transversal force was written as [51]:

$$\overline{F_{T,g}^i} = \frac{3}{4} \bar{\alpha}_l \bar{\alpha}_g \frac{\mu_l}{d_S^2} C_D \frac{C_\tau}{(1 + \frac{\tau_L}{t_p})} (\frac{d_S}{\nu_l})^2 \frac{(\bar{v}_l - \bar{v}_g)_k}{Re_P} (-\nu_{l,t} (\frac{\partial \bar{v}_{l,i}}{\partial x_k} + \frac{\partial \bar{v}_{l,k}}{\partial x_i})) (1 - \delta_{ik}) \quad (\text{F.51})$$

where  $\overline{Re_P}$  is the time averaged turbulent particle Reynolds number:

$$\overline{Re_P} = \frac{d_s \sqrt{(v_{l,i} + v'_{l,i} - v_{g,i} - v'_{g,i})^2}}{\nu_l}. \quad (\text{F.52})$$

### Variable Local Bubble size model

Jakobsen [51] developed a simple model for the bubble size postulating that the bubble diameter was proportional to the turbulence length scale determined by the  $k$ - $\varepsilon$  turbulence model. The bubble diameter was thus approximated by:

$$d_s = C_{\text{SMD}} \frac{k^{\frac{3}{2}}}{\varepsilon} \quad (\text{F.53})$$

in which  $C_{\text{SMD}} = 0.04$  was considered a constant system parameter tuned to the air-water system.

## F.2 Tensor Transformation Laws

The two-fluid model has been derived in Cartesian coordinates. However, for working problems it is often more natural to use curvilinear coordinates like cylindrical and spherical coordinates. In reactor modeling cylindrical coordinates are of particular interest because many reactors have the shape of a tube. In this section we are thus primarily interested in knowing how to convert the various differential operations written in Cartesian coordinates into vector notation and from thence into curvilinear coordinates. The first operation is relatively easy to perform since the elementary operators can be found in many introductory textbooks on fluid mechanics. The second operation can also be achieved in a rigorous manner provided that we know, for the coordinate being used, two mathematical characteristics<sup>6</sup>: The expressions for  $\nabla$  and the spatial derivatives of the unit vectors in curvilinear coordinates. In the following subsections we define the formulas that are necessary to convert the equations from the general vector notation to cylinder coordinates. Finally, the governing equations for the two-fluid model are given in cylinder coordinates.

### F.2.1 Curvilinear Coordinate Systems

The position of a point  $P$  in any coordinate system may be specified by three coordinates. To determine these we must first establish a frame of reference by

---

<sup>6</sup> The textbooks by Bird et al. [7], Aris [2], Malvern [63], Slattery [88], Irgens [49, 50] and Borisenko and Tarapov [10] may be consulted for thorough-going studies of the extensive theory of vector and tensor analysis.

taking any point  $\mathbf{O}$  as the origin and drawing through it three lines, the coordinates. A reference frame with origin  $\mathbf{O}$  consists of three base vectors pointing in three different directions which do not all lie in the same plane. The set of three base vectors is called a basis. A coordinate system is said to be curvilinear if its coordinate curves are not straight lines. A characteristic property of curvilinear coordinate systems is that the orientation of the axes vary from point to point. Considering the general non-orthogonal curvilinear coordinate systems the base vectors are not orthogonal and need not be the same at different points in space. In these non-orthogonal curvilinear coordinate systems, two distinct frames of basis vectors exist at any point. One frame follows the coordinate lines, i.e., the covariant basis vectors are tangents to the coordinate curves. In the other frame, the contravariant basis vectors are normal to the coordinate surface. The orthogonal curvilinear coordinates can be considered a special case of the non-orthogonal curvilinear coordinates. These orthogonal coordinate systems are characterized by tangential basis vectors to the coordinate lines which are mutually perpendicular at every point. In this book only orthogonal coordinate systems are considered. The Cartesian coordinate system is defined by three mutually orthogonal unit vectors with equal units of measurement. The unit vectors may then be thought of as lines of unit length lying along the three axes. The orthogonal curvilinear coordinate systems, like the cylindrical and spherical coordinates, are defined by three mutually orthogonal unit vectors with unequal units of measurement. Considering a generalized orthogonal coordinate system, the orthogonal curvilinear coordinates are defined as  $q_\alpha$ . In this  $\mathbf{O}$ -system the base vectors  $\mathbf{e}_\alpha$  are defined as unit vectors along the coordinates. The position of the point  $P$  is given by the coordinates, or by the position vector  $\mathbf{r} = \mathbf{r}(q_\alpha, t)$ .

### F.2.2 The Tensor Concept

A *scalar* is a quantity associated with a point in space, whose specification requires just one number. For example, the fluid density, mass fraction, temperature, pressure and work are all scalar quantities. Scalars can be compared only if they have the same physical dimensions. Scalars measured in the same system of units are said to be equal if they have the same magnitude and sign. A *vector* is an entity that possesses both magnitude and direction and obeys certain laws. For example, velocity, acceleration, force are all vectors. Two vectors are equal if they have the same direction and the same magnitude. Moreover, a direction has to be specified in relation to a given frame of reference and this frame of reference is just as arbitrary as the system of units in which the magnitude is expressed. We distinguish therefore between the vector as an entity and its components which allow us to reconstruct it in a particular system of reference. *Second-order tensors* (also called second-rank tensors<sup>7</sup>) are next in order of complexity after scalars and vectors. Scalars and vectors are both special cases of the more general mathematical entity called a *tensor of order  $n$* , whose specification

---

<sup>7</sup> The rank of a particular tensor is the number of array indices required to describe such a quantity.

in any given coordinate system requires  $3^n$  numbers for 3D tensors, these are called the components of the tensor. In this way, we may consider that scalars are tensors of order 0, with  $3^0 = 1$  components, and vectors are tensors of order 1, with  $3^1 = 3$  components. By a second-order tensor is thus meant a quantity uniquely specified by  $3^2 = 9$  numbers denoting the components of the tensor. Higher-order tensors can naturally be defined too, but the second-order tensors are the ones of primary interest in this book. For brevity, we often use the word tensor to mean second-order tensor. The stress tensor is customarily considered the primary tensor in fluid mechanics. A fluid stress has the units of a force per unit area. This tensor is thus an entity associated with two directions (those of the force and the normal to the area). The Cauchy's stress principle establishes that the stress in fluids can be represented by a tensor (e.g., Aris [2], Chap. 5; Borisenko and Tarapov [10], Sect. 2.4.2; Slattery [88], Sect. 2.2.2). Basically, Cauchy's stress principle asserts that  $\mathbf{f}/\delta A$ , tends towards a finite limit as  $\delta A \rightarrow 0$ . This limit is called the stress vector. To elucidate the nature of the stress system at a point  $P$  one considers a fluid element with shape like a small tetrahedron with three of its faces perpendicular to the coordinate axes, while the fourth has an area  $\delta A$  with normal  $\mathbf{n}$ . The three faces are mutually orthogonal and coincide with a set of Cartesian coordinate planes intersecting at  $\mathbf{z}$ . By the law of action and reaction, the stress forces acting on the inside faces of the tetrahedron are equal and opposite to those acting on the outside faces. Applying the principle of local equilibrium then shows that if the tetrahedral fluid element shrink in volume toward a point  $P$ , the net surface force will approach zero. It follows that the stress vector can be re-written as  $\mathbf{f} = -(\mathbf{f}_1 n_1 + \mathbf{f}_2 n_2 + \mathbf{f}_3 n_3)$ . With the convention that  $-T_{mk}$  is the  $k$ th component of the stress vector acting upon the positive side of the plane  $z_m = \text{constant}$ , we project  $\mathbf{f}$  onto the axes of the system:

$$\mathbf{f} = -n_i T_{ij} \mathbf{e}_j, \quad (\text{F.54})$$

where  $T_{ij}$  is a matrix of nine stress components constituting a tensor.

This allow us to write (F.54) as:

$$\mathbf{f} = -\mathbf{n} \cdot \mathbf{T} \quad (\text{F.55})$$

Thus, in order to describe completely the state of stress at a point in a continuum, we must specify the stress tensor  $\mathbf{T}$ . A key property of a tensor is the *transformation law* of its components. This law expresses the way in which the tensor components in one coordinate system are related to its components in another coordinate system. The precise form of this transformation law is a consequence of the physical or geometric meaning of the tensor.

### F.2.3 Coordinate Transformation Prerequisites

In this section we explain how to determine  $\nabla$  and the spatial derivatives of the unit vectors in cylindrical coordinates.

In Cartesian coordinates the position vector is given by:

$$\mathbf{r} = x\mathbf{e}_x + y\mathbf{e}_y + z\mathbf{e}_z \quad (\text{F.56})$$

The nabla operator yields:

$$\nabla = \frac{\partial}{\partial x}\mathbf{e}_x + \frac{\partial}{\partial y}\mathbf{e}_y + \frac{\partial}{\partial z}\mathbf{e}_z \quad (\text{F.57})$$

The gradient of a scalar field  $\psi$  is defined by:

$$\nabla\psi = \frac{\partial\psi}{\partial x}\mathbf{e}_x + \frac{\partial\psi}{\partial y}\mathbf{e}_y + \frac{\partial\psi}{\partial z}\mathbf{e}_z \quad (\text{F.58})$$

The divergence of a vector field  $\mathbf{v}$  is defined by:

$$\nabla \cdot \mathbf{v} = \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z} \quad (\text{F.59})$$

The divergence of a tensor field  $\boldsymbol{\sigma}$  is defined by:

$$\nabla \cdot \boldsymbol{\sigma} = \sum_i \frac{\partial}{\partial x_i} \mathbf{e}_i \cdot (\boldsymbol{\sigma}_{jk} \mathbf{e}_j \mathbf{e}_k) = \sum_k \mathbf{e}_k \frac{\partial}{\partial x_i} \sigma_{ik} \quad (\text{F.60})$$

The Laplacian of a scalar field  $\psi$  is defined by:

$$\nabla^2\psi = \frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} \quad (\text{F.61})$$

The Curl of a vector field  $\mathbf{v}$  is defined by:

$$\nabla \times \mathbf{v} = \begin{vmatrix} \mathbf{e}_x & \mathbf{e}_y & \mathbf{e}_z \\ \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \\ v_x & v_y & v_z \end{vmatrix} \quad (\text{F.62})$$

The governing equations can be transformed directly from Cartesian coordinates into cylindrical coordinates without considering the vector notation. In this appendix the relationships between the Cartesian coordinates and the cylindrical coordinates are defined solely, but the method of coordinate transformation is generic and can thus be applied to any orthogonal coordinate system.

In cylindrical coordinates, instead of locating a point in space by  $x, y, z$  as in Cartesian coordinates, we designate the coordinates of the point by  $r, \theta, z$ . The Cartesian coordinates are related to the cylindrical coordinates by [7]:

$$x = r \cos \theta, \quad y = r \sin \theta, \quad z = z \quad (\text{F.63})$$

To convert the derivatives of scalars with respect to  $x, y, z$  into derivatives with respect to  $r, \theta, z$ , the chain rule of partial differentiation is used. The derivative operators are thus related as:

$$\frac{\partial}{\partial x} = \cos \theta \frac{\partial}{\partial r} - \frac{\sin \theta}{r} \frac{\partial}{\partial \theta}, \quad \frac{\partial}{\partial y} = \sin \theta \frac{\partial}{\partial r} + \frac{\cos \theta}{r} \frac{\partial}{\partial \theta}, \quad \frac{\partial}{\partial z} = \frac{\partial}{\partial z} \quad (\text{F.64})$$

Trigonometrical arguments lead to the following relations between the unit vectors:

$$\mathbf{e}_x = \cos \theta \mathbf{e}_r + \sin \theta \mathbf{e}_\theta, \quad \mathbf{e}_\theta = -\sin \theta \mathbf{e}_r + \cos \theta \mathbf{e}_\theta, \quad \mathbf{e}_z = \mathbf{e}_z \quad (\text{F.65})$$

From these equations one can derive the formulas required for the spatial derivatives of the unit vectors  $\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z$ .

The given trigonometrical relationships may also be solved for  $\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z$ , giving:

$$\mathbf{e}_x = \cos \theta \mathbf{e}_r - \sin \theta \mathbf{e}_\theta, \quad \mathbf{e}_y = \sin \theta \mathbf{e}_r + \cos \theta \mathbf{e}_\theta, \quad \mathbf{e}_z = \mathbf{e}_z \quad (\text{F.66})$$

To obtain the formula for  $\nabla$  in cylindrical coordinates we employ the definition of the  $\nabla$ -operator in Cartesian coordinates (F.57), eliminate the Cartesian unit vectors by (F.66) and eliminate the Cartesian derivative operators by (F.64). The resulting formula for the  $\nabla$  operator in cylindrical coordinates can then be used to calculate all the necessary differential operators in cylindrical coordinates provided that the spatial derivatives of the unit vectors  $\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z$  are used to differentiate the unit vectors on which  $\nabla$  operates.

The spatial derivatives of the unit vectors  $\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z$  can be determined from (F.65):

$$\frac{\partial}{\partial r} \mathbf{e}_r = 0 \quad \frac{\partial}{\partial r} \mathbf{e}_\theta = 0 \quad \frac{\partial}{\partial r} \mathbf{e}_z = 0 \quad (\text{F.67})$$

$$\frac{\partial}{\partial \theta} \mathbf{e}_r = \mathbf{e}_\theta \quad \frac{\partial}{\partial \theta} \mathbf{e}_\theta = -\mathbf{e}_r \quad \frac{\partial}{\partial \theta} \mathbf{e}_z = 0 \quad (\text{F.68})$$

$$\frac{\partial}{\partial z} \mathbf{e}_r = 0 \quad \frac{\partial}{\partial z} \mathbf{e}_\theta = 0 \quad \frac{\partial}{\partial z} \mathbf{e}_z = 0 \quad (\text{F.69})$$

By use of (F.56), (F.63) and (F.68) the position vector can be transformed into cylindrical coordinates:

$$\mathbf{r} = r \mathbf{e}_r(\theta) + z \mathbf{e}_z. \quad (\text{F.70})$$

### ***F.2.4 Orthogonal Curvilinear Coordinate Systems and Differential Operators***

In this section the relevant differential operators are defined for generalized orthogonal curvilinear coordinate systems. Let  $(q_1, q_2, q_3)$  be curvilinear orthogonal coordinates connected with the Cartesian coordinates  $(x, y, z)$  by the vector relation

$\mathbf{r} = \mathbf{r}(q_1, q_2, q_3)$ , where  $\mathbf{r}$  is the radius vector of the point  $P$  considered. The Cartesian coordinates are then related to the generalized curvilinear coordinates by:

$$x = x(q_1, q_2, q_3), \quad y = y(q_1, q_2, q_3), \quad z = z(q_1, q_2, q_3) \quad (\text{F.71})$$

If the Jacobian is nonzero,

$$\frac{\partial(x, y, z)}{\partial(q_1, q_2, q_3)} \neq 0, \quad (\text{F.72})$$

then

$$q_1 = q_1(x, y, z), \quad q_2 = q_2(x, y, z), \quad q_3 = q_3(x, y, z) \quad (\text{F.73})$$

form a basis for the orthogonal curvilinear coordinate system.

The basis vectors (not necessarily unit vectors) in the generalized curvilinear coordinate system are defined as (e.g., [1], p. 193; [101], p. 6; [7], p. 737):

$$\mathbf{g}_\alpha = \frac{\partial \mathbf{r}}{\partial q_\alpha} = \frac{\partial \mathbf{r}}{\partial x_k} \frac{\partial x_k}{\partial q_\alpha} = \frac{\partial x_k}{\partial q_\alpha} \mathbf{e}_k \quad \text{or} \quad \mathbf{e}_k = \frac{\partial q_\alpha}{\partial x_k} \mathbf{g}_\alpha \quad (\text{F.74})$$

where  $x_k$  is the Cartesian coordinates, and  $\mathbf{g}_\alpha$  are the tangent basis vectors which are tangents to the coordinate lines.

From these basis vectors we can define the Lamé coefficients denoting the length of the basis vectors (also named *scale factors*) and expressed by:

$$h_{q_\alpha} = |\mathbf{g}_\alpha| = \left| \frac{\partial \mathbf{r}}{\partial q_\alpha} \right| = h_\alpha = \sqrt{\mathbf{g}_\alpha \cdot \mathbf{g}_\alpha} = \sqrt{\frac{\partial \mathbf{r}}{\partial q_\alpha} \cdot \frac{\partial \mathbf{r}}{\partial q_\alpha}} = \sqrt{\frac{\partial x_k}{\partial q_\alpha} \frac{\partial x_k}{\partial q_\alpha}} \quad (\text{F.75})$$

The unit tangent vectors to the coordinate lines  $q_\alpha$  can thus be determined by:

$$\mathbf{e}_\alpha = \frac{\mathbf{g}_\alpha}{|\mathbf{g}_\alpha|} = \frac{\mathbf{g}_\alpha}{\sqrt{g_\alpha g_\alpha}} = \frac{\mathbf{g}_\alpha}{h_\alpha} \quad (\text{F.76})$$

For orthogonal coordinate systems, we can write:

$$\sqrt{\mathbf{g}_\alpha \cdot \mathbf{g}_\beta} = \sqrt{\frac{\partial x_k}{\partial q_\alpha} \frac{\partial x_k}{\partial q_\beta}} = 0, \quad \text{for } \alpha \neq \beta. \quad (\text{F.77})$$

We may then present a generalization of (F.75), the relation for  $h_\alpha$ :

$$\sqrt{\frac{\partial x_k}{\partial q_\alpha} \frac{\partial x_k}{\partial q_\beta}} = h_\alpha \delta_{\alpha\beta} \quad (\text{F.78})$$

Moreover, since:

$$\frac{\partial q_\alpha}{\partial q_\beta} = \frac{\partial q_\alpha}{\partial x_k} \frac{\partial x_k}{\partial q_\beta} = \delta_{\alpha\beta} \quad (\text{F.79})$$

The equality relation between the last two terms in the above expression can be rewritten as:

$$\left( \frac{\partial q_\alpha}{\partial x_k} \right) = \left( \frac{\partial x_k}{\partial q_\alpha} \right)^{-1} \quad (\text{F.80})$$

Combining the latter three relationships, we obtain:

$$\left( \frac{\partial q_\alpha}{\partial x_k} \frac{\partial q_\beta}{\partial x_k} \right) = \left( \frac{\partial x_k}{\partial q_\alpha} \frac{\partial x_k}{\partial q_\beta} \right)^{-1} = \frac{1}{h_\alpha^2} \delta_{\alpha\beta} \quad (\text{F.81})$$

In Cartesian coordinates the position vector (F.56) is expressed in terms of the unit base vectors  $\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z$ , hence a position vector increment  $d\mathbf{r}$  between two infinitely close points yields:  $d\mathbf{r} = dx\mathbf{e}_x + dy\mathbf{e}_y + dz\mathbf{e}_z$ . The base vectors  $g_\alpha$  in the curvilinear system, called the natural basis of the curvilinear system (also called covariant base vectors), is defined such that the same position vector increment  $d\mathbf{r}$  is given in terms of the curvilinear increments  $dq_\alpha$  by:  $d\mathbf{r} = dq_\alpha \mathbf{e}_\alpha$ . The distance element in curvilinear coordinate systems is then computed as the square of the element of arc length between the two infinitely close points:

$$(ds)^2 = |d\mathbf{r}|^2 = d\mathbf{r} \cdot d\mathbf{r} = g_{\alpha\gamma} dq_\alpha dq_\gamma \quad (\text{F.82})$$

where  $g_{\alpha\gamma} = \mathbf{e}_\alpha \cdot \mathbf{e}_\gamma$  is called the metric tensor.

The basic quantities describing an orthogonal coordinate system are the metric coefficients  $h_1 = \sqrt{g_{11}}, h_2 = \sqrt{g_{22}}, h_3 = \sqrt{g_{33}}$ , which satisfy the formula:

$$(ds)^2 = d\mathbf{r} \cdot d\mathbf{r} = (h_1 dq_1)^2 + (h_2 dq_2)^2 + (h_3 dq_3)^2 \quad (\text{F.83})$$

For the cylindrical coordinates the metric coefficients can be determined from (F.75):

$$h_r = \sqrt{\frac{\partial \mathbf{r}}{\partial r} \cdot \frac{\partial \mathbf{r}}{\partial r}} = 1, \quad h_\theta = \sqrt{\frac{\partial \mathbf{r}}{\partial \theta} \cdot \frac{\partial \mathbf{r}}{\partial \theta}} = r, \quad h_z = \sqrt{\frac{\partial \mathbf{r}}{\partial z} \cdot \frac{\partial \mathbf{r}}{\partial z}} = 1 \quad (\text{F.84})$$

in which we have used the following relations deduced from (F.70):

$$\frac{\partial \mathbf{r}}{\partial r} = \mathbf{e}_r, \quad \frac{\partial \mathbf{r}}{\partial \theta} = r \frac{\partial \mathbf{e}_r}{\partial \theta} = r \mathbf{e}_\theta, \quad \frac{\partial \mathbf{r}}{\partial z} = \mathbf{e}_z \quad (\text{F.85})$$

The del operator can then be written in a generalized form using (F.56), (F.74) and (F.81):

$$\begin{aligned}
\nabla &= \mathbf{e}_k \frac{\partial ()}{\partial x_k} = \left( \frac{\partial q_\alpha}{\partial x_k} \mathbf{g}_\alpha \right) \left( \frac{\partial ()}{\partial q_\beta} \frac{\partial q_\beta}{\partial x_k} \right) = \sum_\alpha \left( \frac{1}{h_\alpha^2} \delta_{\alpha\beta} \right) \mathbf{g}_\alpha \frac{\partial ()}{\partial q_\beta} \\
&= \sum_\alpha \frac{1}{h_\alpha^2} \mathbf{g}_\alpha \frac{\partial ()}{\partial q_\alpha} = \sum_\alpha \frac{1}{h_\alpha} \mathbf{e}_\alpha \frac{\partial ()}{\partial q_\alpha}
\end{aligned} \tag{F.86}$$

where  $\mathbf{e}_k$  denotes the unit vectors in the Cartesian coordinate system and  $\mathbf{e}_\alpha = \frac{\mathbf{g}_\alpha}{h_\alpha}$  is the unit tangent vectors to the coordinate lines  $q_\alpha$ .

The resulting expression for the nabla operator (F.86) are then employed to deduce the transformation formulas for the gradient, divergence, and curl operators in any orthogonal curvilinear coordinate system [49]:

$$\nabla \psi = \sum_\alpha \frac{1}{h_\alpha} \mathbf{e}_\alpha \frac{\partial \psi}{\partial q_\alpha} \tag{F.87}$$

$$\nabla \cdot \mathbf{v} = \sum_\alpha \frac{1}{h_\alpha} \mathbf{e}_\alpha \cdot \frac{\partial (v_\beta \mathbf{e}_\beta)}{\partial q_\alpha} \tag{F.88}$$

$$\text{curl}(\mathbf{v}) = \text{rot}(\mathbf{v}) = \nabla \times \mathbf{v} = \sum_\alpha \frac{1}{h_\alpha} \mathbf{e}_\alpha \times \frac{\partial (v_\beta \mathbf{e}_\beta)}{\partial q_\alpha} \tag{F.89}$$

$$\nabla \mathbf{v} = \sum_\alpha \frac{1}{h_\alpha} \mathbf{e}_\alpha \frac{\partial (v_\beta \mathbf{e}_\beta)}{\partial q_\alpha} \tag{F.90}$$

$$\nabla \cdot \boldsymbol{\sigma} = \sum_\alpha \frac{1}{h_\alpha} \mathbf{e}_\alpha \frac{\partial (\sigma_{\beta\gamma} \mathbf{e}_\beta \mathbf{e}_\gamma)}{\partial q_\alpha} \tag{F.91}$$

The vector  $\mathbf{v}$  is presented in terms of its physical components  $v_\alpha$  in such a way that:

$$\mathbf{v} = v_\alpha \mathbf{e}_\alpha \tag{F.92}$$

where  $\mathbf{e}_\alpha$  is the unit tangent vector to the coordinate lines in the orthogonal  $q_\alpha$ -system.

The orthogonal curvilinear unit vectors just introduced obey certain laws, which are used in the subsequent paragraphs. The scalar or dot product of two unit vectors yields:

$$\mathbf{e}_\alpha \cdot \mathbf{e}_\beta = \delta_{\alpha\beta} \tag{F.93}$$

The vector or cross product of two unit vectors is defined by:

$$\mathbf{e}_\alpha \times \mathbf{e}_\beta = \sum_{\gamma=1}^3 \epsilon_{\alpha\beta\gamma} \mathbf{e}_\gamma \tag{F.94}$$

Many formulas in tensor analysis are expressed compactly in terms of the *Kronecker delta*,  $\delta_{\alpha\beta}$ , and the *alternating unit tensor*,  $\epsilon_{\alpha\beta\gamma}$ . These entities are defined as:

$$\delta_{\alpha\beta} = \begin{cases} +1 & \text{if } \alpha = \beta \\ 0 & \text{if } \alpha \neq \beta \end{cases} \quad (\text{F.95})$$

$$\epsilon_{\alpha\beta\gamma} = \begin{cases} +1 & \text{if } \alpha\beta\gamma = 123, 231, \text{ or } 312 \\ -1 & \text{if } \alpha\beta\gamma = 321, 132, \text{ or } 213 \\ 0 & \text{if any two indices are alike} \end{cases} \quad (\text{F.96})$$

### ***F.2.5 Differential Operators in Cylindrical Coordinates***

In this section the cylindrical coordinate transforms are deduced from the formulas presented in the preceding subsections.

From (F.92) we recognize that a vector in cylindrical coordinates yields:

$$\mathbf{v} = v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z \quad (\text{F.97})$$

where  $\mathbf{e}_r$ ,  $\mathbf{e}_\theta$ , and  $\mathbf{e}_z$  are the unit vectors in the radial, azimuthal, and axial directions, respectively.

The nabla-operator is given by (F.86):

$$\nabla = \sum_{\alpha} \frac{1}{h_{\alpha}} \mathbf{e}_{\alpha} \frac{\partial}{\partial q_{\alpha}} = \mathbf{e}_r \frac{\partial}{\partial r} + \mathbf{e}_{\theta} \frac{1}{r} \frac{\partial}{\partial \theta} + \mathbf{e}_z \frac{\partial}{\partial z}. \quad (\text{F.98})$$

#### **Gradient of a scalar**

The gradient of a scalar  $\psi$  is:

$$\text{grad}(\psi) = \nabla\psi = \sum_{\alpha} \frac{1}{h_{\alpha}} \mathbf{e}_{\alpha} \frac{\partial \psi}{\partial q_{\alpha}} = \mathbf{e}_r \frac{\partial \psi}{\partial r} + \mathbf{e}_{\theta} \frac{1}{r} \frac{\partial \psi}{\partial \theta} + \mathbf{e}_z \frac{\partial \psi}{\partial z} \quad (\text{F.99})$$

which is a vector.

#### **Divergence of a vector**

If  $\mathbf{v}$  is a vector, the divergence of  $\mathbf{v}$  is:

$$\begin{aligned} \text{div}(\mathbf{v}) &= \nabla \cdot \mathbf{v} = \sum_{\alpha} \frac{1}{h_{\alpha}} \mathbf{e}_{\alpha} \cdot \frac{\partial}{\partial q_{\alpha}} (v_{\beta} \mathbf{e}_{\beta}) \\ &= \mathbf{e}_r \cdot \frac{\partial}{\partial r} (v_{\beta} \mathbf{e}_{\beta}) + \mathbf{e}_{\theta} \frac{1}{r} \cdot \frac{\partial}{\partial \theta} (v_{\beta} \mathbf{e}_{\beta}) + \mathbf{e}_z \cdot \frac{\partial}{\partial z} (v_k \mathbf{e}_k) \end{aligned} \quad (\text{F.100})$$

$$\begin{aligned}
&= \frac{\partial v_r}{\partial r} + \mathbf{e}_\theta \frac{1}{r} \cdot \frac{\partial}{\partial \theta} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta) + \frac{\partial v_z}{\partial z} \\
&= \frac{\partial v_r}{\partial r} + \mathbf{e}_\theta \frac{1}{r} \cdot \left( v_r \frac{\partial \mathbf{e}_r}{\partial \theta} + \mathbf{e}_r \frac{\partial v_r}{\partial \theta} + \frac{\partial}{\partial \theta} (v_\theta \mathbf{e}_\theta) \right) + \frac{\partial v_z}{\partial z} \\
&= \frac{\partial v_r}{\partial r} + \mathbf{e}_\theta \frac{1}{r} \cdot \left( v_r \mathbf{e}_\theta + \mathbf{e}_r \frac{\partial v_r}{\partial \theta} + \frac{\partial}{\partial \theta} (v_\theta \mathbf{e}_\theta) \right) + \frac{\partial v_z}{\partial z} \\
&= \frac{\partial v_r}{\partial r} + \frac{1}{r} \left( v_r + \frac{\partial v_\theta}{\partial \theta} \right) + \frac{\partial v_z}{\partial z} \\
&= \frac{1}{r} \frac{\partial}{\partial r} (r v_r) + \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{\partial v_z}{\partial z}
\end{aligned}$$

which is scalar.

### Gradient of a vector

Let  $\mathbf{v}$  represent a vector, the gradient of  $\mathbf{v}$  is:

$$\begin{aligned}
\text{grad } (\mathbf{v}) &= \nabla \mathbf{v} = \sum_{\alpha} \frac{1}{h_{\alpha}} \mathbf{e}_{\alpha} \frac{\partial}{\partial q_{\alpha}} (v_{\beta} \mathbf{e}_{\beta}) \\
&= \mathbf{e}_r \frac{\partial}{\partial r} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z) \\
&\quad + \frac{1}{r} \mathbf{e}_\theta \frac{\partial}{\partial \theta} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z) \\
&\quad + \mathbf{e}_z \frac{\partial}{\partial z} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z) \\
&= \mathbf{e}_r \mathbf{e}_r \frac{\partial v_r}{\partial r} + \mathbf{e}_r \mathbf{e}_\theta \frac{\partial v_\theta}{\partial r} + \mathbf{e}_r \mathbf{e}_z \frac{\partial v_z}{\partial r} \\
&\quad + \frac{1}{r} \mathbf{e}_\theta \mathbf{e}_r \frac{\partial v_r}{\partial \theta} + \frac{1}{r} \mathbf{e}_\theta \mathbf{e}_\theta v_r + \frac{1}{r} \mathbf{e}_\theta \mathbf{e}_\theta \frac{\partial v_\theta}{\partial \theta} - \frac{1}{r} \mathbf{e}_\theta \mathbf{e}_r v_\theta + \frac{1}{r} \mathbf{e}_\theta \mathbf{e}_z \frac{\partial v_z}{\partial \theta} \\
&\quad + \mathbf{e}_z \mathbf{e}_r \frac{\partial v_r}{\partial z} + \mathbf{e}_z \mathbf{e}_\theta \frac{\partial v_\theta}{\partial z} + \mathbf{e}_z \mathbf{e}_z \frac{\partial v_z}{\partial z} \\
&= \mathbf{e}_r \mathbf{e}_r \frac{\partial v_r}{\partial r} + \mathbf{e}_r \mathbf{e}_\theta \frac{\partial v_\theta}{\partial r} + \mathbf{e}_r \mathbf{e}_z \frac{\partial v_z}{\partial r} \\
&\quad + \mathbf{e}_\theta \mathbf{e}_r \frac{\partial}{\partial \theta} \left( \frac{1}{r} \frac{\partial v_r}{\partial \theta} - \frac{1}{r} v_\theta \right) + \mathbf{e}_\theta \mathbf{e}_\theta \left( \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{1}{r} v_r \right) + \mathbf{e}_\theta \mathbf{e}_z \frac{1}{r} \frac{\partial v_z}{\partial \theta} \\
&\quad + \mathbf{e}_z \mathbf{e}_r \frac{\partial v_r}{\partial z} + \mathbf{e}_z \mathbf{e}_\theta \frac{\partial v_\theta}{\partial z} + \mathbf{e}_z \mathbf{e}_z \frac{\partial v_z}{\partial z} \tag{F.101}
\end{aligned}$$

The product is a second-order tensor, or a dyadic product.

### Divergence of a second-order tensor

The unit dyads may be multiplied with each other and with the unit vectors:

$$\mathbf{e}_\alpha : \mathbf{e}_\beta = \delta_{\alpha\kappa} \delta_{\beta\gamma} \quad (\text{F.102})$$

$$\mathbf{e}_\alpha \mathbf{e}_\beta \cdot \mathbf{e}_\gamma = \mathbf{e}_\alpha \delta_{\beta\gamma} \quad (\text{F.103})$$

$$\mathbf{e}_\alpha \cdot \mathbf{e}_\beta \mathbf{e}_\gamma = \delta_{\alpha\beta} \mathbf{e}_\gamma \quad (\text{F.104})$$

$$\mathbf{e}_\alpha \mathbf{e}_\beta \cdot \mathbf{e}_\gamma \mathbf{e}_\kappa = \delta_{\beta\gamma} \mathbf{e}_\alpha \mathbf{e}_\kappa \quad (\text{F.105})$$

Then, if  $\mathbf{A}$  is a second order tensor, or a dyad, the divergence of  $\mathbf{A}$  is:

$$\begin{aligned} \text{div } (\mathbf{A}) = \nabla \cdot \mathbf{A} &= \sum_{\alpha} \frac{1}{h_{\alpha}} \frac{\partial}{\partial q_{\alpha}} (A_{\gamma\kappa} \mathbf{e}_{\gamma} \mathbf{e}_{\kappa} \cdot \mathbf{e}_{\alpha}) \\ &= \frac{\partial}{\partial r} (A_{\gamma\kappa} \mathbf{e}_{\gamma} \mathbf{e}_{\kappa}) \cdot \mathbf{e}_r + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{\gamma\kappa} \mathbf{e}_{\gamma} \mathbf{e}_{\kappa}) \cdot \mathbf{e}_{\theta} + \frac{\partial}{\partial z} (A_{\gamma\kappa} \mathbf{e}_{\gamma} \mathbf{e}_{\kappa}) \cdot \mathbf{e}_z \\ &= \frac{\partial}{\partial r} (A_{\gamma\kappa}) \mathbf{e}_{\gamma} \mathbf{e}_{\kappa} \cdot \mathbf{e}_r + A_{\gamma\kappa} \frac{\partial}{\partial r} (\mathbf{e}_{\gamma} \mathbf{e}_{\kappa}) \cdot \mathbf{e}_r \\ &\quad + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{\gamma\kappa}) \mathbf{e}_{\gamma} \mathbf{e}_{\kappa} \cdot \mathbf{e}_{\theta} + \frac{1}{r} A_{\gamma\kappa} \frac{\partial}{\partial \theta} (\mathbf{e}_{\gamma} \mathbf{e}_{\kappa}) \cdot \mathbf{e}_{\theta} \\ &\quad + \frac{\partial}{\partial z} (A_{\gamma\kappa}) \mathbf{e}_{\gamma} \mathbf{e}_{\kappa} \cdot \mathbf{e}_z + A_{\gamma\kappa} \frac{\partial}{\partial z} (\mathbf{e}_{\gamma} \mathbf{e}_{\kappa}) \cdot \mathbf{e}_z \\ &= \frac{\partial}{\partial r} (A_{rr}) \mathbf{e}_r + \frac{\partial}{\partial r} (A_{\theta r}) \mathbf{e}_{\theta} + \frac{\partial}{\partial r} (A_{zr}) \mathbf{e}_z \\ &\quad + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{r\theta}) \mathbf{e}_r + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{\theta\theta}) \mathbf{e}_{\theta} + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{z\theta}) \mathbf{e}_z \\ &\quad + \frac{1}{r} A_{kr} \mathbf{e}_k + \frac{1}{r} A_{k\theta} \left( \frac{\partial \mathbf{e}_k}{\partial \theta} \mathbf{e}_{\theta} \cdot \mathbf{e}_{\theta} \right) \\ &\quad + \frac{\partial}{\partial z} (A_{rz}) \mathbf{e}_r + \frac{\partial}{\partial z} (A_{\theta z}) \mathbf{e}_{\theta} + \frac{\partial}{\partial z} (A_{zz}) \mathbf{e}_z \\ &= \frac{\partial}{\partial r} (A_{rr}) \mathbf{e}_r + \frac{\partial}{\partial r} (A_{\theta r}) \mathbf{e}_{\theta} + \frac{\partial}{\partial r} (A_{zr}) \mathbf{e}_z \\ &\quad + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{r\theta}) \mathbf{e}_r + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{\theta\theta}) \mathbf{e}_{\theta} + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{z\theta}) \mathbf{e}_z \\ &\quad + \frac{1}{r} A_{rr} \mathbf{e}_r + \frac{1}{r} A_{\theta r} \mathbf{e}_{\theta} + \frac{1}{r} A_{zr} \mathbf{e}_z + \frac{1}{r} A_{\theta\theta} \mathbf{e}_{\theta} - \frac{1}{r} A_{\theta\theta} \mathbf{e}_r \\ &\quad + \frac{\partial}{\partial z} (A_{rz}) \mathbf{e}_r + \frac{\partial}{\partial z} (A_{\theta z}) \mathbf{e}_{\theta} + \frac{\partial}{\partial z} (A_{zz}) \mathbf{e}_z \\ &= \mathbf{e}_r \left[ \frac{\partial}{\partial r} (A_{rr}) + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{r\theta}) + \frac{1}{r} A_{rr} - \frac{1}{r} A_{\theta\theta} + \frac{\partial}{\partial z} (A_{rz}) \right] \\ &\quad + \mathbf{e}_{\theta} \left[ \frac{\partial}{\partial r} (A_{\theta r}) + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{\theta\theta}) + \frac{1}{r} A_{\theta r} + \frac{1}{r} A_{r\theta} + \frac{\partial}{\partial z} (A_{\theta z}) \right] \end{aligned}$$

$$\begin{aligned}
& + \mathbf{e}_z \left[ \frac{\partial}{\partial r} (A_{zr}) + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{z\theta}) + \frac{1}{r} A_{zr} + \frac{\partial}{\partial z} (A_{zz}) \right] \\
= & \mathbf{e}_r \left[ \frac{1}{r} \frac{\partial}{\partial r} (rA_{rr}) + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{r\theta}) + \frac{\partial}{\partial z} (A_{rz}) - \frac{1}{r} A_{\theta\theta} \right] \\
& + \mathbf{e}_\theta \left[ \frac{1}{r} \frac{\partial}{\partial r} (rA_{\theta r}) + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{\theta\theta}) + \frac{\partial}{\partial z} (A_{\theta z}) + \frac{1}{r} A_{r\theta} \right] \\
& + \mathbf{e}_z \left[ \frac{1}{r} \frac{\partial}{\partial r} (rA_{zr}) + \frac{1}{r} \frac{\partial}{\partial \theta} (A_{z\theta}) + \frac{\partial}{\partial z} (A_{zz}) \right] \tag{F.106}
\end{aligned}$$

which is a vector.

### The Laplacian of a Scalar Field

If we take the divergence of the gradient of the scalar function  $\psi$ , as is done for the pressure field formulating an equation for the pressure, we obtain:

$$\begin{aligned}
\nabla^2 \psi &= \nabla \cdot \nabla \psi = \nabla \cdot \text{grad}(\psi) \\
&= \left( \mathbf{e}_r \frac{\partial}{\partial r} + \mathbf{e}_\theta \frac{1}{r} \frac{\partial}{\partial \theta} + \mathbf{e}_z \frac{\partial}{\partial z} \right) \cdot \left( \mathbf{e}_r \frac{\partial \psi}{\partial r} + \mathbf{e}_\theta \frac{1}{r} \frac{\partial \psi}{\partial \theta} + \mathbf{e}_z \frac{\partial \psi}{\partial z} \right) \\
&= \frac{\partial^2 \psi}{\partial r^2} + \mathbf{e}_r \frac{\partial}{\partial r} \cdot \mathbf{e}_\theta \frac{1}{r} \frac{\partial \psi}{\partial \theta} + \mathbf{e}_\theta \frac{1}{r} \frac{\partial}{\partial \theta} \cdot \mathbf{e}_r \frac{\partial \psi}{\partial r} + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial z^2} \\
&= \frac{\partial^2 \psi}{\partial r^2} + \left( \mathbf{e}_r \cdot \frac{1}{r} \frac{\partial \psi}{\partial \theta} \frac{\partial \mathbf{e}_\theta}{\partial r} \right) + \mathbf{e}_r \cdot \mathbf{e}_\theta \frac{\partial}{\partial r} \left( \frac{1}{r} \frac{\partial \psi}{\partial \theta} \right) \\
&\quad + \mathbf{e}_\theta \frac{1}{r} \cdot \frac{\partial}{\partial \theta} \left( \mathbf{e}_r \frac{\partial \psi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial z^2} \tag{F.107} \\
&= \frac{\partial^2 \psi}{\partial r^2} + \mathbf{e}_\theta \frac{1}{r} \cdot \left( \frac{\partial \alpha}{\partial r} \frac{\partial \mathbf{e}_r}{\partial \theta} + \mathbf{e}_r \frac{\partial}{\partial \theta} \frac{\partial \psi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \alpha}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial z^2} \\
&= \frac{\partial^2 \psi}{\partial r^2} + \mathbf{e}_\theta \frac{1}{r} \cdot \frac{\partial \alpha}{\partial r} \mathbf{e}_\theta + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial z^2} \\
&= \frac{\partial^2 \psi}{\partial r^2} + \frac{1}{r} \frac{\partial \psi}{\partial r} + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial z^2} \\
&= \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \psi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \psi}{\partial \theta^2} + \frac{\partial^2 \psi}{\partial z^2}
\end{aligned}$$

The result is a scalar.

### The Curl of a Vector Field

$$\text{curl}(\mathbf{v}) = \text{rot}(\mathbf{v}) = \nabla \times \mathbf{v} = \sum_{\alpha} \frac{1}{h_{\alpha}} \mathbf{e}_{\alpha} \times \frac{\partial (v_{\beta} \mathbf{e}_{\beta})}{\partial q_{\alpha}}$$

$$\begin{aligned}
&= \mathbf{e}_r \times \frac{\partial (v_\beta \mathbf{e}_\beta)}{\partial r} + \frac{1}{r} \mathbf{e}_\theta \times \frac{\partial (v_\beta \mathbf{e}_\beta)}{\partial \theta} + \mathbf{e}_z \times \frac{\partial (v_\beta \mathbf{e}_\beta)}{\partial z} \\
&= \mathbf{e}_r \times \frac{\partial}{\partial r} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z) + \frac{1}{r} \mathbf{e}_\theta \times \frac{\partial}{\partial \theta} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z) \\
&\quad + \mathbf{e}_z \times \frac{\partial}{\partial z} (v_r \mathbf{e}_r + v_\theta \mathbf{e}_\theta + v_z \mathbf{e}_z) \\
&= \mathbf{e}_r \times \left( v_r \frac{\partial \mathbf{e}_r}{\partial r} + \frac{\partial v_r}{\partial r} \mathbf{e}_r + v_\theta \frac{\partial \mathbf{e}_\theta}{\partial r} + \frac{\partial v_\theta}{\partial r} \mathbf{e}_\theta + v_z \frac{\partial \mathbf{e}_z}{\partial r} + \frac{\partial v_z}{\partial r} \mathbf{e}_z \right) \\
&\quad + \frac{1}{r} \mathbf{e}_\theta \times \left( v_r \frac{\partial \mathbf{e}_r}{\partial \theta} + \frac{\partial v_r}{\partial \theta} \mathbf{e}_r + v_\theta \frac{\partial \mathbf{e}_\theta}{\partial \theta} + \frac{\partial v_\theta}{\partial \theta} \mathbf{e}_\theta + v_z \frac{\partial \mathbf{e}_z}{\partial \theta} + \frac{\partial v_z}{\partial \theta} \mathbf{e}_z \right) \\
&\quad + \mathbf{e}_z \times \left( v_r \frac{\partial \mathbf{e}_r}{\partial z} + \frac{\partial v_r}{\partial z} \mathbf{e}_r + v_\theta \frac{\partial \mathbf{e}_\theta}{\partial z} + \frac{\partial v_\theta}{\partial z} \mathbf{e}_\theta + v_z \frac{\partial \mathbf{e}_z}{\partial z} + \frac{\partial v_z}{\partial z} \mathbf{e}_z \right) \\
&= \mathbf{e}_r \times \left( \frac{\partial v_r}{\partial r} \mathbf{e}_r + \frac{\partial v_\theta}{\partial r} \mathbf{e}_\theta + \frac{\partial v_z}{\partial r} \mathbf{e}_z \right) \\
&\quad + \frac{1}{r} \mathbf{e}_\theta \times \left( v_r \mathbf{e}_\theta + \frac{\partial v_r}{\partial \theta} \mathbf{e}_r - v_\theta \mathbf{e}_r + \frac{\partial v_\theta}{\partial \theta} \mathbf{e}_\theta + \frac{\partial v_z}{\partial \theta} \mathbf{e}_z \right) \\
&\quad + \mathbf{e}_z \times \left( \frac{\partial v_r}{\partial z} \mathbf{e}_r + \frac{\partial v_\theta}{\partial z} \mathbf{e}_\theta + \frac{\partial v_z}{\partial z} \mathbf{e}_z \right) \\
&= \mathbf{e}_r \times \left( \frac{\partial v_\theta}{\partial r} \mathbf{e}_\theta + \frac{\partial v_z}{\partial r} \mathbf{e}_z \right) + \frac{1}{r} \mathbf{e}_\theta \times \left( \frac{\partial v_r}{\partial \theta} \mathbf{e}_r - v_\theta \mathbf{e}_r + \frac{\partial v_z}{\partial \theta} \mathbf{e}_z \right) \\
&\quad + \mathbf{e}_z \times \left( \frac{\partial v_r}{\partial z} \mathbf{e}_r + \frac{\partial v_\theta}{\partial z} \mathbf{e}_\theta \right)
\end{aligned}$$

The vector or cross product of two unit vectors was defined by (F.94), hence in cylindrical coordinates the following relations are valid:

$$\mathbf{e}_r \times \mathbf{e}_\theta = \epsilon_{r\theta\gamma} \mathbf{e}_\gamma = \epsilon_{r\theta z} \mathbf{e}_z = \mathbf{e}_z \quad (\text{F.108})$$

$$\mathbf{e}_r \times \mathbf{e}_z = \epsilon_{rz\theta} \mathbf{e}_\theta = -\mathbf{e}_\theta \quad (\text{F.109})$$

$$\mathbf{e}_\theta \times \mathbf{e}_r = \epsilon_{\theta rz} \mathbf{e}_z = -\mathbf{e}_z \quad (\text{F.110})$$

$$\mathbf{e}_\theta \times \mathbf{e}_z = \epsilon_{\theta zr} \mathbf{e}_r = \mathbf{e}_r \quad (\text{F.111})$$

$$\mathbf{e}_z \times \mathbf{e}_r = \epsilon_{zr\theta} \mathbf{e}_\theta = \mathbf{e}_\theta \quad (\text{F.112})$$

$$\mathbf{e}_z \times \mathbf{e}_\theta = \epsilon_{z\theta r} \mathbf{e}_r = -\mathbf{e}_r \quad (\text{F.113})$$

Introducing these relations into the above expression for the *Curl* operator gives:

$$\begin{aligned}
\text{curl}(\mathbf{v}) &= \frac{\partial v_\theta}{\partial r} \mathbf{e}_z - \frac{\partial v_z}{\partial r} \mathbf{e}_\theta - \frac{1}{r} \frac{\partial v_r}{\partial \theta} \mathbf{e}_z + \frac{v_\theta}{r} \mathbf{e}_z + \frac{1}{r} \frac{\partial v_z}{\partial \theta} \mathbf{e}_r + \frac{\partial v_r}{\partial z} \mathbf{e}_\theta - \frac{\partial v_\theta}{\partial z} \mathbf{e}_r \\
&= \mathbf{e}_r \left( \frac{1}{r} \frac{\partial v_z}{\partial \theta} - \frac{\partial v_\theta}{\partial z} \right) + \mathbf{e}_\theta \left( \frac{\partial v_r}{\partial z} - \frac{\partial v_z}{\partial r} \right) + \mathbf{e}_z \left( \frac{\partial v_\theta}{\partial r} - \frac{1}{r} \frac{\partial v_r}{\partial \theta} + \frac{v_\theta}{r} \right)
\end{aligned}$$

$$= \mathbf{e}_r \left( \frac{1}{r} \frac{\partial v_z}{\partial \theta} - \frac{\partial v_\theta}{\partial z} \right) + \mathbf{e}_\theta \left( \frac{\partial v_r}{\partial z} - \frac{\partial v_z}{\partial r} \right) + \mathbf{e}_z \left( \frac{1}{r} \frac{\partial (rv_\theta)}{\partial r} - \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right).$$

### ***F.2.6 Differential Operators Required for the Two-fluid Model***

In this section the governing equations are transformed from vector notation to cylindrical coordinates.

#### **Gradient of a scalar**

The pressure gradient is one of the gradients of a scalar variable that are part of the equations in question. In cylindrical coordinates it is determined as:

$$\nabla \bar{p} = \frac{\partial \bar{p}}{\partial r} \mathbf{e}_r + \frac{1}{r} \frac{\partial \bar{p}}{\partial \theta} \mathbf{e}_\theta + \frac{\partial \bar{p}}{\partial z} \mathbf{e}_z. \quad (\text{F.114})$$

#### **Divergence of a vector**

In all the scalar equations a convective term on the form  $\nabla \cdot (\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l)$  is included. In cylindrical coordinates this term is expressed as:

$$\nabla \cdot (\bar{\alpha}_l \rho_l \bar{\mathbf{v}}_l) = \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r}) + \frac{1}{r} \frac{\partial}{\partial \theta} (\bar{\alpha}_l \rho_l \bar{v}_{l,\theta}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z}). \quad (\text{F.115})$$

#### **Divergence of a gradient**

In the scalar equations there are also terms like  $\nabla \cdot \left( \frac{\mu_{l,t}}{\sigma_t} \nabla \bar{\alpha}_l \right)$ . This term is identical in form to the previous one, since the gradient is just a vector. In cylindrical coordinates the term is written as:

$$\nabla \cdot \left( \frac{\mu_{l,t}}{\sigma_t} \nabla \bar{\alpha}_l \right) = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_t} \frac{\partial \bar{\alpha}_l}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_t} \frac{1}{r} \frac{\partial \bar{\alpha}_l}{\partial \theta} \right) + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_t} \frac{\partial \bar{\alpha}_l}{\partial z} \right). \quad (\text{F.116})$$

#### **Divergence of a dyad**

Generally, the divergence of a dyad or 2. order tensor, say  $\boldsymbol{\sigma}$ , is transformed as:

$$\begin{aligned}
\nabla \cdot \boldsymbol{\sigma} = & \left( \frac{1}{r} \frac{\partial}{\partial r} (r \sigma_{rr}) + \frac{1}{r} \frac{\partial}{\partial \theta} (\sigma_{\theta r}) - \frac{1}{r} \sigma_{\theta \theta} + \frac{\partial}{\partial z} (\sigma_{zr}) \right) \mathbf{e}_r \\
& + \left( \frac{1}{r} \frac{\partial}{\partial \theta} (\sigma_{\theta \theta}) + \frac{1}{r} \frac{\partial}{\partial r} (r \sigma_{r\theta}) + \frac{1}{r} \sigma_{\theta r} + \frac{\partial}{\partial z} (\sigma_{z\theta}) \right) \mathbf{e}_\theta \\
& + \left( \frac{1}{r} \frac{\partial}{\partial r} (r \sigma_{rz}) + \frac{1}{r} \frac{\partial}{\partial \theta} (\sigma_{\theta z}) + \frac{\partial}{\partial z} (\sigma_{zz}) \right) \mathbf{e}_z
\end{aligned} \quad (\text{F.117})$$

The dyad  $\bar{\mathbf{v}} \bar{\mathbf{v}}$  is symmetric. In cylindrical coordinates  $\nabla \cdot (\bar{\alpha} \rho \bar{\mathbf{v}} \bar{\mathbf{v}})$  is given as:

$$\begin{aligned}
\nabla \cdot (\bar{\alpha} \rho \bar{\mathbf{v}} \bar{\mathbf{v}}) = & \left( \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha} \rho \bar{v}_r \bar{v}_r) + \frac{1}{r} \frac{\partial}{\partial \theta} (\bar{\alpha} \rho \bar{v}_\theta \bar{v}_r) - \frac{1}{r} \bar{\alpha} \rho \bar{v}_\theta \bar{v}_\theta + \frac{\partial}{\partial z} (\bar{\alpha} \rho \bar{v}_z \bar{v}_r) \right) \mathbf{e}_r \\
& + \left( \frac{1}{r} \frac{\partial}{\partial \theta} (\bar{\alpha} \rho \bar{v}_\theta \bar{v}_\theta) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha} \rho \bar{v}_r \bar{v}_\theta) + \frac{1}{r} \bar{\alpha} \rho \bar{v}_\theta \bar{v}_r + \frac{\partial}{\partial z} (\bar{\alpha} \rho \bar{v}_z \bar{v}_\theta) \right) \mathbf{e}_\theta \\
& + \left( \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha} \rho \bar{v}_r \bar{v}_z) + \frac{1}{r} \frac{\partial}{\partial \theta} (\bar{\alpha} \rho \bar{v}_\theta \bar{v}_z) + \frac{\partial}{\partial z} (\bar{\alpha} \rho \bar{v}_z \bar{v}_z) \right) \mathbf{e}_z
\end{aligned} \quad (\text{F.118})$$

The terms similar to  $\nabla \cdot (\frac{\mu_{l,t}}{\sigma_{\alpha,t}} \nabla \bar{\alpha} \bar{\mathbf{v}})$  are also divergences of a dyad.  $\nabla \bar{\alpha} \bar{\mathbf{v}}$  is not symmetric.

$$\begin{aligned}
\nabla \cdot \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \nabla \bar{\alpha} \bar{\mathbf{v}} \right) = & \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} \bar{v}_r \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \bar{v}_r \right) - \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r^2} \frac{\partial \bar{\alpha}}{\partial \theta} \bar{v}_\theta + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial z} \bar{v}_r \right) \right) \mathbf{e}_r \\
& + \left( \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \bar{v}_\theta \right) + \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} \bar{v}_\theta \right) + \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r^2} \frac{\partial \bar{\alpha}}{\partial \theta} \bar{v}_r + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial z} \bar{v}_\theta \right) \right) \mathbf{e}_\theta \\
& + \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} \bar{v}_z \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \bar{v}_z \right) + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial z} \bar{v}_z \right) \right) \mathbf{e}_z
\end{aligned} \quad (\text{F.119})$$

The term  $\nabla \cdot (\frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{\mathbf{v}} \nabla \bar{\alpha})$  is very similar to the previous one:

$$\begin{aligned}
\nabla \cdot \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{\mathbf{v}} \nabla \bar{\alpha} \right) = & \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_r \frac{\partial \bar{\alpha}}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_\theta \frac{\partial \bar{\alpha}}{\partial r} \right) - \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r^2} \bar{v}_\theta \frac{\partial \bar{\alpha}}{\partial \theta} + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_z \frac{\partial \bar{\alpha}}{\partial r} \right) \right) \mathbf{e}_r \\
& + \left( \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_\theta \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \right) + \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_r \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \right) + \frac{1}{r^2} \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_r \frac{\partial \bar{\alpha}}{\partial \theta} + \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \bar{v}_\theta \frac{\partial \bar{\alpha}}{\partial r} \right. \\
& \left. + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_z \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \right) \right) \mathbf{e}_\theta \\
& + \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_r \frac{\partial \bar{\alpha}}{\partial z} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_\theta \frac{\partial \bar{\alpha}}{\partial z} \right) + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \bar{v}_z \frac{\partial \bar{\alpha}}{\partial z} \right) \right) \mathbf{e}_z
\end{aligned} \quad (\text{F.120})$$

In cylindrical coordinates the term  $\nabla \cdot (\bar{\alpha} \mu \nabla \bar{\mathbf{v}})$  is expressed as:

$$\begin{aligned}
& \nabla \cdot \left( \bar{\alpha} \mu \nabla \bar{\mathbf{v}} \right) \\
&= \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \bar{\alpha} \mu \frac{\partial \bar{v}_r}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_r}{\partial \theta} - \frac{\bar{v}_\theta}{r} \right) \right) - \frac{1}{r} \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_\theta}{\partial \theta} + \frac{\bar{v}_r}{r} \right) \right. \\
&\quad \left. + \frac{\partial}{\partial z} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_r}{\partial z} \right) \right) \mathbf{e}_r \\
&\quad + \left( \frac{1}{r} \frac{\partial}{\partial \theta} \left( \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_\theta}{\partial \theta} + \frac{\bar{v}_r}{r} \right) \right) + \frac{1}{r} \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_r}{\partial \theta} - \frac{\bar{v}_\theta}{r} \right) + \frac{1}{r} \frac{\partial}{\partial r} \left( r \bar{\alpha} \mu \frac{\partial \bar{v}_\theta}{\partial r} \right) \right. \\
&\quad \left. + \frac{\partial}{\partial z} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_\theta}{\partial z} \right) \right) \mathbf{e}_\theta \\
&\quad + \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \bar{\alpha} \mu \frac{\partial \bar{v}_z}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_z}{\partial \theta} \right) + \frac{\partial}{\partial z} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_z}{\partial z} \right) \right) \mathbf{e}_z
\end{aligned} \tag{F.121}$$

The divergence of the transpose of the gradient of a vector  $\nabla(\bar{\alpha} \mu (\nabla \bar{\mathbf{v}})^T)$  in cylindrical coordinates is written:

$$\begin{aligned}
& \nabla \cdot \left( \bar{\alpha} \mu (\nabla \bar{\mathbf{v}})^T \right) \\
&= \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \bar{\alpha} \mu \frac{\partial \bar{v}_r}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_\theta}{\partial r} \right) - \frac{1}{r} \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_\theta}{\partial \theta} + \frac{\bar{v}_r}{r} \right) + \frac{\partial}{\partial z} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_z}{\partial r} \right) \right) \mathbf{e}_r \\
&\quad + \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_r}{\partial \theta} - \frac{\bar{v}_\theta}{r} \right) \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \bar{\alpha} \mu \left( \frac{1}{r} \frac{\partial \bar{v}_\theta}{\partial \theta} + \frac{\bar{v}_r}{r} \right) \right) + \frac{1}{r} \bar{\alpha} \mu \frac{\partial \bar{v}_\theta}{\partial r} \right. \\
&\quad \left. + \frac{\partial}{\partial z} \left( \bar{\alpha} \mu \frac{1}{r} \frac{\partial \bar{v}_z}{\partial \theta} \right) \right) \mathbf{e}_\theta \\
&\quad + \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \bar{\alpha} \mu \frac{\partial \bar{v}_r}{\partial z} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_\theta}{\partial z} \right) + \frac{\partial}{\partial z} \left( \bar{\alpha} \mu \frac{\partial \bar{v}_z}{\partial z} \right) \right) \mathbf{e}_z.
\end{aligned} \tag{F.122}$$

### Gradient of a vector

The gradient of  $\bar{\mathbf{v}}$  is part of the momentum equations. In cylindrical coordinates it is expressed as:

$$\begin{aligned}
\nabla \bar{\mathbf{v}} &= \frac{\partial \bar{v}_r}{\partial r} \mathbf{e}_r \mathbf{e}_r + \frac{\partial \bar{v}_\theta}{\partial r} \mathbf{e}_r \mathbf{e}_\theta + \frac{\partial \bar{v}_z}{\partial r} \mathbf{e}_r \mathbf{e}_z \\
&\quad + \left( \frac{1}{r} \frac{\partial \bar{v}_r}{\partial \theta} - \frac{\bar{v}_\theta}{r} \right) \mathbf{e}_\theta \mathbf{e}_r + \left( \frac{1}{r} \frac{\partial \bar{v}_\theta}{\partial \theta} + \frac{\bar{v}_r}{r} \right) \mathbf{e}_\theta \mathbf{e}_\theta + \frac{1}{r} \frac{\partial \bar{v}_z}{\partial \theta} \mathbf{e}_\theta \mathbf{e}_z \\
&\quad + \frac{\partial \bar{v}_r}{\partial z} \mathbf{e}_z \mathbf{e}_r + \frac{\partial \bar{v}_\theta}{\partial z} \mathbf{e}_z \mathbf{e}_\theta + \frac{\partial \bar{v}_z}{\partial z} \mathbf{e}_z \mathbf{e}_z.
\end{aligned} \tag{F.123}$$

### The dot product $\nabla \bar{\alpha} \cdot \nabla \bar{\mathbf{v}}$

In cylindrical coordinates this term is written as:

$$\begin{aligned} \nabla \bar{\alpha} \cdot \nabla \bar{\mathbf{v}} = & \left( \frac{\partial \bar{\alpha}}{\partial r} \frac{\partial \bar{v}_r}{\partial r} + \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \left( \frac{1}{r} \frac{\partial \bar{v}_r}{\partial \theta} - \frac{\bar{v}_\theta}{r} \right) + \frac{\partial \bar{\alpha}}{\partial z} \frac{\partial \bar{v}_r}{\partial z} \right) \mathbf{e}_r \\ & + \left( \frac{\partial \bar{\alpha}}{\partial r} \frac{\partial \bar{v}_\theta}{\partial r} + \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \left( \frac{1}{r} \frac{\partial \bar{v}_\theta}{\partial \theta} + \frac{\bar{v}_r}{r} \right) + \frac{\partial \bar{\alpha}}{\partial z} \frac{\partial \bar{v}_\theta}{\partial z} \right) \mathbf{e}_\theta \\ & + \left( \frac{\partial \bar{\alpha}}{\partial r} \frac{\partial \bar{v}_z}{\partial r} + \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \frac{1}{r} \frac{\partial \bar{v}_z}{\partial \theta} + \frac{\partial \bar{\alpha}}{\partial z} \frac{\partial \bar{v}_z}{\partial z} \right) \mathbf{e}_z. \end{aligned} \quad (\text{F.124})$$

### The dot product $\bar{\mathbf{v}} \cdot \nabla \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \nabla \bar{\alpha} \right)$

In cylindrical coordinates this term is written as:

$$\begin{aligned} & \bar{\mathbf{v}} \cdot \nabla \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \nabla \bar{\alpha} \right) \\ = & \left( \bar{v}_r \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} \right) + \bar{v}_\theta \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} \right) - \bar{v}_\theta \frac{1}{r^2} \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial \theta} + \bar{v}_z \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} \right) \right) \mathbf{e}_r \\ & + \left( \bar{v}_r \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \right) + \bar{v}_\theta \frac{1}{r} \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial r} + \bar{v}_\theta \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \right) + \bar{v}_z \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{1}{r} \frac{\partial \bar{\alpha}}{\partial \theta} \right) \right) \mathbf{e}_\theta \\ & + \left( \bar{v}_r \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial z} \right) + \bar{v}_\theta \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial z} \right) + \bar{v}_z \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \bar{\alpha}}{\partial z} \right) \right) \mathbf{e}_z. \end{aligned} \quad (\text{F.125})$$

## F.3 Two-Fluid Equations in cylindrical coordinates

By use of the transformations defined above, the governing 3D equations are written in cylindrical coordinates.

### Liquid Phase Continuity Equation in Cylindrical Coordinates

$$\begin{aligned} & \frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r}) + \frac{1}{r} \frac{\partial}{\partial \theta} (\bar{\alpha}_l \rho_l \bar{v}_{l,\theta}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z}) \\ = & \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial \theta} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial \theta} \right) + \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha,l,t}} \frac{\partial \bar{\alpha}_l}{\partial z} \right). \end{aligned} \quad (\text{F.126})$$

### Liquid Phase Radial Momentum Balance in Cylindrical Coordinates

$$\begin{aligned}
& \frac{\partial}{\partial t} \left( \bar{\alpha}_l \rho_l \bar{v}_{l,r} \right) \\

### Turbulence Model

The transport equation for turbulent kinetic energy in cylindrical coordinates is written as:

$$\begin{aligned} & \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l k) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \rho_l \bar{v}_{l,r} k) + \frac{1}{r} \frac{\partial}{\partial \theta}(\bar{\alpha}_l \rho_l \bar{v}_{l,\theta} k) + \frac{\partial}{\partial z}(\bar{\alpha}_l \rho_l \bar{v}_{l,z} k) \\ &= \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_k} \frac{\partial k}{\partial r}) + \frac{1}{r} \frac{\partial}{\partial \theta}(\bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_k} \frac{1}{r} \frac{\partial k}{\partial \theta}) + \frac{\partial}{\partial z}(\bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_k} \frac{\partial k}{\partial z}) \\ &+ \bar{\alpha}_l (P_k + P_b - \rho_l \varepsilon) \end{aligned} \quad (\text{F.130})$$

The transport equation for the turbulent energy dissipation rate in cylindrical coordinates is written as:

$$\begin{aligned} & \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l \varepsilon) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \varepsilon) + \frac{1}{r} \frac{\partial}{\partial \theta}(\bar{\alpha}_l \rho_l \bar{v}_{l,\theta} \varepsilon) + \frac{\partial}{\partial z}(\bar{\alpha}_l \rho_l \bar{v}_{l,z} \varepsilon) \\ &= \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial r}) + \frac{1}{r} \frac{\partial}{\partial \theta}(\bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_\varepsilon} \frac{1}{r} \frac{\partial \varepsilon}{\partial \theta}) + \frac{\partial}{\partial z}(\bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial z}) \\ &+ \bar{\alpha}_l \frac{\varepsilon}{k} (C_1 (P_k + P_b) - C_2 \rho_l \varepsilon) \end{aligned} \quad (\text{F.131})$$

where

$$\begin{aligned} P_k = & 2\mu_{l,t} \left[ \left( \frac{\partial \bar{v}_{l,r}}{\partial r} \right)^2 + \left( \frac{1}{r} \frac{\partial \bar{v}_{l,\theta}}{\partial \theta} + \frac{\bar{v}_{l,r}}{r} \right)^2 + \left( \frac{\partial \bar{v}_{l,z}}{\partial z} \right)^2 \right] \\ & + \mu_{l,t} \left[ \left( \frac{\partial \bar{v}_{l,z}}{\partial r} + \frac{\partial \bar{v}_{l,r}}{\partial z} \right)^2 + \left( \frac{1}{r} \frac{\partial \bar{v}_{l,z}}{\partial \theta} + \frac{\partial \bar{v}_{l,\theta}}{\partial z} \right)^2 + \left( \frac{\partial \bar{v}_{l,\theta}}{\partial r} + \left( \frac{1}{r} \frac{\partial \bar{v}_{l,r}}{\partial \theta} - \frac{\bar{v}_{l,\theta}}{r} \right) \right)^2 \right] \end{aligned} \quad (\text{F.132})$$

and

$$P_b = C_b \left( \overline{F_{D,r}} (\bar{v}_{g,r} - \bar{v}_{l,r}) + \overline{F_{D,\theta}} (\bar{v}_{g,\theta} - \bar{v}_{l,\theta}) + \overline{F_{D,z}} (\bar{v}_{g,z} - \bar{v}_{l,z}) \right). \quad (\text{F.133})$$

### Gas phase equations in cylindrical coordinates

The gas phase continuity and momentum equations are almost identical to those for the liquid phase, and are not repeated to save space.

## F.4 The 2D axi-symmetric Bubble Column Model

### Liquid phase equations in cylindrical coordinates:

In an axi-symmetric case the liquid phase continuity equation simplifies as:

$$\begin{aligned} \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \rho_l \bar{v}_{l,r}) + \frac{\partial}{\partial z}(\bar{\alpha}_l \rho_l \bar{v}_{l,z}) \\ = \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}\right) + \frac{\partial}{\partial z}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z}\right) \end{aligned} \quad (\text{F.134})$$

The corresponding radial liquid phase momentum balance reduces as:

$$\begin{aligned} \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l \bar{v}_{l,r}) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \bar{v}_{l,r}) + \frac{\partial}{\partial z}(\bar{\alpha}_l \rho_l \bar{v}_{l,z} \bar{v}_{l,r}) \\ = \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r} \bar{v}_{l,r}\right) + \frac{\partial}{\partial z}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z} \bar{v}_{l,r}\right) \\ + \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r} \bar{v}_{l,z}\right) + \frac{\partial}{\partial z}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r} \bar{v}_{l,z}\right) \\ + \frac{1}{r} \frac{\partial}{\partial r}\left(r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial r}\right) - \frac{1}{r} \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\bar{v}_{l,r}}{r} + \frac{\partial}{\partial z}\left(\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial z}\right) \\ + \frac{1}{r} \frac{\partial}{\partial r}\left(r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial r}\right) - \frac{1}{r} \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\bar{v}_{l,z}}{r} + \frac{\partial}{\partial z}\left(\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial z}\right) \\ - \frac{\partial}{\partial r}\left(\frac{2}{3} \bar{\alpha}_l \rho_l \left(k + \nu_{l,\text{eff}} \left(\frac{1}{r} \frac{\partial}{\partial r}(r \bar{v}_{l,r}) + \frac{\partial \bar{v}_{l,z}}{\partial z}\right)\right)\right) \\ - \bar{\alpha}_l \frac{\partial \bar{p}}{\partial r} - \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \left(\frac{\partial \bar{\alpha}_l}{\partial r} \frac{\partial \bar{v}_{l,r}}{\partial r} + \frac{\partial \bar{\alpha}_l}{\partial z} \frac{\partial \bar{v}_{l,r}}{\partial z}\right) \\ - \left(\bar{v}_{l,r} \frac{\partial}{\partial r}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}\right) + \bar{v}_{l,z} \frac{\partial}{\partial z}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}\right)\right) \\ + \bar{\alpha}_l \rho_l g_r + \bar{F}_{l,r}^C + \bar{F}_{l,r}^{C'} \end{aligned} \quad (\text{F.135})$$

Using the product rule of calculus a few terms cancel out and the equation yields:

$$\begin{aligned} \frac{\partial}{\partial t}(\bar{\alpha}_l \rho_l \bar{v}_{l,r}) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \bar{v}_{l,r}) + \frac{\partial}{\partial z}(\bar{\alpha}_l \rho_l \bar{v}_{l,z} \bar{v}_{l,r}) \\ = \frac{\bar{v}_{l,r}}{r} \frac{\partial}{\partial r}\left(r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}\right) + \bar{v}_{l,r} \frac{\partial}{\partial z}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z}\right) \\ + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial r}) - \frac{1}{r} \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\bar{v}_{l,r}}{r} + \frac{\partial}{\partial z}(\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial z}) \end{aligned}$$

$$\begin{aligned}
& + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial r}) - \frac{1}{r} \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\bar{v}_{l,r}}{r} + \frac{\partial}{\partial z} (\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial r}) \\
& - \frac{\partial}{\partial r} (\frac{2}{3} \bar{\alpha}_l \rho_l (k + \nu_{l,\text{eff}} (\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_{l,r}) + \frac{\partial \bar{v}_{l,z}}{\partial z}))) \\
& + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r} [\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_{l,r}) + \frac{\partial \bar{v}_{l,z}}{\partial z}] - \bar{\alpha}_l \frac{\partial \bar{p}}{\partial r} \\
& + \bar{\alpha}_l \rho_l g_r + \bar{F}_{l,r}^C + \bar{F}_{l,r}^{C'} \tag{F.136}
\end{aligned}$$

Assuming axi-symmetry the azimuthal liquid phase momentum balance vanishes completely.

The liquid phase axial momentum balance becomes:

$$\begin{aligned}
& \frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l \bar{v}_{l,z}) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \bar{v}_{l,z}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z} \bar{v}_{l,z}) = \\
& \frac{1}{r} \frac{\partial}{\partial r} (r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r} \bar{v}_{l,z}) + \frac{\partial}{\partial z} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z} \bar{v}_{l,z}) \\
& + \frac{1}{r} \frac{\partial}{\partial r} (r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z} \bar{v}_{l,r}) + \frac{\partial}{\partial z} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z} \bar{v}_{l,z}) \\
& + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial r}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial z}) \\
& + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial z}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial z}) \\
& - \frac{\partial}{\partial z} (\frac{2}{3} \bar{\alpha}_l \rho_l (k + \nu_{l,\text{eff}} (\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_{l,r}) + \frac{\partial \bar{v}_{l,z}}{\partial z}))) \\
& - \bar{\alpha}_l \frac{\partial \bar{p}}{\partial z} - \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} (\frac{\partial \bar{\alpha}_l}{\partial r} \frac{\partial \bar{v}_{l,z}}{\partial r} + \frac{\partial \bar{\alpha}_l}{\partial z} \frac{\partial \bar{v}_{l,z}}{\partial z}) \\
& - (\bar{v}_{l,r} \frac{\partial}{\partial r} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z}) + \bar{v}_{l,z} \frac{\partial}{\partial z} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z})) \\
& + \bar{\alpha}_l \rho_l g_z + \bar{F}_{l,z}^C + \bar{F}_{l,z}^{C'} \tag{F.137}
\end{aligned}$$

Using the product rule of calculus a few terms cancel out and the equation yields:

$$\begin{aligned}
& \frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l \bar{v}_{l,z}) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \bar{v}_{l,z}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z} \bar{v}_{l,z}) \\
& = \bar{v}_{l,z} \frac{1}{r} \frac{\partial}{\partial r} (r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}) + \bar{v}_{l,z} \frac{\partial}{\partial z} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z}) \\
& + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z} (\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_{l,r}) + \frac{\partial \bar{v}_{l,z}}{\partial z}) \\
& + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial r}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial z})
\end{aligned}$$

$$\begin{aligned}
& + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,r}}{\partial z}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \mu_{l,\text{eff}} \frac{\partial \bar{v}_{l,z}}{\partial z}) \\
& - \frac{\partial}{\partial z} (\frac{2}{3} \bar{\alpha}_l \rho_l (k + \nu_{l,\text{eff}} (\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_{l,r}) + \frac{\partial \bar{v}_{l,z}}{\partial z}))) \\
& - \bar{\alpha}_l \frac{\partial \bar{p}}{\partial z} + \bar{\alpha}_l \rho_l g_z + \bar{F}_{l,z}^C + \bar{F}_{l,z}^{C'} \quad (\text{F.138})
\end{aligned}$$

A generalized transport equation for a scalar quantity in the liquid phase can be formulated as:

$$\begin{aligned}
& \frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l \bar{\phi}_l) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \bar{\phi}_l) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z} \bar{\phi}_l) \\
& = \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \Gamma_{\phi_l, \text{eff}} \frac{\partial \bar{\phi}_l}{\partial r}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \Gamma_{\phi_l, \text{eff}} \frac{\partial \bar{\phi}_l}{\partial z}) + \bar{S}_{\phi,l} \quad (\text{F.139})
\end{aligned}$$

The particular scalar transport equation for the liquid phase turbulent kinetic energy is written:

$$\begin{aligned}
& \frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l k) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r} k) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z} k) \\
& = \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_k} \frac{\partial k}{\partial r}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_k} \frac{\partial k}{\partial z}) + \bar{\alpha}_l (P_k + P_b - \rho_l \varepsilon) \quad (\text{F.140})
\end{aligned}$$

where

$$P_k = \mu_{l,t} (2[(\frac{\partial \bar{v}_{l,r}}{\partial r})^2 + (\frac{\partial \bar{v}_{l,z}}{\partial z})^2 + (\frac{\bar{v}_{l,r}}{r})^2] + (\frac{\partial \bar{v}_{l,r}}{\partial z} + \frac{\partial \bar{v}_{l,z}}{\partial r})^2) \quad (\text{F.141})$$

and

$$P_b = C_b (\bar{F}_{D,z} (\bar{v}_{g,z} - \bar{v}_{l,z}) + \bar{F}_{D,r} (\bar{v}_{g,r} - \bar{v}_{l,r})) \quad (\text{F.142})$$

The particular transport equation for the liquid phase turbulent energy dissipation rate is written:

$$\begin{aligned}
& \frac{\partial}{\partial t} (\bar{\alpha}_l \rho_l \varepsilon) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \rho_l \bar{v}_{l,r} \varepsilon) + \frac{\partial}{\partial z} (\bar{\alpha}_l \rho_l \bar{v}_{l,z} \varepsilon) \\
& = \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial r}) + \frac{\partial}{\partial z} (\bar{\alpha}_l \frac{\mu_{l,\text{eff}}}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial z}) + \bar{\alpha}_l \frac{\varepsilon}{k} (C_1 (P_k + P_b) - C_2 \rho_l \varepsilon). \quad (\text{F.143})
\end{aligned}$$

**Gas phase equations in cylindrical coordinates:**

The gas phase mass balance equation for the axisymmetric case is:

$$\begin{aligned} \frac{\partial}{\partial t}(\bar{\alpha}_g \rho_g) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_g \rho_g \bar{v}_{g,r}) + \frac{\partial}{\partial z}(\bar{\alpha}_g \rho_g \bar{v}_{g,z}) \\ = \frac{1}{r} \frac{\partial}{\partial r}(r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial r}) + \frac{\partial}{\partial z}(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial z}) \end{aligned} \quad (\text{F.144})$$

The radial gas phase momentum balance equation is:

$$\begin{aligned} \frac{\partial}{\partial t}(\bar{\alpha}_g \rho_g \bar{v}_{g,r}) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_g \rho_g \bar{v}_{g,r} \bar{v}_{g,r}) + \frac{\partial}{\partial z}(\bar{\alpha}_g \rho_g \bar{v}_{g,z} \bar{v}_{g,r}) \\ = \frac{1}{r} \frac{\partial}{\partial r}(r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial r} \bar{v}_{g,r}) + \frac{\partial}{\partial z}(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial z} \bar{v}_{g,r}) \\ + \frac{1}{r} \frac{\partial}{\partial r}(r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial r} \bar{v}_{g,r}) + \frac{\partial}{\partial z}(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial r} \bar{v}_{g,z}) \\ + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,r}}{\partial r}) - \frac{1}{r} \bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\bar{v}_{g,r}}{r} + \frac{\partial}{\partial z}(\bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,r}}{\partial z}) \\ + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,r}}{\partial r}) - \frac{1}{r} \bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\bar{v}_{g,r}}{r} + \frac{\partial}{\partial z}(\bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,z}}{\partial r}) \\ - \frac{\partial}{\partial r}(\frac{2}{3} \bar{\alpha}_g \rho_g (k + \frac{\nu_{g,t}}{\sigma_{g,t}} (\frac{1}{r} \frac{\partial}{\partial r}(r \bar{v}_{g,r}) + \frac{\partial \bar{v}_{g,z}}{\partial z}))) \\ - \bar{\alpha}_g \frac{\partial \bar{p}}{\partial r} + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} (\frac{\partial \bar{\alpha}_l}{\partial r} \frac{\partial \bar{v}_{l,r}}{\partial r} + \frac{\partial \bar{\alpha}_l}{\partial z} \frac{\partial \bar{v}_{l,r}}{\partial z}) \\ + \bar{v}_{l,r} \frac{\partial}{\partial r}(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}) + \bar{v}_{l,z} \frac{\partial}{\partial z}(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial r}) \\ + \bar{\alpha}_g \rho_g g_r + \overline{F_{g,r}^C} + \overline{F_{g,r}^{C'}} \end{aligned} \quad (\text{F.145})$$

Assuming axi-symmetry the azimuthal gas phase momentum balance vanishes completely.

The axial gas phase momentum balance equation is:

$$\begin{aligned} \frac{\partial}{\partial t}(\bar{\alpha}_g \rho_g \bar{v}_{g,z}) + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_g \rho_g \bar{v}_{g,r} \bar{v}_{g,z}) + \frac{\partial}{\partial z}(\bar{\alpha}_g \rho_g \bar{v}_{g,z} \bar{v}_{g,z}) \\ = \frac{1}{r} \frac{\partial}{\partial r}(r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial r} \bar{v}_{g,z}) + \frac{\partial}{\partial z}(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial z} \bar{v}_{g,z}) \\ + \frac{1}{r} \frac{\partial}{\partial r}(r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial z} \bar{v}_{g,r}) + \frac{\partial}{\partial z}(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \bar{\alpha}_g}{\partial z} \bar{v}_{g,z}) \\ + \frac{1}{r} \frac{\partial}{\partial r}(r \bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,z}}{\partial r}) + \frac{\partial}{\partial z}(\bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,z}}{\partial z}) \end{aligned} \quad (\text{F.146})$$

$$\begin{aligned}
& + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,r}}{\partial z}) + \frac{\partial}{\partial z} (\bar{\alpha}_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial \bar{v}_{g,z}}{\partial z}) \\
& - \frac{\partial}{\partial z} (\frac{2}{3} \bar{\alpha}_g \rho_g (k + \frac{\nu_{g,t}}{\sigma_{g,t}} (\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_{g,r}) + \frac{\partial \bar{v}_{g,z}}{\partial z}))) \\
& - \bar{\alpha}_g \frac{\partial \bar{p}}{\partial z} + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} (\frac{\partial \bar{\alpha}_l}{\partial r} \frac{\partial \bar{v}_{l,z}}{\partial r} + \frac{\partial \bar{\alpha}_l}{\partial z} \frac{\partial \bar{v}_{l,z}}{\partial z}) \\
& + (\bar{v}_{l,r} \frac{\partial}{\partial r} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z}) + \bar{v}_{l,z} \frac{\partial}{\partial z} (\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \bar{\alpha}_l}{\partial z})) \\
& + \bar{\alpha}_g \rho_g g_z + \overline{F_{g,z}^C} + \overline{F_{g,z}^{C'}}
\end{aligned}$$

A generalized transport equation for a scalar quantity in the gas phase can be formulated:

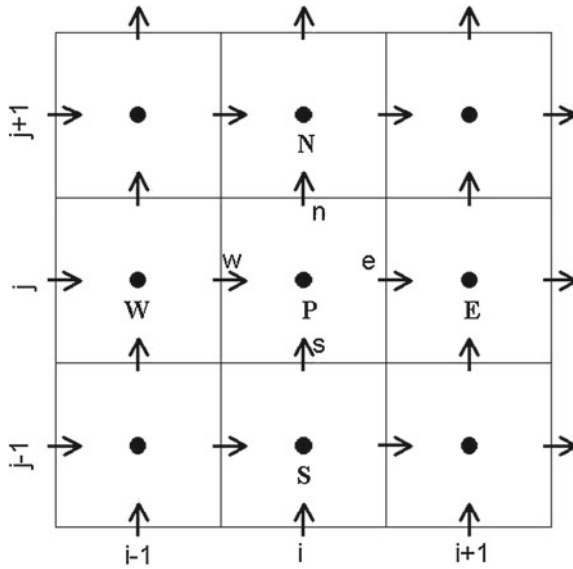

$$\begin{aligned}
& \frac{\partial}{\partial t} (\bar{\alpha}_g \rho_g \bar{\phi}_g) + \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_g \rho_g \bar{v}_{g,r} \bar{\phi}_g) + \frac{\partial}{\partial z} (\bar{\alpha}_g \rho_g \bar{v}_{g,z} \bar{\phi}_g) \\
& = \frac{1}{r} \frac{\partial}{\partial r} (r \bar{\alpha}_g \Gamma_{\phi_{g,t}} \frac{\partial \bar{\phi}_g}{\partial r}) + \frac{\partial}{\partial z} (\bar{\alpha}_g \Gamma_{\phi_{g,t}} \frac{\partial \bar{\phi}_g}{\partial z}) + \bar{S}_{\phi,g}.
\end{aligned} \tag{F.147}$$

#### F.4.1 Discretization of the Trondheim Bubble Column Model

In this section the *Trondheim Bubble Column model* is discretized using the finite volume technique on a staggered grid. The Trondheim Bubble Column model consists of a two-dimensional two-fluid model written in cylindrical coordinates. The governing equations are defined in appendix F.

In the first subsection, the discretization of the continuity equations is outlined. The discretization of these equations follows the basic principles as outlined earlier for single phase flow. In the second subsection the generic part of the discretization procedure, being similar for all the transport equations, is outlined for a generalized variable  $\psi$  of phase  $k$ . The discretization concepts applied are the same as those used for the generic equation for single phase flow. In the third section the discretization scheme used for the volume fraction is presented. The volume fraction of the gas phase is calculated using a combination of the two continuity equations based on a scheme given by Spalding [93]. In the fourth section the discretization procedure used for the momentum equations is presented. The momentum equation was solved using the SIMPLEC method (the SIMPLE- Consistent approximation) by van Doormal and Raithby [29], and the PEA method (Partial Elimination Algorithm) by Spalding [91, 92]. The pressure-correction was calculated by use of the liquid phase continuity equation only, based on the scheme given by Grienberger [46] and the single phase algorithm of Patankar [73].

The two-fluid model discretization procedure outlined in this appendix is to a large extent based on the single phase flow algorithm implemented in the pioneering

**Fig. F.1** Staggered Cartesian grid arrangement in the scalar cell notation. The scalar variables are located in the cell centers, while the velocity components are centered around the cell faces. The velocity components are located in the centers of their own grid cell volumes (not shown) which are staggered in one dimension compared to the scalar grid

TEACH-T code [43]. In order to simulate two phase bubble driven flow in bubble columns, the original TEACH-T code was extended to enable solution of the two-fluid model described previously in this appendix.

### Uniform Staggered Grid Arrangement

The first step in any discretization procedure is to define the grid to be used by dividing the computational domain into a number of grid cells and distribute the variables on the grid. In this work a uniform staggered grid arrangement was used as sketched in Fig. F.1 using the scalar cell notation.

The indices of the nodes  $(i, j)$  vary between 1 and  $NI$  and 1 and  $NJ$  in the  $z$ - and  $r$ - directions, respectively. Boundary nodes are located at  $i = 1, NI$  and  $j = 1, NJ$ , thus the equations are solved in the range  $2 < i < NI - 1$  and  $2 < j < NJ - 1$ .

#### Scalar Grid Cell Definition

The uniform distance between two node points in the *axial direction* is given by:

$$\Delta z = \frac{\text{Height of reactor}}{(\text{number of discretization points} - 2)} = \frac{L}{NI - 2} \quad (\text{F.148})$$

The location of the different points in the  $z$ -direction can then be calculated as follows, for  $i > 1$ :

$$z_i = z_{i-1} + \Delta z \quad \text{where} \quad z_1 = -\Delta z/2 \quad (\text{F.149})$$

For  $i \geq 1$ :

$$\delta z_{EP,i} = z_{i+1} - z_i, \quad (\text{F.150})$$

$$\delta z_{PW,i} = z_i - z_{i-1} \quad (\text{F.151})$$

$$\delta z_{EW,i} = \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}) \quad (\text{F.152})$$

The uniform distance between two node points in the *radial direction* is given by:

$$\Delta r = \frac{\text{Radius of reactor}}{(\text{number of discretization points} - 2)} = \frac{R}{NJ - 2} \quad (\text{F.153})$$

The location of the node points in the  $r$ -direction can then be calculated as follows, for  $j > 1$ :

$$r_j = r_{j-1} + \Delta r \quad \text{where} \quad r_1 = -\Delta r/2 \quad (\text{F.154})$$

For  $j \geq 1$ :

$$\delta r_{NP,j} = r_{j+1} - r_j, \quad (\text{F.155})$$

$$\delta r_{PS,j} = r_j - r_{j-1} \quad (\text{F.156})$$

$$\delta r_{NS,j} = \frac{1}{2}(\delta r_{NP,j} + \delta r_{PS,j}) \quad (\text{F.157})$$

In cylindrical coordinates, a typical three dimensional volume integral of a function  $\psi(r, \theta, z)$  would be of the form [8] (A. 8):

$$\int_{z_1}^{z_2} \int_{\theta_1}^{\theta_2} \int_{r_1}^{r_2} \psi(r, \theta, z) r \, dr \, d\theta \, dz \quad (\text{F.158})$$

Integration can also be performed on one of the surfaces of the coordinate system.

In cylindrical coordinates there are three different kinds of surfaces, defined by keeping one of the coordinates constant at the time:

$$\int_{z_1}^{z_2} \int_{\theta_1}^{\theta_2} \psi(r_0, \theta, z) r_0 \, d\theta \, dz, \quad \text{On the surface } r = r_0. \quad (\text{F.159})$$

$$\int_{z_1}^{z_2} \int_{r_1}^{r_2} \psi(r, \theta_0, z) \, dr \, dz, \quad \text{On the surface } \theta = \theta_0. \quad (\text{F.160})$$

$$\int_{\theta_1}^{\theta_2} \int_{r_1}^{r_2} \psi(r, \theta, z_0) r \, dr \, d\theta, \quad \text{On the surface } z = z_0. \quad (\text{F.161})$$

In two-dimensional problems, the volume and surface integrals reduce accordingly. The scalar grid cell surface areas and cell volume are defined as follows:

$$A_w = A_e = r_p \times \delta r_{NS,j} = r_j \times \frac{1}{2}(\delta r_{NP,j} + \delta r_{PS,j}), \quad (\text{F.162})$$

$$A_n = r_n \times \delta z_{EW,i} = r_{j+1}^v \times \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}), \quad (\text{F.163})$$

$$A_s = r_s \times \delta z_{EW,i} = r_j^v \times \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}) \quad (\text{F.164})$$

and

$$\Delta V = r_p \times \delta z_{EW,i} \times \delta r_{NS,j} = r_j \times \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}) \times \frac{1}{2}(\delta r_{NP,j} + \delta r_{PS,j}) \quad (\text{F.165})$$

#### *Staggered Axial Velocity Component (w) Grid Cell Definition*

The location of the different points in the  $z$ -direction are calculated as follows, for  $i > 1$ :

$$\Delta z^w = \frac{1}{2}(z_i + z_{i-1}) \quad \text{where} \quad z_1^w = 0 \quad (\text{F.166})$$

For  $i \geq 1$ :

$$\delta z_{EP,i}^w = z_{i+1}^w - z_i^w, \quad (\text{F.167})$$

$$\delta z_{PW,i}^w = z_i^w - z_{i-1}^w, \quad (\text{F.168})$$

$$\delta z_{EW,i}^w = \frac{1}{2}(\delta z_{EP,i}^w + \delta z_{PW,i}^w) \quad (\text{F.169})$$

The radial position of the grid for the axial velocity component ( $w$ ) coincides with that of the scalar grid cell.

The staggered axial velocity component grid cell surface areas and cell volume are defined by:

$$A_w = A_e = r_p \times \delta r_{NS,j} = r_p \times \frac{1}{2}(\delta r_{NP,j} + \delta r_{PS,j}), \quad (\text{F.170})$$

$$A_n = r_n \times \delta z_{EW,i}^w = r_{j+1}^v \times \frac{1}{2}(\delta z_{EP,i}^w + \delta z_{PW,i}^w), \quad (\text{F.171})$$

$$A_s = r_s \times \delta z_{EW,i}^w = r_j^v \times \frac{1}{2}(\delta z_{EP,i}^w + \delta z_{PW,i}^w) \quad (\text{F.172})$$

and

$$\Delta V = r_p \times \delta z_{EW,i}^w \times \delta r_{NS,j} = r_j \times \frac{1}{2}(\delta z_{EP,i}^w + \delta z_{PW,i}^w) \times \frac{1}{2}(\delta r_{NP,j} + \delta r_{PS,j}) \quad (\text{F.173})$$

#### *Staggered Radial Velocity Component (v) Grid Cell Definition*

The axial position of the grid cell for the radial velocity component ( $v$ ) coincides with that of the scalar grid cell defined above. The location of the different points in the  $r$ -direction can then be calculated as follows, for  $j > 1$ :

$$r_j^v = \frac{1}{2}(r_j + r_{j-1}) \quad \text{where} \quad r_1 = 0 \quad (\text{F.174})$$

For  $j \geq 1$ :

$$\delta r_{NP,j}^v = r_{j+1}^v - r_j^v, \quad (\text{F.175})$$

$$\delta r_{PS,j}^v = r_j^v - r_{j-1}^v \quad (\text{F.176})$$

$$\delta r_{NS,j}^v = \frac{1}{2}(\delta r_{NP,j}^v + \delta r_{PS,j}^v) \quad (\text{F.177})$$

For the radial velocity component ( $v$ ) grid cell, the surface areas and cell volume are defined by:

$$A_w = A_e = r_p^v \times \delta r_{NS,j}^v = r_j^v \times \frac{1}{2}(\delta r_{NP,j}^v + \delta r_{PS,j}^v), \quad (\text{F.178})$$

$$A_n = r_n \times \delta z_{EW,i} = r_{j+1} \times \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}), \quad (\text{F.179})$$

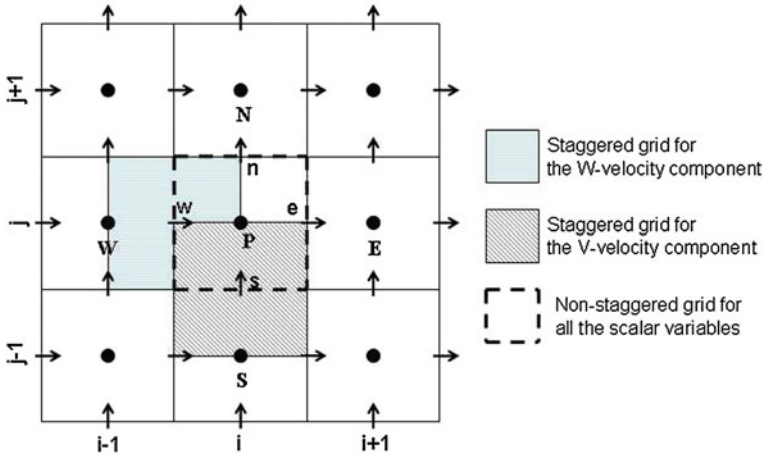

$$A_s = r_s \times \delta z_{EW,i} = r_j \times \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}) \quad (\text{F.180})$$

and

$$\Delta V = r_p^v \times \delta z_{EW,i} \times \delta r_{NS,j}^v = r_j^v \times \frac{1}{2}(\delta z_{EP,i} + \delta z_{PW,i}) \times \frac{1}{2}(\delta r_{NP,j}^v + \delta r_{PS,j}^v) \quad (\text{F.181})$$

To discretize the governing equations using the finite volume method, the differential equations are written on the integral form by integrating over a grid cell volume. The volume integrals of the convective and diffusive flux terms are transformed into surface integrals by use of the Gauss theorem. It is further assumed that the source term is constant throughout the grid cell volume, and the fluxes are uniform over the cell faces. The resulting semi-discrete equation is then integrated over a time step. After the integrations all the terms are divided by the time step length  $\Delta t$ . The transient term is approximated by the midpoint rule, hence it is considered an average value representative for the whole grid cell volume. The order of the time and volume integration is interchangeable.

The solution of the discretized forms of the governing equations can be based on general geometrical dimensions such as  $\delta z_{EP}$ ,  $\delta z_{PW}$ ,  $\delta r_{NP}$  and  $\delta r_{PS}$  which are valid for non-uniform grids as well as for uniform grids. However, the implementation of the discretized equations on uniform grids into a computer code can be simplified adopting a grid dependent notation which is faster to compute.

**Fig. F.2** A sketch of a scalar Cartesian grid cell showing the distribution of the variables in the grid and the configuration of the staggered velocity grids. In cylindrical coordinates equivalent grid cells can be defined

#### F.4.2 The Continuity Equation

The phasic continuity equations are defined by:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \frac{1}{r} \frac{\partial}{\partial r}(r \alpha_k \rho_k v_k) + \frac{\partial}{\partial z}(\alpha_k \rho_k w_k) = \frac{1}{r} \frac{\partial}{\partial r}(r \Gamma \frac{\partial \alpha_k}{\partial r}) + \frac{\partial}{\partial z}(\Gamma \frac{\partial \alpha_k}{\partial z}) + S$$

The continuity equation is re-written on the integral form, integrated in time and over a grid cell volume in the non-staggered grid for the scalar variables sketched in Fig. F.2. The transient terms are discretized with the implicit Euler scheme.

$$\begin{aligned} & \frac{((\alpha_k \rho_k)_P - (\alpha_k \rho_k)_P^o) \Delta V}{\Delta t} + \Delta z((r \alpha_k \rho_k v_k)_n - (r \alpha_k \rho_k v_k)_s) \\ & + r_p \Delta r((\alpha_k \rho_k w_k)_e - (\alpha_k \rho_k w_k)_w) = \Delta z((r \Gamma \frac{\partial \alpha_k}{\partial r})_n - (r \Gamma \frac{\partial \alpha_k}{\partial r})_s) \quad (F.182) \\ & + r_p \Delta r((\Gamma \frac{\partial \alpha_k}{\partial z})_e - (\Gamma \frac{\partial \alpha_k}{\partial z})_w) + S \Delta V \end{aligned}$$

The gradient terms were then approximated by the central difference scheme. For simplicity, the variables  $\delta_{rPN}, \delta_{rSP}, \delta_{zPE}, \delta_{zWP}, A, C, D$  and  $F$  are commonly introduced. The resulting equation can thus be written as:

$$\begin{aligned} & \frac{(\alpha_k \rho_k)_P \Delta V}{\Delta t} + C_n - C_s + C_e - C_w = \frac{(\alpha_k \rho_k)_P^o \Delta V}{\Delta t} + D_n(\alpha_{k,N} - \alpha_{k,P}) \\ & - D_s(\alpha_{k,P} - \alpha_{k,S}) + D_e(\alpha_{k,E} - \alpha_{k,P}) - D_w(\alpha_{k,P} - \alpha_{k,W}) + S \Delta V \quad (F.183) \end{aligned}$$

The novel variables are defined as follows:

$$\begin{aligned} C_n &= A_n F_n = A_n (\alpha_k \rho_k v_k)_n, \\ C_s &= A_s F_s = A_s (\alpha_k \rho_k v_k)_s, \\ C_e &= A_e F_e = A_e (\alpha_k \rho_k w_k)_e, \\ C_w &= A_w F_w = A_w (\alpha_k \rho_k w_k)_w \end{aligned} \quad (\text{F.184})$$

The  $C$ -variables represent the convective fluxes through the grid cell surfaces and are normally approximated by the central difference scheme:

$$\begin{aligned} D_n &= A_n \frac{\Gamma_n}{\delta r_{NP}}, \\ D_s &= A_s \frac{\Gamma_s}{\delta r_{PS}}, \\ D_e &= A_e \frac{\Gamma_e}{\delta z_{EP}}, \\ D_w &= A_w \frac{\Gamma_w}{\delta z_{PW}} \end{aligned} \quad (\text{F.185})$$

The  $D$ -variables represent the generalized diffusion conductance and are related to the diffusive fluxes through the grid cell surfaces. In order to approximate these terms the gradients of the transported properties and the diffusion coefficients  $\Gamma$  are required. The property gradients are normally approximated by the central difference scheme. In a uniform grid the diffusion coefficients are obtained by linear interpolation from the node values (i.e., using arithmetic mean values):

$$\begin{aligned} \Gamma_n &= \frac{1}{2}(\Gamma_P + \Gamma_N), \\ \Gamma_s &= \frac{1}{2}(\Gamma_P + \Gamma_S), \\ \Gamma_e &= \frac{1}{2}(\Gamma_P + \Gamma_E), \\ \Gamma_w &= \frac{1}{2}(\Gamma_P + \Gamma_W) \end{aligned} \quad (\text{F.186})$$

We can re-organize (F.183) to:

$$C_n - C_s + C_e - C_w = \text{transient} + mC_1 + mC_2 \quad (\text{F.187})$$

where

$$\begin{aligned} \text{transient} &= \frac{(\alpha_k \rho_k)_P^o \Delta V}{\Delta t} - \frac{(\alpha_k \rho_k)_P \Delta V}{\Delta t} \\ mC_1 &= D_n \alpha_{k,N} + D_s \alpha_{k,S} + D_e \alpha_{k,E} + D_w \alpha_{k,W} \\ mC_2 &= -(D_n + D_s + D_e + D_w) \alpha_{k,P} \end{aligned} \quad (\text{F.188})$$

The  $LHS$  of (F.187) can be recognized as part of the  $ap$ -factor of the discretized equations for all the other variables. To keep the  $ap$ -coefficient always positive during the iterative process, the  $LHS$  terms can be substituted by the  $RHS$  terms.

### F.4.3 The Generalized Equation

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_k \rho_k \psi_k) + \frac{1}{r} \frac{\partial}{\partial r}(r \alpha_k \rho_k v_k \psi_k) + \frac{\partial}{\partial z}(\alpha_k \rho_k w_k \psi_k) \\ = \frac{1}{r} \frac{\partial}{\partial r}(r \alpha_k \rho_k \frac{\mu_{k,t}}{\sigma_{\alpha_k,t}} \frac{\partial \Phi}{\partial r}) + \frac{\partial}{\partial z}(\alpha_k \rho_k \frac{\mu_{k,t}}{\sigma_{\alpha_k,t}} \frac{\partial \Phi}{\partial z}) \end{aligned}$$

The finite volume discretization of the generalized multi-fluid equation coincides with the corresponding equation for single phase flows as outlined in the preceding subsections.

#### The Transient term

The transient term is discretized using the implicit Euler scheme.

$$\begin{aligned} \int_{\Delta V} \int_{\Delta t} \frac{\partial}{\partial t}(\alpha_k \rho_k \psi_k) dt dz r dr &= \left[ (\alpha_k \rho_k \psi_k)_P - (\alpha_k \rho_k \psi_k)_P^o \right] \Delta V \\ &= \frac{\Delta V}{\Delta t} (\alpha_k \rho_k \psi_k)_P \Delta t - \frac{\Delta V}{\Delta t} (\alpha_k \rho_k \psi_k)_P^o \Delta t \\ &= \frac{\Delta V}{\Delta t} (\alpha_k \rho_k \psi_k)_P \Delta t - a_P^o \psi_{k,P}^o \Delta t \end{aligned} \quad (\text{F.189})$$

where

$$a_P^o = \frac{\Delta V}{\Delta t} (\alpha_k \rho_k)_P^o. \quad (\text{F.190})$$

#### The Convection terms

Radial direction:

$$\begin{aligned} \int_{\Delta t} \int_{\Delta V} \frac{1}{r} \frac{\partial}{\partial r}(r \alpha_k \rho_k v_k \psi_k) dz r dr dt &= \Delta z [(r \alpha_k \rho_k v_k \psi_k)_n - (r \alpha_k \rho_k v_k \psi_k)_s] \Delta t \\ &= A_n (\alpha_k \rho_k v_k \psi_k)_n \Delta t - A_s (r \alpha_k \rho_k v_k \psi_k)_s \Delta t \\ &= A_n F_n \psi_n \Delta t - A_s F_s \psi_s \Delta t \\ &= C_n \psi_n \Delta t - C_s \psi_s \Delta t \end{aligned} \quad (\text{F.191})$$

where

$$\begin{aligned} F_n &= (\alpha_k \rho_k v_k)_n \\ F_s &= (\alpha_k \rho_k v_k)_s \end{aligned} \quad (\text{F.192})$$

Axial direction:

$$\begin{aligned}
 \int_{\Delta t} \int_{\Delta V} \frac{\partial}{\partial z} (\alpha_k \rho_k w_k \psi_k) dz r dr dt &= r \Delta r [(\alpha_k \rho_k w_k \psi_k)_e - (\alpha_k \rho_k w_k \psi_k)_w] \Delta t \\
 &= A_e (\alpha_k \rho_k w_k \psi_k)_e \Delta t - A_w (\alpha_k \rho_k w_k \psi_k)_w \Delta t \\
 &= A_e F_e \psi_e \Delta t - A_w F_w \psi_w \Delta t \\
 &= C_e \psi_e \Delta t - C_w \psi_w \Delta t
 \end{aligned} \tag{F.193}$$

where

$$\begin{aligned}
 F_e &= (\alpha_k \rho_k w_k)_e \\
 F_w &= (\alpha_k \rho_k w_k)_w
 \end{aligned} \tag{F.194}$$

### The Diffusion terms

The the diffusion terms are discretized using the central-difference scheme.

Radial direction:

$$\begin{aligned}
 \int_{\Delta t} \int_{\Delta V} \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_k \frac{\mu_{k,eff}}{\sigma_\psi} \frac{\partial \psi_k}{\partial r}) r dr dz dt \\
 &= \Delta z [(r \alpha_k \frac{\mu_{k,eff}}{\sigma_\psi} \frac{\partial \psi_k}{\partial r})_n - (r \alpha_k \frac{\mu_{k,eff}}{\sigma_\psi} \frac{\partial \psi_k}{\partial r})_s] \Delta t \\
 &= A_n \Gamma_n \left( \frac{\psi_{k,N} - \psi_{k,P}}{\delta_{rPN}} \right) \Delta t - A_s \Gamma_s \left( \frac{\psi_{k,P} - \psi_{k,S}}{\delta_{rSP}} \right) \Delta t \\
 &= D_n (\psi_{k,N} - \psi_{k,P}) \Delta t - D_s (\psi_{k,P} - \psi_{k,S}) \Delta t
 \end{aligned} \tag{F.195}$$

where

$$\begin{aligned}
 \Gamma_n &= (\alpha_k \frac{\mu_{k,eff}}{\sigma_\psi})_n \quad \text{and} \quad \Gamma_s = (\alpha_k \frac{\mu_{k,eff}}{\sigma_\psi})_s \\
 D_n &= \frac{A_n \Gamma_n}{\delta_{rPN}} \quad \text{and} \quad D_s = \frac{A_s \Gamma_s}{\delta_{rSP}}
 \end{aligned} \tag{F.196}$$

Axial direction:

$$\begin{aligned}
 \int_{\Delta t} \int_{\Delta V} \frac{\partial}{\partial z} (\alpha_k \frac{\mu_{k,eff}}{\sigma_\psi} \frac{\partial \psi_k}{\partial z}) dz r dr dt \\
 &= r_p \Delta r \left( \alpha_k \frac{\mu_{k,eff}}{\sigma_\psi} \frac{\partial \psi_k}{\partial z} \right)_e \Delta t - r_p \Delta r \left( \alpha_k \frac{\mu_{k,eff}}{\sigma_\psi} \frac{\partial \psi_k}{\partial z} \right)_w \Delta t \\
 &= A_e \Gamma_e \left( \frac{\psi_{k,E} - \psi_{k,P}}{\delta_{zEP}} \right) \Delta t - A_w \Gamma_w \left( \frac{\psi_{k,P} - \psi_{k,W}}{\delta_{zWP}} \right) \Delta t \\
 &= D_e (\psi_{k,E} - \psi_{k,P}) \Delta t - D_w (\psi_{k,P} - \psi_{k,W}) \Delta t
 \end{aligned} \tag{F.197}$$

where

$$\begin{aligned}\Gamma_w &= (\alpha_k \frac{\mu_{k,eff}}{\sigma_\psi})_w \quad \text{and} \quad \Gamma_e = (\alpha_k \frac{\mu_{k,eff}}{\sigma_\psi})_e \\ D_e &= \frac{A_e \Gamma_n}{\delta_{zEP}} \quad \text{and} \quad D_w = \frac{A_w \Gamma_s}{\delta_{zWP}}.\end{aligned}\tag{F.198}$$

### The Source terms

The source terms are approximated by the midpoint rule, in which  $S$  is considered an average value representative for the whole grid cell volume.

### Upwind Discretized Form of the Generalized Equation

After the given approximations of the terms have been substituted into the generic equation, and dividing all the terms by  $\Delta t$ , the balance equation yields:

$$\begin{aligned}\frac{\Delta V}{\Delta t} (\alpha_k \rho_k)_P \psi_{k,P} - a_P^0 \psi_{k,P}^0 + C_n \psi_{k,n} - C_s \psi_{k,s} + C_e \psi_{k,e} - C_w \psi_{k,w} \\ = D_n (\psi_{k,N} - \psi_{k,P}) - D_s (\psi_{k,P} - \psi_{k,S}) + D_e (\psi_{k,E} - \psi_{k,P}) \\ - D_w (\psi_{k,P} - \psi_{k,W}) + S \Delta V\end{aligned}\tag{F.199}$$

By use of the upwind scheme for the convective terms, the generalized transport equation becomes:

$$\begin{aligned}\left( \frac{\Delta V}{\Delta t} (\alpha_k \rho_k)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - S_{P,1} \Delta V \right) \psi_{k,P} \\ = a_N \psi_{k,N} + a_S \psi_{k,S} + a_E \psi_{k,E} + a_W \psi_{k,W} + S_{C,1} \Delta V + a_P^0 \psi_{k,P}^0\end{aligned}\tag{F.200}$$

The discretized equation can then be written on the standard algebraic form:

$$a_P \psi_P = a_N \psi_N + a_S \psi_S + a_E \psi_E + a_W \psi_W + b\tag{F.201}$$

in which the coefficients are defined as follows:

$$\begin{aligned}a_N &= D_n + \max[-C_n, 0] \\ a_S &= D_s + \max[C_s, 0] \\ a_E &= D_e + \max[-C_e, 0] \\ a_W &= D_w + \max[C_w, 0] \\ b &= S_{C,1} + a_P^0 \psi_{k,P}^0 \\ a_P &= \frac{\Delta V}{\Delta t} (\alpha_k \rho_k)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - S_{P,1} \Delta V\end{aligned}\tag{F.202}$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity Eq. (F.187). The result is:

$$a_P = \frac{(\alpha_k \rho_k)_P^0 \Delta V}{\Delta t} + a_N + a_S + a_E + a_W + mC_1 + mC_2 - S_{P,1} \Delta V \quad (\text{F.203})$$

The negative  $mC_2$ -term must then be moved to the RHS of the discretized transport equation and included as part of the  $b$ -term (multiplied with  $\psi_k^\nu$ , the value at the previous iteration). The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

$$\begin{aligned} b^* &= -mC_2 \psi_{k,P}^\nu + S_{C,1} + a_P^0 \psi_{k,P}^0 \\ a_P^* &= \frac{\Delta V}{\Delta t} (\alpha_k \rho_k)_P^0 + a_N + a_S + a_E + a_W + mC_1 - S_{P,1} \Delta V. \end{aligned} \quad (\text{F.204})$$

#### F.4.4 The Liquid Phase Radial Momentum Balance

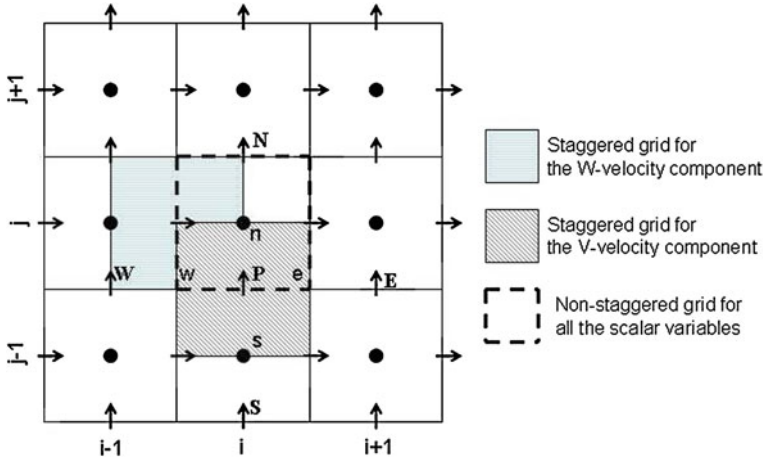

The radial momentum balance is given in (F.135).

$$\begin{aligned} & \frac{\partial}{\partial t} (\alpha_l \rho_l v_l) + \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \rho_l v_l v_l) + \frac{\partial}{\partial z} (\alpha_l \rho_l w_l v_l) \\ &= \frac{v_l}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right) + v_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) \\ &+ \frac{1}{r} \frac{\partial}{\partial r} \left( r \alpha_l \mu_{l,\text{eff}} \frac{\partial v_l}{\partial r} \right) - \frac{1}{r} \alpha_l \mu_{l,\text{eff}} \frac{v_l}{r} + \frac{\partial}{\partial z} \left( \alpha_l \mu_{l,\text{eff}} \frac{\partial v_l}{\partial z} \right) \\ &+ \frac{1}{r} \frac{\partial}{\partial r} \left( r \alpha_l \mu_{l,\text{eff}} \frac{\partial v_l}{\partial r} \right) - \frac{1}{r} \alpha_l \mu_{l,\text{eff}} \frac{v_l}{r} + \frac{\partial}{\partial z} \left( \alpha_l \mu_{l,\text{eff}} \frac{\partial w_l}{\partial r} \right) \\ &- \frac{\partial}{\partial r} \left( \frac{2}{3} \alpha_l \rho_l \left[ k + \nu_{l,\text{eff}} \left( \frac{1}{r} \frac{\partial}{\partial r} (r v_l) + \frac{\partial w_l}{\partial z} \right) \right] \right) \\ &+ \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \left[ \frac{1}{r} \frac{\partial}{\partial r} (r v_l) + \frac{\partial w_l}{\partial z} \right] - \alpha_l \frac{\partial p}{\partial r} \\ &+ \alpha_l \rho_l g_r + F_{l,r}^C + \overline{F_{l,r}^{C'}} \end{aligned} \quad (\text{F.205})$$

In the FVM, the integral form of the momentum equation is used. The differential equation is thus integrated in time and over a grid cell volume in the staggered grid for the  $v$ -velocity sketched in Fig. F.3.

#### The transient term

$$\int_{\Delta V} \int_t^{t+\Delta t} \frac{\partial}{\partial t} (\alpha_l \rho_l v_l) dt dV = \left[ (\alpha_l \rho_l v_l)_P - (\alpha_l \rho_l v_l)_P^0 \right] \Delta V \quad (\text{F.206})$$

**Fig. F.3** A sketch of the staggered  $v$ -grid cell in Cartesian coordinates. The figure shows the distribution of the variables in this grid, and the configuration of the staggered  $w$ -velocity grid and the non-staggered scalar grid. In cylindrical coordinates equivalent grid cells can be defined

To approximate the scalar grid cell variables  $\alpha$  and  $\rho$  at the staggered velocity grid cell nodes, arithmetic interpolation is needed:

$$(\alpha_l \rho_l v_l)_P = \frac{1}{2} \left[ (\alpha_{l,P} \rho_{l,P}) + (\alpha_{l,S} \rho_{l,S}) \right] v_{l,P} \quad (\text{F.207})$$

$$(\alpha_l \rho_l v_l)_P^o = \frac{1}{2} \left[ (\alpha_{l,P} \rho_{l,P})^o + (\alpha_{l,S} \rho_{l,S})^o \right] v_{l,P}^o \quad (\text{F.208})$$

### The convection terms

The locations of the node points in the staggered grid for the  $v$ -velocity are shown in Fig. F.3.

Radial direction:

$$\begin{aligned} \int_{\Delta t \Delta V} \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \rho_l v_l v_l) r dr dz dt &= \Delta z \left[ (r \alpha_l \rho_l v_l)_n v_{l,n} - (r \alpha_l \rho_l v_l)_s v_{l,s} \right] \Delta t \\ &= C_n v_{l,n} \Delta t - C_s v_{l,s} \Delta t \end{aligned} \quad (\text{F.209})$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
C_n &= A_n \frac{1}{2} [F_N + F_P] \\
C_s &= A_s \frac{1}{2} [F_P + F_S] \\
F_N &= (\alpha_l \rho_l v_l)_N = \frac{1}{2} [\alpha_{l,N} \rho_{l,N} + \alpha_{l,P} \rho_{l,P}] v_{l,N} \\
F_P &= (\alpha_l \rho_l v_l)_P = \frac{1}{2} [\alpha_{l,P} \rho_{l,P} + \alpha_{l,S} \rho_{l,S}] v_{l,P} \\
F_S &= (\alpha_l \rho_l v_l)_S = \frac{1}{2} [\alpha_{l,S} \rho_{l,S} + \alpha_{l,SS} \rho_{l,SS}] v_{l,S}
\end{aligned} \tag{F.210}$$

Axial direction:

$$\begin{aligned}
\int_{\Delta t \Delta V} \int \frac{\partial}{\partial z} (\alpha_l \rho_l w_l v_l) dz r dr dt &= [(r \Delta r \alpha_l \rho_l w_l)_e v_{l,e} - (r \Delta r \alpha_l \rho_l w_l)_w v_{l,w}] \Delta t \\
&= C_e v_{l,e} \Delta t - C_w v_{l,w} \Delta t
\end{aligned} \tag{F.211}$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
C_e &= A_e \frac{1}{2} [F_E + F_{SE}] \\
C_w &= A_w \frac{1}{2} [F_W + F_{SW}] \\
F_E &= (\alpha_l \rho_l v)_E = \frac{1}{2} [\alpha_{l,E} \rho_{l,E} + \alpha_{l,P} \rho_{l,P}] v_{l,E} \\
F_{SE} &= (\alpha_l \rho_l v)_{SE} = \frac{1}{2} [\alpha_{l,S} \rho_{l,S} + \alpha_{l,SE} \rho_{l,SE}] v_{l,SE} \\
F_W &= (\alpha_l \rho_l v)_W = \frac{1}{2} [\alpha_{l,P} \rho_{l,P} + \alpha_{l,W} \rho_{l,W}] v_{l,P} \\
F_{SW} &= (\alpha_l \rho_l v)_{SW} = \frac{1}{2} [\alpha_{l,S} \rho_{l,S} + \alpha_{l,SW} \rho_{l,SW}] v_{l,S}.
\end{aligned} \tag{F.212}$$

### The Diffusion terms

The location of the node points in the staggered grid for the  $v$ -velocity are shown in Fig. F.3.

Radial direction:

$$\int_{\Delta t \Delta V} \int \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial r}) r dr dz dt = \Delta z [(r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial r})_n - (r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial r})_s] \Delta t$$

$$\begin{aligned}
&= A_n \Gamma_n \left[ \frac{v_{l,N} - v_{l,P}}{\delta r_{NP}} \right] \Delta t - A_s \Gamma_s \left[ \frac{v_{l,P} - v_{l,S}}{\delta r_{PS}} \right] \Delta t \\
&= D_n (v_{l,N} - v_{l,P}) \Delta t - D_s (v_{l,P} - v_{l,S}) \Delta t
\end{aligned} \tag{F.213}$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
D_n &= \frac{A_n \Gamma_n}{\delta r_{NP}} \\
D_s &= \frac{A_s \Gamma_s}{\delta r_{PS}} \\
\Gamma_n &= (\alpha_l \mu_{l,eff})_n = \alpha_{l,P} \mu_{l,eff,P} \\
\Gamma_s &= (\alpha_l \mu_{l,eff})_s = \alpha_{l,S} \mu_{l,eff,S}
\end{aligned} \tag{F.214}$$

Axial direction:

$$\begin{aligned}
\int_{\Delta t} \int_{\Delta V} \frac{\partial}{\partial z} (\alpha_l \mu_{l,eff} \frac{\partial v}{\partial z}) dz r dr dt &= [r_p \Delta r (\alpha_l \mu_{l,eff} \frac{\partial v}{\partial z})_e - r_p \Delta r (\alpha_l \mu_{l,eff} \frac{\partial v}{\partial z})_w] \Delta t \\
&= A_e \Gamma_e \left[ \frac{v_{l,E} - v_{l,P}}{\delta z_{EP}} \right] \Delta t - A_w \Gamma_w \left[ \frac{v_{l,P} - v_{l,W}}{\delta z_{PW}} \right] \Delta t \\
&= D_e (v_{l,E} - v_{l,P}) \Delta t - D_w (v_{l,P} - v_{l,W}) \Delta t
\end{aligned} \tag{F.215}$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
D_e &= \frac{A_e \Gamma_e}{\delta z_{EP}} \\
D_w &= \frac{A_w \Gamma_w}{\delta z_{PW}} \\
\Gamma_e &= (\alpha_l \mu_{l,eff})_e \\
&= \frac{1}{4} [\alpha_{l,P} \mu_{l,eff,P} + \alpha_{l,E} \mu_{l,eff,E} + \alpha_{l,S} \mu_{l,eff,S} + \alpha_{l,SE} \mu_{l,eff,SE}] \\
\Gamma_w &= (\alpha_l \mu_{l,eff})_w \\
&= \frac{1}{4} [\alpha_{l,P} \mu_{l,eff,P} + \alpha_{l,W} \mu_{l,eff,W} + \alpha_{l,S} \mu_{l,eff,S} + \alpha_{l,SW} \mu_{l,eff,SW}].
\end{aligned} \tag{F.216}$$

### The source terms

The the source terms are approximated by the midpoint rule, in which  $S$  is considered an average value representative for the whole grid cell volume. The derivatives are

represented by an abbreviated Taylor series expansion, usually a central difference expansion of second order is employed.

Term 1 on the RHS of the momentum equation:

$$\int_{\Delta t \Delta V} \frac{v_l}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt = \frac{v_{l,P} \Delta V \Delta t}{r_P^v \frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \left[ \left( r \mu_{l,t} \frac{\partial \alpha_l}{\partial r} \right)_n - \left( r \mu_{l,t} \frac{\partial \alpha_l}{\partial r} \right)_s \right] \quad (\text{F.217})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,1} = \frac{v_{l,P} \Delta V \Delta t}{r_P^v \frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \left[ r_P \mu_{l,P} \left( \frac{\partial \alpha_l}{\partial r} \right)_n - r_S \mu_{l,S} \left( \frac{\partial \alpha_l}{\partial r} \right)_s \right] \quad (\text{F.218})$$

To approximate derivatives of scalar grid cell variables and scalar grid cell variables at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial r} \right)_n &= \frac{(\alpha_l)_N - (\alpha_l)_P}{\delta r_{NP}} = \frac{\frac{1}{2}(\alpha_{l,N} + \alpha_{l,P}) - \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S})}{\delta r_{NP}} \\ \left( \frac{\partial \alpha_l}{\partial r} \right)_s &= \frac{(\alpha_l)_P - (\alpha_l)_S}{\delta r_{PS}} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) - \frac{1}{2}(\alpha_{l,S} + \alpha_{l,SS})}{\delta r_{PS}} \end{aligned} \quad (\text{F.219})$$

Term 2 on the RHS of the momentum equation:

$$\int_{\Delta t \Delta V} v_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = \frac{v_{l,P} \Delta V \Delta t}{\frac{1}{2} (\delta z_{EP} + \delta z_{PW})} \left[ \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_e - \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_w \right] \quad (\text{F.220})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,2} = \frac{v_{l,P} \Delta V \Delta t}{\frac{1}{2} (\delta z_{EP} + \delta z_{PW})} \left[ (\mu_l)_e \left( \frac{\partial \alpha_l}{\partial z} \right)_e - (\mu_l)_w \left( \frac{\partial \alpha_l}{\partial z} \right)_w \right] \quad (\text{F.221})$$

To approximate derivatives of scalar grid cell variables and scalar grid cell variables at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\left( \frac{\partial \alpha_l}{\partial z} \right)_e = \frac{(\alpha_l)_E - (\alpha_l)_P}{\delta z_{PE}} = \frac{\frac{1}{2}(\alpha_{l,E} + \alpha_{l,SE}) - \frac{1}{2}(\alpha_{l,E} + \alpha_{l,SE})}{\delta z_{PE}} \quad (\text{F.222})$$

$$\begin{aligned}
\left(\frac{\partial \alpha_l}{\partial z}\right)_w &= \frac{(\alpha_l)_P - (\alpha_l)_W}{\delta z_{WP}} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) - \frac{1}{2}(\alpha_{l,W} + \alpha_{l,SW})}{\delta z_{WP}} \\
(\mu_l)_e &= \frac{1}{4}(\mu_{l,P} + \mu_{l,E} + \mu_{l,S} + \mu_{l,SE}) \\
(\mu_l)_w &= \frac{1}{4}(\mu_{l,P} + \mu_{l,W} + \mu_{l,S} + \mu_{l,SW})
\end{aligned}$$

The 3rd and 6th terms on the RHS of the momentum equation are identical and are approximated as follows:

$$\begin{aligned}
&\int \int \frac{1}{\Delta t \Delta V} r \frac{\partial}{\partial r} (r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial r}) dV dt \\
&= \frac{\Delta V \Delta t}{r_P^v \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} [(r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial r})_n - (r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial r})_s] \quad (F.223)
\end{aligned}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,3} = \frac{\Delta V \Delta t}{r_P^v \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} \left[ r_P \alpha_{l,P} \mu_{l,P} \left( \frac{v_{l,N} - v_{l,P}}{\delta r_{NP}^v} \right) - r_S \alpha_{l,S} \mu_{l,S} \left( \frac{v_{l,P} - v_{l,S}}{\delta r_{PS}^v} \right) \right] \quad (F.224)$$

The scalar grid cell variables at the staggered velocity grid cell surface points coincide with center nodes, hence no interpolation is needed.

The 4th and 7th terms on the RHS of the momentum equation are identical. They are approximated as follows:

$$\begin{aligned}
&-2 \int \int \frac{1}{\Delta t \Delta V} r \alpha_l \mu_{l,eff} \frac{v_l}{r} dV dt = -2 (\alpha_l \mu_{l,eff})_P \frac{v_{l,P}}{r_P^{2,v}} \Delta V \Delta t \\
&= -2 \times \frac{1}{2} (\alpha_{l,P} \mu_{l,eff,P} + \alpha_{l,eff,S} \mu_{l,S}) \frac{v_{l,P}}{r_P^{2,v}} \Delta V \Delta t \quad (F.225)
\end{aligned}$$

This term is implemented through the source term  $S_p$  as:

$$S_{P,1} = -2 \times \frac{1}{2} (\alpha_{l,P} \mu_{l,eff,P} + \alpha_{l,eff,S} \mu_{l,S}) \frac{1}{r_P^{2,v}} \Delta V \Delta t \quad (F.226)$$

To approximate scalar grid cell variables at the staggered velocity grid cell surface points, arithmetic interpolation is used:

$$(\mu_l)_P = \frac{1}{2} (\mu_{l,P} + \mu_{l,S}) \quad (F.227)$$

The 5th term on the RHS of the momentum equation:

$$\begin{aligned} & \int_{\Delta t \Delta V} \frac{\partial}{\partial z} (\alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial z}) dV dt \\ &= \frac{\Delta V \Delta t}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} [(\alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial z})_e - (\alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial z})_w] \end{aligned} \quad (F.228)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,4} = \frac{\Delta V \Delta t}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} [(\alpha_l \mu_l)_e (\frac{\partial v_l}{\partial z})_e - (\alpha_l \mu_l)_w (\frac{\partial v_l}{\partial z})_w] \quad (F.229)$$

To velocity derivatives are approximated by use of the central difference scheme:

$$\begin{aligned} (\frac{\partial v_l}{\partial z})_e &= \frac{v_{l,E} - v_{l,P}}{\delta z_{PE}} \\ (\frac{\partial v_l}{\partial z})_w &= \frac{v_{l,P} - v_{l,W}}{\delta z_{WP}} \end{aligned} \quad (F.230)$$

The 8th term on the RHS of the momentum equation:

$$\begin{aligned} & \int_{\Delta t \Delta V} \frac{\partial}{\partial r} (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r}) dV dt \\ &= \frac{\Delta V \Delta t}{\frac{1}{2}(\delta z_{PW} + \delta r_{EP}^v)} \left[ (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r})_e - (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r})_w \right] \end{aligned} \quad (F.231)$$

The 8th term is implemented through the source term  $S_C$  as:

$$S_{C,5} = \frac{\Delta V \Delta t}{\frac{1}{2}(\delta z_{PW} + \delta r_{EP}^v)} \left[ \Gamma_e \frac{(w_{l,E} - w_{l,SE})}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} - \Gamma_w \frac{(w_{l,P} - w_{l,S})}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} \right] \quad (F.232)$$

Term 9A on the RHS of the momentum equation:

$$- \int_{\Delta t \Delta V} \frac{\partial}{\partial r} (\frac{2}{3} \alpha_l \rho_l k) dV dt = - \frac{2 \Delta V \Delta t}{3 \times \frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} [(\alpha_l \rho_l k)_n - (\alpha_l \rho_l k)_s] \quad (F.233)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,6} = \frac{2 \Delta V \Delta t}{3 \frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} [\alpha_{l,P} \rho_{l,P} k_P - \alpha_{l,S} \rho_{l,S} k_S] \quad (F.234)$$

The scalar grid cell variables at the staggered velocity grid cell surface points coincide with center nodes, hence no interpolation is needed.

Term 9B on the RHS of the momentum equation:

$$\begin{aligned}
 & - \int_{\Delta t \Delta V} \frac{\partial}{\partial r} \left( \frac{2}{3} \alpha_l \rho_l v_{l,eff} \frac{1}{r} \frac{\partial(rv_l)}{\partial r} \right) dV dt \\
 & = - \frac{2 \Delta V \Delta t}{3 \times \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} \left[ \left( \frac{\alpha_l \mu_{l,eff}}{r} \frac{\partial(rv_l)}{\partial r} \right)_n - \left( \frac{\alpha_l \mu_{l,eff}}{r} \frac{\partial(rv_l)}{\partial r} \right)_s \right] \quad (F.235)
 \end{aligned}$$

The 9B-th term is implemented through the source term  $S_C$  as:

$$S_{C,7} = - \frac{2 \Delta V \Delta t}{3 \times \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} \left[ \frac{\alpha_{l,P} \mu_{l,eff,P}}{r_P} \frac{\partial(rv_l)}{\partial r} |_n - \frac{\alpha_{l,W} \mu_{l,eff,W}}{r_S} \frac{\partial(rv_l)}{\partial r} |_s \right] \quad (F.236)$$

where

$$\begin{aligned}
 \frac{\partial(rv_l)}{\partial r} |_n &= \frac{(rv_l)_N - (rv_l)_P}{\delta r_{NP}^v} = \frac{r_N^v v_{l,N} - r_P^v v_{l,P}}{\delta r_{NP}^v} \\
 \frac{\partial(rv_l)}{\partial r} |_s &= \frac{(rv_l)_P - (rv_l)_S}{\delta r_{PS}^v} = \frac{r_P^v v_{l,P} - r_S^v v_{l,S}}{\delta r_{PS}^v} \quad (F.237)
 \end{aligned}$$

Term 9C on the RHS of the momentum equation:

$$\begin{aligned}
 & - \int_{\Delta t \Delta V} \frac{\partial}{\partial r} \left( \frac{2}{3} \alpha_l \rho_l v_{l,eff} \frac{\partial w_l}{\partial z} \right) dV dt \\
 & = - \frac{2 \Delta V \Delta t}{3 \times \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} \left[ (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z})_n - (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z})_s \right] \quad (F.238)
 \end{aligned}$$

The term 9C is implemented through the source term  $S_C$  as:

$$\begin{aligned}
 S_{C,8} &= - \frac{2 \Delta V \Delta t}{3 \times \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} \left[ \alpha_{l,P} \mu_{l,eff,P} \frac{1}{\frac{1}{2} (\delta z_{EP} + \delta z_{PW})} \frac{(w_{l,E} - w_{l,P})}{2} \right] \\
 &+ \frac{2 \Delta V \Delta t}{3 \times \frac{1}{2} (\delta r_{NP}^v + \delta r_{PS}^v)} \left[ \alpha_{l,W} \mu_{l,eff,W} \frac{1}{\frac{1}{2} (\delta z_{EP} + \delta z_{PW})} \frac{(w_{l,P} - w_{l,W})}{2} \right] \quad (F.239)
 \end{aligned}$$

Term 10 on the RHS of the momentum equation:

$$\int_{\Delta t \Delta V} \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \alpha_l}{\partial r} \left( \frac{1}{r} \frac{\partial}{\partial r} (rv_l) + \frac{\partial w_l}{\partial z} \right) dV dt = \left( \frac{\mu_{l,t}}{\sigma_{\alpha,t}} \frac{\partial \alpha_l}{\partial r} \right)_P \left[ \frac{1}{r} \frac{\partial}{\partial r} (rv_l) + \frac{\partial w_l}{\partial z} \right]_P \Delta V \Delta t \quad (F.240)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,9} = \frac{\frac{1}{2}(\frac{\mu_{l,t,P}}{\sigma_{\alpha,t}} + \frac{\mu_{l,t,S}}{\sigma_{\alpha,t}})}{\sigma_{\alpha,t}} (\frac{\partial \alpha_l}{\partial r})_P [\frac{1}{r_P^v} \frac{(r_P v_n - r_S v_s)}{\delta r_{PS}} + (\frac{\partial w_l}{\partial z})_P] \Delta V \Delta t \quad (F.241)$$

To approximate derivatives of velocity variables and scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is frequently used:

$$\begin{aligned} (\frac{\partial \alpha_l}{\partial r})_P &= \frac{(\alpha_l)_n - (\alpha_l)_s}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} = \frac{\alpha_{l,P} - \alpha_{l,S}}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} \\ (\mu_l)_P &= \frac{1}{2}(\mu_{l,P} + \mu_{l,S}) \\ (\frac{\partial w_l}{\partial z})_P &= \frac{(w_l)_e - (w_l)_w}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} = \frac{\frac{1}{2}(w_E + w_{SE}) - \frac{1}{2}(w_P + w_S)}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})}. \end{aligned} \quad (F.242)$$

### Pressure force:

$$- \int_{\Delta t \Delta V} \alpha_l \frac{\partial p}{\partial r} dV dt = -\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) \frac{(P_P - P_S)}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} \Delta V \Delta t \quad (F.243)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,10} = -(\alpha_l)_P \frac{(P_P - P_S)}{\delta r_{PS}} \Delta V \Delta t \quad (F.244)$$

To approximate scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is frequently used:

$$(\alpha_l)_P = \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}). \quad (F.245)$$

### Gravity force:

There is no gravity force in radial direction.

### Added Mass force:

$$\begin{aligned} - \int_{\Delta t \Delta V} \alpha_l \alpha_g \rho_l f_v [w_l \frac{\partial v_l}{\partial z} + v_l \frac{\partial v_l}{\partial r} - (w_g \frac{\partial v_g}{\partial z} + v_g \frac{\partial v_g}{\partial r})] dV dt \\ = -f_v (\alpha_l)_P (\alpha_g)_P (\rho_l)_P [w_l \frac{\partial v_l}{\partial z} + v_l \frac{\partial v_l}{\partial r} - (w_g \frac{\partial v_g}{\partial z} + v_g \frac{\partial v_g}{\partial r})]_P \Delta V \Delta t \end{aligned} \quad (F.246)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,11} = -f_v \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) \frac{1}{2}(\alpha_{g,P} + \alpha_{g,S}) \frac{1}{2}(\rho_{l,P} + \rho_{l,S}) \times [w_l \frac{\partial v_l}{\partial z} + v_l \frac{\partial v_l}{\partial r} - (w_g \frac{\partial v_g}{\partial z} + v_g \frac{\partial v_g}{\partial r})]_P \Delta V \Delta t \quad (\text{F.247})$$

To approximate derivatives of velocity variables and scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is frequently used:

$$\begin{aligned} (\alpha_l)_P &= \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) \\ (w_l)_P &= \frac{1}{4}(v_{l,P} + v_{l,S} + v_{l,E} + v_{l,SE}) \\ (\frac{\partial v_l}{\partial r})_P &= \frac{v_{l,n} - v_{l,s}}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} = \frac{\frac{1}{2}(v_{l,P} + v_{l,N}) - \frac{1}{2}(v_{l,P} + v_{l,S})}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} \\ (\frac{\partial v_l}{\partial z})_P &= \frac{v_{l,e} - v_{l,w}}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} = \frac{\frac{1}{2}(v_{l,P} + v_{l,E}) - \frac{1}{2}(v_{l,P} + v_{l,W})}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})}. \end{aligned} \quad (\text{F.248})$$

### Transversal force:

$$\begin{aligned} & - \int_{\Delta t \Delta t} \alpha_l \alpha_g \rho_l C_L (w_l - w_g) \frac{\partial w_l}{\partial r} dV dt \\ & = -(\alpha_l)_P (\alpha_g)_P (\rho_l)_P C_L \Delta w_P (\frac{\partial w_l}{\partial r})_P \Delta V \Delta t \end{aligned} \quad (\text{F.249})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,12} = -\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) \frac{1}{2}(\alpha_{g,P} + \alpha_{g,S}) \frac{1}{2}(\rho_{l,P} + \rho_{l,S}) C_L \Delta w_P (\frac{\partial w_l}{\partial r})_P \Delta V \Delta t \quad (\text{F.250})$$

To approximate derivatives of velocity variables and scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is used:

$$\begin{aligned} (\alpha_l)_P &= \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) \\ \Delta w_P &= (w_l - w_g)_P \\ &= \frac{1}{4}(w_{l,P} - w_{g,P} + w_{l,E} - w_{g,E} + w_{l,S} - w_{g,S} + w_{l,SE} - w_{g,SE}) \\ \left(\frac{\partial w_l}{\partial r}\right)_P &= \frac{w_{l,n} - w_{l,s}}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} = \frac{\frac{1}{2}(w_{l,P} + w_{l,E}) - \frac{1}{2}(w_{l,S} + w_{l,SE})}{\frac{1}{2}(\delta r_{NP}^v + \delta r_{PS}^v)} \end{aligned}$$

$$C_L = f_L - \frac{3}{4} \frac{\nu_{l,t}}{\nu_l} \frac{C_D C_\tau}{(1 + \frac{\tau_L}{t_p}) Re_p}. \quad (F.251)$$

**Steady drag force:**

$$\int_{\Delta t} \int_{\Delta V} \frac{3}{4} \alpha_l \alpha_g \rho_l \frac{C_D}{d_S} |\mathbf{v}_l - \mathbf{v}_g| (v_l - v_g) dV dt \approx (K)_P (v_{l,P} - v_{g,P}) \Delta V \Delta t \quad (F.252)$$

To approximate scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is used:

$$\begin{aligned} (K)_P &= \frac{1}{2} (K_P + K_S) \\ K_P &= \left[ \frac{3}{4} \alpha_l \alpha_g \rho_l \frac{C_D}{d_S} |\mathbf{v}_l - \mathbf{v}_g| \right]_P = [\alpha_l \alpha_g C_W]_P = \frac{3}{4} \alpha_{l,P} \alpha_{g,P} \rho_{l,P} \left( \frac{C_D}{d_S} \right)_P |\mathbf{v}_l - \mathbf{v}_g|_P \end{aligned} \quad (F.253)$$

The relative speed at the center node in the staggered  $v$ -grid cell volume is approximated by:

$$\begin{aligned} |\mathbf{v}_l - \mathbf{v}_g|_P &\approx \left[ \left[ \frac{1}{2} (w_{l,P} + w_{l,S}) - \frac{1}{2} (w_{g,P} + w_{g,S}) \right]^2 \right. \\ &\quad \left. + \left[ \frac{1}{2} (v_{l,P} + v_{l,W}) - \frac{1}{2} (v_{g,P} + v_{g,W}) \right]^2 \right]^{1/2} \end{aligned} \quad (F.254)$$

To deal with the strong coupling between the phasic momentum equations, the *partial elimination algorithm* (PEA)-method proposed by Spalding [91, 92] is frequently used.

To outline the PEA-method, the discretized momentum equations for the gas phase at the  $e$  location in the staggered grid for the  $w$  variable (i.e., between the P and E grid points in the scalar grid) is re-written pulling the drag force out of the source term:

$$a_{g,n} v_{g,n} = \sum_{nb} a_{g,nb} v_{g,nb} + K(v_{l,n} - v_{g,n}) \Delta V + S_g \quad (F.255)$$

One part of the drag term is put on the LHS of the equation, thus we may write:

$$v_{g,n} (a_{g,n} + K \Delta V) = \sum_{nb} a_{g,nb} v_{g,nb} + K \Delta V v_{l,n} + S_g \quad (F.256)$$

The  $v_{g,n}$  is then given by:

$$v_{g,n} = \frac{\sum_{nb} a_{g,nb} w_{g,nb} + K \Delta V v_{l,n} + S_g}{a_{g,n} + K \Delta V} \quad (\text{F.257})$$

In the same way we can write for the liquid velocity (shown shortly):

$$v_{l,n} = \frac{\sum_{nb} a_{l,nb} v_{l,nb} + K \Delta V v_{g,n} + S_l}{a_{l,n} + K \Delta V} \quad (\text{F.258})$$

Combining these two equations to take out  $v_{l,n}$  in the gas calculations and  $v_{g,n}$  in the liquid calculations we get:

$$v_{g,n} = \frac{\sum_{nb} a_{g,nb} v_{g,nb} + K \Delta V \frac{\sum_{nb} a_{l,nb} v_{l,nb} + K \Delta V v_{g,n} + S_l}{a_{l,n} + K \Delta V} + S_g}{a_{g,n} + K \Delta V} \quad (\text{F.259})$$

and

$$v_{l,n} = \frac{\sum_{nb} a_{l,nb} v_{l,nb} + K \Delta V \frac{\sum_{nb} a_{g,nb} v_{g,nb} + K \Delta V v_{l,n} + S_g}{a_{g,n} + K \Delta V} + S_l}{a_{l,n} + K \Delta V} \quad (\text{F.260})$$

In the equation for phase  $k$  all the  $v_{k,n}$  terms can be regrouped on the left, hence for  $k = g, l$  we get:

$$v_{g,n} (a_{g,n} + K \Delta V - \frac{(K \Delta V)^2}{a_{l,n} + K \Delta V}) = \sum_{nb} a_{g,nb} v_{g,nb} + K \Delta V \frac{\sum_{nb} a_{l,nb} v_{l,nb} + S_l}{a_{l,n} + K \Delta V} + S_g \quad (\text{F.261})$$

$$v_{l,n} (a_{l,n} + K \Delta V - \frac{(K \Delta V)^2}{a_{g,n} + K \Delta V}) = \sum_{nb} a_{l,nb} v_{l,nb} + K \Delta V \frac{\sum_{nb} a_{g,nb} v_{g,nb} + S_g}{a_{g,n} + K \Delta V} + S_l \quad (\text{F.262})$$

This means that the modified coupling terms  $K \Delta V \frac{\sum a_{k,i} v_{k,i} + S_k}{a_{k,n} + K \Delta V}$  and  $K \Delta V - \frac{(K \Delta V)^2}{a_{k,n} + K \Delta V}$  must be calculated separately for the momentum balance components in each phase, then transferred and employed in the corresponding equation for the other phase. In particular, after the coupling terms have been received from the phase where they are calculated, the modified terms are added to the source  $S_e$  and the coefficient  $a_e$  terms in the other phase, respectively. In this case,  $S_k$  denotes the sum of all source terms except the drag force.

### Algebraic discretization equation

Finally, after dividing all the terms by  $\Delta t$ , the discretized equation can be written on the standard algebraic form:

$$a_P v_{l,P} = a_N v_{l,N} + a_S v_{l,S} + a_E v_{l,E} + a_W v_{l,W} + b_{v_l} \quad (\text{F.263})$$

The coefficients are defined by:

$$\begin{aligned} a_N &= D_n + \max[-C_n, 0] \\ a_S &= D_s + \max[C_s, 0] \\ a_E &= D_e + \max[-C_e, 0] \\ a_W &= D_w + \max[C_w, 0] \\ b &= \sum_m S_{C,m} + a_P^0 v_{l,P}^0 \\ a_P &= \frac{\Delta V}{\Delta t} (\alpha_l \rho_l)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - \sum_q S_{P,q} \Delta V \end{aligned} \quad (\text{F.264})$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity Eq. (F.187). The negative  $mC_2$ -term is then moved to the RHS of the discretized transport equation and included as part of the  $b$ -term. The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

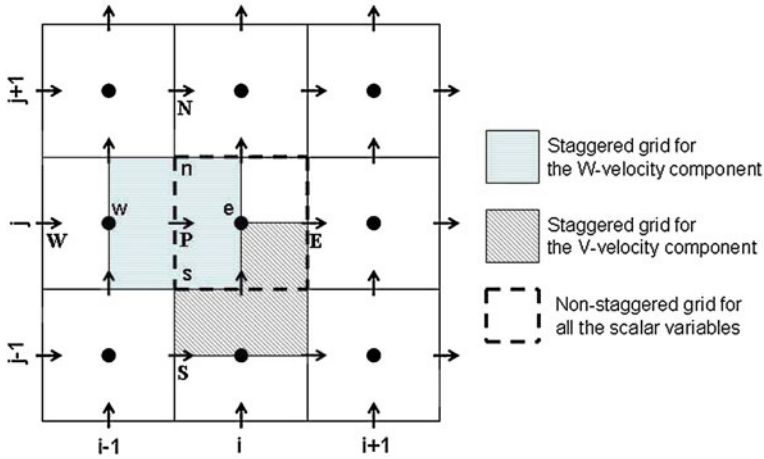

$$\begin{aligned} b^* &= -mC_2 v_{l,P}^\nu + \sum_m S_{C,m,l} + a_P^0 v_{l,P}^0 \\ a_P^* &= \frac{\Delta V}{\Delta t} (\alpha_l \rho_l)_P^0 + a_N + a_S + a_E + a_W + mC_1 - \sum_q S_{P,q,l} \Delta V. \end{aligned} \quad (\text{F.265})$$

### F.4.5 Liquid Phase Axial Momentum Balance

The axial component of the momentum balance is given in (F.137).

$$\begin{aligned} \frac{\partial}{\partial t} (\alpha_l \rho_l w_l) + \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \rho_l v_l w_l) + \frac{\partial}{\partial z} (\alpha_l \rho_l w_l w_l) \\ = w_l \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right) + w_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) \\ + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \left( \frac{1}{r} \frac{\partial}{\partial r} (r v_l) + \frac{\partial w_l}{\partial z} \right) \\ + \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \mu_{l,\text{eff}} \frac{\partial w_l}{\partial r}) + \frac{\partial}{\partial z} (\alpha_l \mu_{l,\text{eff}} \frac{\partial w_l}{\partial z}) \end{aligned}$$

**Fig. F.4** A staggered Cartesian  $w$ -grid cell, the distribution of the variables in this grid and the configuration of the staggered  $v$ -velocity grid cell and the non-staggered scalar grid. In cylindrical coordinates equivalent grid cells can be defined

$$\begin{aligned}
 & + \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \mu_{l,\text{eff}} \frac{\partial v_l}{\partial z}) + \frac{\partial}{\partial z} (\alpha_l \mu_{l,\text{eff}} \frac{\partial w_l}{\partial z}) \\
 & - \frac{\partial}{\partial z} (\frac{2}{3} \alpha_l \rho_l (k + \nu_{l,\text{eff}} (\frac{1}{r} \frac{\partial}{\partial r} (r v_l) + \frac{\partial w_l}{\partial z}))) \\
 & - \alpha_l \frac{\partial p}{\partial z} + \alpha_l \rho_l g_z + F_{l,z}^C + \overline{F_{l,z}^{C'}}
 \end{aligned} \tag{F.266}$$

In the FVM, the integral form of the momentum equation is used. The differential equation is thus integrated in time and over a grid cell volume in the staggered grid for the  $w$ -velocity sketched in Fig. F.4.

### The Transient term

$$\int_{\Delta V} \int_t^{t+\Delta t} \frac{\partial}{\partial t} (\alpha_l \rho_l w_l) dt dV = \left[ (\alpha_l \rho_l w_l)_P - (\alpha_l \rho_l w_l)_P^o \right] \Delta V \tag{F.267}$$

To approximate the scalar grid cell variables  $\alpha$  and  $\rho$  at the staggered velocity grid cell nodes, arithmetic interpolation is needed:

$$(\alpha_l \rho_l w_l)_P = \frac{1}{2} [(\alpha_{l,P} \rho_{l,P}) + (\alpha_{l,W} \rho_{l,W})] w_{l,P} \tag{F.268}$$

$$(\alpha_l \rho_l w_l)_P^o = \frac{1}{2} [(\alpha_{l,P} \rho_{l,P})^o + (\alpha_{l,W} \rho_{l,W})^o] w_{l,P}^o. \quad (\text{F.269})$$

### The convection term

The locations of the node points in the staggered grid for the  $w$ -velocity component are shown in Fig. F.4.

Radial direction:

$$\begin{aligned} \int_{\Delta t} \int_{\Delta V} \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \rho_l v_l w_l) r dr dz dt &= \Delta z [(r \alpha_l \rho_l v_l w_l)_n - (r \alpha_l \rho_l v_l w_l)_s] \Delta t \\ &= C_n v_{l,n} \Delta t - C_s v_{l,s} \Delta t \end{aligned} \quad (\text{F.270})$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned} C_n &= A_n F_n = A_n \frac{1}{2} [F_N + F_{NW}] \\ C_s &= A_n F_n = A_s \frac{1}{2} [F_S + F_{SW}] \\ F_N &= (\alpha_l \rho_l v_l)_N = \frac{1}{2} [\alpha_{l,N} \rho_{l,N} + \alpha_{l,P} \rho_{l,P}] v_{l,N} \\ F_{NW} &= (\alpha_l \rho_l v_l)_{NW} = \frac{1}{2} [\alpha_{l,W} \rho_{l,W} + \alpha_{l,NW} \rho_{l,NW}] v_{l,NW} \\ F_S &= (\alpha_l \rho_l v_l)_S = \frac{1}{2} [\alpha_{l,S} \rho_{l,S} + \alpha_{l,P} \rho_{l,P}] v_{l,P} \\ F_{SW} &= (\alpha_l \rho_l v_l)_{SW} = \frac{1}{2} [\alpha_{l,W} \rho_{l,W} + \alpha_{l,SW} \rho_{l,SW}] v_{l,W} \end{aligned} \quad (\text{F.271})$$

Axial direction:

$$\begin{aligned} \int_{\Delta t} \int_{\Delta V} \frac{\partial}{\partial z} (\alpha_l \rho_l w_l w_l) dz r dr dt &= [r_p \Delta r (\alpha_l \rho_l w_l w_l)_e - r_p \Delta r (\alpha_l \rho_l w_l w_l)_w] \Delta t \\ &= C_e v_{l,e} \Delta t - C_w v_{l,w} \Delta t \end{aligned} \quad (\text{F.272})$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned} C_e &= A_e F_e = A_e \frac{1}{2} [F_E + F_P] \\ C_w &= A_w F_w = A_w \frac{1}{2} [F_P + F_W] \end{aligned} \quad (\text{F.273})$$

$$\begin{aligned}
 F_E &= (\alpha_l \rho_l w_l)_E = \frac{1}{2} [\alpha_{l,P} \rho_{l,P} + \alpha_{l,E} \rho_{l,E}] w_{l,E} \\
 F_P &= (\alpha_l \rho_l w_l)_P = \frac{1}{2} [\alpha_{l,P} \rho_{l,P} + \alpha_{l,W} \rho_{l,W}] w_{l,P} \\
 F_W &= (\alpha_l \rho_l w_l)_W = \frac{1}{2} [\alpha_{l,W} \rho_{l,W} + \alpha_{l,WW} \rho_{l,WW}] w_{l,W}.
 \end{aligned}$$

### The diffusion terms

The locations of the node points in the staggered grid for the  $w$ -velocity are shown in Fig. F.4.

Radial direction:

$$\begin{aligned}
 & \int_{\Delta t \Delta V} \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r}) r dr dz dt \\
 &= \left[ (\Delta z r \alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r})_n - (\Delta z r \alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r})_s \right] \Delta t \\
 &= A_n \Gamma_n \left( \frac{w_{l,N} - w_{l,P}}{\delta r_{NP}} \right) \Delta t - A_s \Gamma_s \left( \frac{w_{l,P} - w_{l,S}}{\delta r_{PS}} \right) \Delta t \\
 &= D_n (w_{l,N} - w_{l,P}) \Delta t - D_s (w_{l,P} - w_{l,S}) \Delta t \quad (F.274)
 \end{aligned}$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
 D_n &= \frac{A_n \Gamma_n}{\delta r_{NP}} \\
 D_s &= \frac{A_s \Gamma_s}{\delta r_{PS}} \\
 \Gamma_n &= (\alpha_l \mu_{l,eff})_n = \frac{1}{4} (\alpha_{l,P} \mu_{l,P} + \alpha_{l,N} \mu_{l,N} + \alpha_{l,W} \mu_{l,W} + \alpha_{l,NW} \mu_{l,NW}) \\
 \Gamma_s &= (\alpha_l \mu_{l,eff})_s = \frac{1}{4} (\alpha_{l,P} \mu_{l,P} + \alpha_{l,S} \mu_{l,S} + \alpha_{l,W} \mu_{l,W} + \alpha_{l,SW} \mu_{l,SW}) \quad (F.275)
 \end{aligned}$$

Axial direction:

$$\begin{aligned}
 & \int_{\Delta t \Delta V} \frac{\partial}{\partial z} (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z}) dz r dr dt \\
 &= [r_p \Delta r (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z})_e - r_p \Delta r (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z})_w] \Delta t
 \end{aligned}$$

$$\begin{aligned}
&= A_e \Gamma_e \left( \frac{w_{l,E} - w_{l,P}}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \right) \Delta t - A_w \Gamma_w \left( \frac{w_{l,P} - w_{l,W}}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \right) \Delta t \\
&= D_e (w_{l,E} - w_{l,P}) \Delta t - D_w (w_{l,P} - w_{l,W}) \Delta t
\end{aligned} \tag{F.276}$$

To approximate the scalar grid cell mass fluxes at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
D_e &= \frac{A_e \Gamma_e}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \\
D_w &= \frac{A_w \Gamma_w}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \\
\Gamma_e &= (\alpha_l \mu_{l,eff})_e = \alpha_{l,P} \mu_{l,P} \\
\Gamma_w &= (\alpha_l \mu_{l,eff})_w = \alpha_{l,W} \mu_{l,W}.
\end{aligned} \tag{F.277}$$

### The source terms

The the source terms are approximated by the midpoint rule, in which  $S$  is considered an average value representative for the whole grid cell volume. The derivatives are represented by an abbreviated Taylor series expansion, usually a central difference expansion of second order is employed.

Term 1 on the RHS of the momentum equation:

$$\begin{aligned}
&\int_{\Delta t} \int_{\Delta V} w_l \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt \\
&= \frac{w_P}{r_P} \left[ \left( r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right)_n - \left( r \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right)_s \right] \frac{\Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})}
\end{aligned} \tag{F.278}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,1} = \frac{w_P}{r_P} \left[ r_N^v \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \right)_n \left( \frac{\partial \alpha_l}{\partial r} \right)_n - r_P^v \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \right)_s \left( \frac{\partial \alpha_l}{\partial r} \right)_s \right] \frac{\Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \tag{F.279}$$

To approximate derivatives of scalar grid cell variables and scalar grid cell variables at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
 \left(\frac{\partial \alpha_l}{\partial r}\right)_n &= \frac{(\alpha_l)_N - (\alpha_l)_P}{\delta r_{NP}} = \frac{\frac{1}{2}(\alpha_{l,N} + \alpha_{l,NW}) - \frac{1}{2}(\alpha_{l,P} + \alpha_{l,W})}{\delta r_{NP}} \\
 \left(\frac{\partial \alpha_l}{\partial r}\right)_s &= \frac{(\alpha_l)_P - (\alpha_l)_S}{\delta r_{PS}} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,W}) - \frac{1}{2}(\alpha_{l,S} + \alpha_{l,SW})}{\delta r_{PS}}
 \end{aligned} \tag{F.280}$$

Term 2 on the RHS of the momentum equation:

$$\int \int_{\Delta t \Delta V} w_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = w_{l,P} \left[ \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_e - \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_w \right] \frac{\Delta V \Delta t}{\delta z_{PW}} \tag{F.281}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,2} = w_{l,P} \frac{\Delta V \Delta t}{\delta z_{PW}} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial z} \right)_e - \frac{\mu_{l,t,W}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial z} \right)_w \right) \tag{F.282}$$

where

$$\begin{aligned}
 \left(\frac{\partial \alpha_l}{\partial z}\right)_e &= \frac{(\alpha_l)_E - (\alpha_l)_P}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} = \frac{\frac{1}{2}(\alpha_{l,E} + \alpha_{l,P}) - \frac{1}{2}(\alpha_{l,P} + \alpha_{l,W})}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \\
 \left(\frac{\partial \alpha_l}{\partial z}\right)_w &= \frac{(\alpha_l)_P - (\alpha_l)_W}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,W}) - \frac{1}{2}(\alpha_{l,W} + \alpha_{l,WW})}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})}
 \end{aligned} \tag{F.283}$$

Term 3 on the RHS of the momentum equation:

$$\begin{aligned}
 &\int \int_{\Delta t \Delta V} \left[ \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \left( \frac{1}{r} \frac{\partial}{\partial r} (rv_l) + \frac{\partial w_l}{\partial z} \right) \right] dV dt \\
 &= \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_P \left( \frac{1}{r_P} \frac{(rv_l)_n - (rv_l)_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} + \left( \frac{\partial w_l}{\partial z} \right)_P \right) \Delta V \Delta t
 \end{aligned} \tag{F.284}$$

This term is implemented through the source term  $S_C$  as:

$$\begin{aligned}
 S_{C,3} &= \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_P \left( \frac{1}{r_P} \frac{r_N^{\frac{1}{2}}(v_{l,N} + v_{l,NW}) - r_P^{\frac{1}{2}}(v_{l,P} + v_{l,W})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right) \Delta V \Delta t \\
 &+ \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_P \left( \frac{\partial w_l}{\partial z} \right)_P \Delta V \Delta t
 \end{aligned} \tag{F.285}$$

To approximate derivatives of scalar grid cell variables and scalar grid cell variables at the staggered velocity grid cell surface points, arithmetic interpolation is frequently used:

$$\begin{aligned}
 (\mu_{l,i})_P &= \frac{1}{2}(\mu_{l,P} + \mu_{l,W}) \\
 \left(\frac{\partial \alpha_l}{\partial z}\right)_P &= \frac{(\alpha_l)_e - (\alpha_l)_w}{\delta z_{PW}} = \frac{\alpha_{l,P} - \alpha_{l,W}}{\delta z_{PW}} \\
 \left(\frac{\partial w_l}{\partial z}\right)_P &= \frac{v_{l,e} - v_{l,w}}{\delta z_{PW}} = \frac{\frac{1}{2}(v_{l,P} + v_{l,E}) - \frac{1}{2}(v_{l,P} + v_{l,W})}{\delta z_{PW}}
 \end{aligned} \tag{F.286}$$

Term 4 on the RHS of the momentum equation:

$$\begin{aligned}
 &\int_{\Delta t \Delta V} \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial r}) dV dt \\
 &= \frac{\Delta V \Delta t}{r_P} \left[ (\alpha_l r \mu_{l,eff} \frac{\partial w_l}{\partial r})_n - (\alpha_l r \mu_{l,eff} \frac{\partial w_l}{\partial r})_s \right]
 \end{aligned} \tag{F.287}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,4} = \frac{\Delta V \Delta t}{r_P} \left[ \Gamma_n r_N^v \left( \frac{w_{l,N} - w_{l,P}}{\delta r_{NP}} \right) - \Gamma_s r_P^v \left( \frac{w_{l,P} - w_{l,S}}{\delta r_{PS}} \right) \right] \tag{F.288}$$

Term 5th and 7th terms on the RHS of the momentum equation are identical and both of them are approximated as follows:

$$\int_{\Delta t \Delta V} \frac{\partial}{\partial z} (\alpha_l \mu_l \frac{\partial w_l}{\partial z}) dV dt = \frac{\Delta V \Delta t}{\delta z_{PW}} \left[ (\alpha_l \mu_l \frac{\partial w_l}{\partial z})_e - (\alpha_l \mu_l \frac{\partial w_l}{\partial z})_w \right] \tag{F.289}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,5} = \frac{\Delta V \Delta t}{\delta z_{PW}} \left[ \alpha_{l,P} \mu_{l,P} \frac{(w_{l,E} - w_{l,P})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} - \alpha_{l,W} \mu_{l,W} \frac{(w_{l,P} - w_{l,W})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right] \tag{F.290}$$

The staggered velocity grid cell surface points coincide with center nodes in the scalar grid, so no interpolation is needed.

Term 6 on the RHS of the momentum equation:

$$\int_{\Delta t \Delta V} \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_l \mu_{l,eff} \frac{\partial v_l}{\partial z}) dV dt$$

$$= \frac{\Delta V \Delta t}{r_P} \left[ (\alpha_l r \mu_{l,eff} \frac{\partial v_l}{\partial z})_n - (\alpha_l r \mu_{l,eff} \frac{\partial v_l}{\partial z})_s \right] \quad (F.291)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,6} = \frac{\Delta V \Delta t}{r_P} \left[ \Gamma_n r_N^v \left( \frac{v_{l,N} - v_{l,NW}}{\delta z_{PW}} \right) - \Gamma_s r_P^v \left( \frac{v_{l,P} - v_{l,W}}{\delta z_{PW}} \right) \right] \quad (F.292)$$

Term 8A on the RHS of the momentum equation:

$$\begin{aligned} - \int \int_{\Delta t \Delta V} \frac{\partial}{\partial z} \left( \frac{2}{3} \alpha_l \rho_l k_l \right) dV dt &= - \frac{2}{3} \frac{\Delta V \Delta t}{\delta z_{PW}} [(\alpha_l \rho_l k_l)_e - (\alpha_l \rho_l k_l)_w] \\ &= - \frac{2}{3} \frac{\Delta V \Delta t}{\delta z_{PW}} [\alpha_{l,P} \rho_{l,P} k_{l,P} - \alpha_{l,W} \rho_{l,W} k_{l,W}] \end{aligned} \quad (F.293)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,7} = \frac{2}{3} \frac{\Delta V \Delta t}{\delta z_{PW}} [\alpha_{l,W} \rho_{l,W} k_W - \alpha_{l,P} \rho_{l,P} k_P] \quad (F.294)$$

The staggered velocity grid cell surface points coincide with center nodes in the scalar grid, so no interpolation is needed.

Term 8B on the RHS of the momentum equation:

$$\begin{aligned} - \int \int_{\Delta t \Delta V} \frac{\partial}{\partial z} \left( \frac{2}{3} \alpha_l \rho_l v_{l,eff} \frac{1}{r} \frac{\partial (rv_l)}{\partial r} \right) dV dt \\ = - \frac{2 \Delta V \Delta t}{3 \delta z_{PW}} \left[ \left( \frac{\alpha_l \mu_{l,eff}}{r} \frac{\partial (rv_l)}{\partial r} \right)_e - \left( \frac{\alpha_l \mu_{l,eff}}{r} \frac{\partial (rv_l)}{\partial r} \right)_w \right] \end{aligned} \quad (F.295)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,8} = - \frac{2 \Delta V \Delta t}{3 \delta z_{PW}} \left[ \frac{\alpha_{l,P} \mu_{l,eff,P}}{r_P} \frac{\partial (rv_l)}{\partial r} |_e - \frac{\alpha_{l,W} \mu_{l,eff,W}}{r_P} \frac{\partial (rv_l)}{\partial r} |_w \right] \quad (F.296)$$

The staggered velocity grid cell surface points coincide with center nodes in the scalar grid, so no interpolation is needed for the scalar grid variables.

The velocity derivatives are approximated by central difference discretizations:

$$\frac{\partial (rv_l)}{\partial r} |_e = \frac{(rv_l)_{ne} - (rv_l)_{se}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{r_N^v v_{l,N} - r_P^v v_{l,P}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \quad (F.297)$$

$$\frac{\partial(rv_l)}{\partial r}|_w = \frac{(rv_l)_{nw} - (rv_l)_{sw}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{r_{NW}^v v_{l,NW} - (r_P^v v_{l,W})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})}$$

Term 8C on the RHS of the momentum equation:

$$\begin{aligned} & - \int_{\Delta t \Delta V} \frac{\partial}{\partial z} \left( \frac{2}{3} \alpha_l \rho_l \nu_{l,eff} \frac{\partial w_l}{\partial z} \right) dV dt \\ & = - \frac{2\Delta V \Delta t}{3 \delta z_{PW}} \left[ (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z})_e - (\alpha_l \mu_{l,eff} \frac{\partial w_l}{\partial z})_w \right] \end{aligned} \quad (F.298)$$

This term is implemented through the source term  $S_C$  as:

$$\begin{aligned} S_{C,9} &= - \frac{2\Delta V}{3 \delta z_{PW}} \alpha_{l,P} \mu_{l,eff,P} \frac{(w_{l,E} - w_{l,P})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \\ &+ \frac{2\Delta V}{3 \delta z_{PW}} \alpha_{l,W} \mu_{l,eff,W} \frac{(w_{l,P} - w_{l,W})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \end{aligned} \quad (F.299)$$

The staggered velocity grid cell surface points coincide with center nodes in the scalar grid, so no interpolation is needed for the scalar grid variables. The velocity gradients are approximated by central difference expansions.

### Pressure force

$$- \int_{\Delta t \Delta V} \alpha_l \frac{\partial p}{\partial z} dV dt = - \frac{1}{2} (\alpha_l)_P \frac{(P_P - P_W)}{\delta z_{PW}} \Delta V \Delta t \quad (F.300)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,10} = - \frac{1}{2} (\alpha_{l,P} + \alpha_{l,W}) \frac{P_P - P_W}{\delta z_{PW}} \Delta V \quad (F.301)$$

To approximate scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is frequently used:

$$(\alpha_l)_P = \frac{1}{2} (\alpha_{l,P} + \alpha_{l,W}). \quad (F.302)$$

**Gravity force**

$$\int_{\Delta t} \int_{\Delta V} \alpha_l \rho_l g \, dV \, dt = g(\alpha_l \rho_l)_P \Delta V \Delta t \quad (\text{F.303})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,11} = g \frac{1}{2} (\alpha_{l,P} \rho_{l,P} + \alpha_{l,W} \rho_{l,W}) \Delta V \Delta t \quad (\text{F.304})$$

To approximate scalar grid cell variables at the staggered velocity grid cell node points, arithmetic interpolation is frequently used:

$$(\alpha_l \rho_l)_P = \frac{1}{2} (\alpha_{l,P} \rho_{l,P} + \alpha_{l,W} \rho_{l,W}). \quad (\text{F.305})$$

**Added Mass force**

$$\begin{aligned} & \int_{\Delta t} \int_{\Delta V} -\alpha_l \alpha_g \rho_l f_v \left[ \left( w_l \frac{\partial w_l}{\partial z} + v_l \frac{\partial w_l}{\partial r} \right) - \left( v_g \frac{\partial v_g}{\partial z} + v_g \frac{\partial v_g}{\partial r} \right) \right] dV \, dt \\ &= -f_v (\alpha_l)_P (\alpha_g)_P (\rho_l)_P \\ & \quad \times \left[ \left( w_l \left( \frac{\partial w_l}{\partial z} \right) + (v_l) \left( \frac{\partial w_l}{\partial r} \right) \right) - \left( w_g \left( \frac{\partial w_g}{\partial z} \right) + (v_g) \left( \frac{\partial w_g}{\partial r} \right) \right) \right]_P \Delta V \Delta t \end{aligned} \quad (\text{F.306})$$

This term is implemented through the source term  $S_C$  as:

$$\begin{aligned} S_{C,12} &= -f_v \frac{1}{2} (\alpha_{l,P} + \alpha_{l,W}) \frac{1}{2} (\alpha_{g,P} + \alpha_{g,W}) \frac{1}{2} (\rho_{l,P} + \rho_{l,W}) \\ & \quad \times \left[ \left( w_l \frac{\partial w_l}{\partial z} + v_l \frac{\partial w_l}{\partial r} \right) - \left( w_g \frac{\partial v_g}{\partial z} + (v_g) \frac{\partial v_g}{\partial r} \right) \right]_P \Delta V \Delta t \end{aligned} \quad (\text{F.307})$$

To approximate scalar grid cell variables at the staggered  $w$ -velocity grid cell center node point, arithmetic interpolation is frequently used. The radial velocity component is discretized in the staggered  $v$ -grid cell volume and need to be interpolated to the  $w$ -grid cell center node point. The derivatives of the  $w$ -velocity component is approximated by a central difference scheme. When needed, arithmetic interpolation is used for the velocity components as well.

$$(\alpha_g)_P = \frac{1}{2} (\alpha_{g,P} + \alpha_{g,W}) \quad (\text{F.308})$$

$$(\rho_l)_P = \frac{1}{2} (\rho_{l,P} + \rho_{l,W})$$

$$\begin{aligned}
 (v_l)_P &= \frac{1}{4}(v_{l,P} + v_{l,N} + v_{l,W} + v_{l,NW}) \\
 \left(\frac{\partial w_l}{\partial r}\right)_P &= \frac{w_{l,n} - w_{l,s}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{\frac{1}{2}(w_{l,P} + w_{l,N}) - \frac{1}{2}(w_{l,P} + w_{l,S})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \\
 \left(\frac{\partial w_l}{\partial z}\right)_P &= \frac{w_{l,e} - w_{l,w}}{\delta z_{PW}} = \frac{\frac{1}{2}(w_{l,P} + w_{l,E}) - \frac{1}{2}(w_{l,P} + w_{l,W})}{\delta z_{PW}}
 \end{aligned}$$

The corresponding terms for the gas phase are discretized in the same way.

### Steady Drag force

The steady drag term is treated in the same way as described for the radial velocity component.

### Algebraic discretization equation

After dividing all the terms by  $\Delta t$ , the discretized equation can be written on the standard algebraic form:

$$a_P w_{l,P} = a_N w_{l,N} + a_S w_{l,S} + a_E w_{l,E} + a_W w_{l,W} + b_{w_l} \quad (\text{F.309})$$

The coefficients are defined by:

$$\begin{aligned}
 a_N &= D_n + \max[-C_n, 0] \\
 a_S &= D_s + \max[C_s, 0] \\
 a_E &= D_e + \max[-C_e, 0] \\
 a_W &= D_w + \max[C_w, 0] \\
 b &= \sum_m S_{C,m} + a_P^0 v_{l,P}^0 \\
 a_P &= \frac{\Delta V}{\Delta t} (\alpha_l \rho_l)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - \sum_q S_{P,q} \Delta V
 \end{aligned} \quad (\text{F.310})$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity Eq. (F.187). The negative  $mC_2$ -term is then moved to the RHS of the discretized transport equation and included as part of the  $b$ -term. The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

$$\begin{aligned}
b^* &= -mC_2w_{l,p}^\nu + \sum_m S_{C,m,l} + a_P^0w_{l,p}^0 \\
a_P^* &= \frac{\Delta V}{\Delta t}(\alpha_l\rho_l)_P^0 + a_N + a_S + a_E + a_W + mC_1 - \sum_q S_{P,q,l}\Delta V.
\end{aligned} \tag{F.311}$$

#### F.4.6 The Gas Phase Radial Momentum Balance

The radial component of the momentum balance for the gas phase is given in (F.145):

$$\begin{aligned}
&\frac{\partial}{\partial t}(\alpha_g\rho_g v_g) + \frac{1}{r}\frac{\partial}{\partial r}(r\alpha_g\rho_g v_g v_g) + \frac{\partial}{\partial z}(\alpha_g\rho_g w_g v_g) \\
&= \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}}\frac{\partial\alpha_g}{\partial r}v_g\right) + \frac{\partial}{\partial z}\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}}\frac{\partial\alpha_g}{\partial z}v_g\right) \\
&\quad + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}}\frac{\partial\alpha_g}{\partial r}v_g\right) + \frac{\partial}{\partial z}\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}}\frac{\partial\alpha_g}{\partial r}w_g\right) \\
&\quad + \frac{1}{r}\frac{\partial}{\partial r}\left(r\alpha_g\frac{\mu_{g,t}}{\sigma_{g,t}}\frac{\partial v_g}{\partial r}\right) - \frac{1}{r}\alpha_g\frac{\mu_{g,t}}{\sigma_{g,t}}\frac{v_g}{r} + \frac{\partial}{\partial z}\left(\alpha_g\frac{\mu_{g,t}}{\sigma_{g,t}}\frac{\partial v_g}{\partial z}\right) \\
&\quad + \frac{1}{r}\frac{\partial}{\partial r}\left(r\alpha_g\frac{\mu_{g,t}}{\sigma_{g,t}}\frac{\partial v_g}{\partial r}\right) - \frac{1}{r}\alpha_g\frac{\mu_{g,t}}{\sigma_{g,t}}\frac{v_g}{r} + \frac{\partial}{\partial z}\left(\alpha_g\frac{\mu_{g,t}}{\sigma_{g,t}}\frac{\partial w_g}{\partial r}\right) \\
&\quad - \frac{\partial}{\partial r}\left(\frac{2}{3}\alpha_g\rho_g\left(k + \frac{\nu_{g,t}}{\sigma_{g,t}}\left(\frac{1}{r}\frac{\partial}{\partial r}(rv_g) + \frac{\partial w_g}{\partial z}\right)\right)\right) \\
&\quad - \alpha_g\frac{\partial p}{\partial r} + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}}\left(\frac{\partial\alpha_l}{\partial r}\frac{\partial v_l}{\partial r} + \frac{\partial\alpha_l}{\partial z}\frac{\partial v_l}{\partial z}\right) \\
&\quad + v_l\frac{\partial}{\partial r}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}}\frac{\partial\alpha_l}{\partial r}\right) + w_l\frac{\partial}{\partial z}\left(\frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}}\frac{\partial\alpha_l}{\partial r}\right) \\
&\quad + \alpha_g\rho_g g_r + F_{g,r}^C + \overline{F_{g,r}^{C'}}
\end{aligned}$$

In the FVM, the integral form of the momentum equation is used. The differential equation is thus integrated in time and over a grid cell volume in the staggered grid for the  $v$ -velocity.

The transient, convective and diffusive terms are discretized just like the corresponding terms in the liquid phase (i.e., see Sect. F.4.4).

#### The source terms

The the source terms are approximated by the midpoint rule, in which  $S$  is considered an average value representative for the whole grid cell volume. The derivatives are

represented by an abbreviated Taylor series expansion, usually a central difference expansion of second order is employed.

Term 1 on the RHS of the momentum equation is split into two parts, term 1a and term 1b:

$$\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial r} v_g \right) = -v_g \frac{\partial}{\partial r} \left( \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) - \frac{1}{r} \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial}{\partial r} (rv_g) \quad (\text{F.312})$$

By use of (8.11), the gas-volume fractions has been substituted with the liquid volume fraction. The gradient of the gas phase volume fraction is thus related to the liquid phase volume fraction in accordance with:

$$\nabla \alpha_g = \nabla (1 - \alpha_l) = -\nabla \alpha_l \quad (\text{F.313})$$

Term 1a on the RHS of the momentum equation:

$$\begin{aligned} & \int_{\Delta t \Delta V} -v_g \frac{\partial}{\partial r} \left( \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt \\ &= -\frac{v_{g,P} \Delta V \Delta t}{\frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \left[ \left( \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_n - \left( \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_s \right] \end{aligned} \quad (\text{F.314})$$

The term 1a is implemented through the source term  $S_C$  as:

$$S_{C,1} = -\frac{v_{g,P} \Delta V \Delta t}{\frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \left[ \mu_{g,P} \left( \frac{\partial \alpha_l}{\partial r} \right)_n - \mu_{g,S} \left( \frac{\partial \alpha_l}{\partial r} \right)_s \right] \quad (\text{F.315})$$

The staggered velocity grid cell surface points coincide with center nodes in the scalar grid, so no interpolation is needed for the scalar grid variables. The scalar gradient terms in the staggered velocity cell volume are approximated by central difference expansions and arithmetic interpolation:

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial r} \right)_n &= \frac{(\alpha_l)_N - (\alpha_l)_P}{\delta r_{NP}} = \frac{\frac{1}{2}(\alpha_{l,N} + \alpha_{l,P}) - \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S})}{\delta r_{NP}} \\ \left( \frac{\partial \alpha_l}{\partial r} \right)_s &= \frac{(\alpha_l)_P - (\alpha_l)_S}{\delta r_{PS}} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) - \frac{1}{2}(\alpha_{l,S} + \alpha_{l,SS})}{\delta r_{PS}} \end{aligned} \quad (\text{F.316})$$

Term 1b on the RHS of the momentum equation:

$$-\int_{\Delta t \Delta V} \frac{1}{r} \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial}{\partial r} (rv_g) dV dt = -\left( \frac{1}{r} \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_P \frac{[(rv_g)_n - (rv_g)_s]}{\frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \Delta V \Delta t \quad (\text{F.317})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,2} = -\frac{(\mu_g)_P}{r_P^v} \left( \frac{\partial \alpha_l}{\partial r} \right)_P \frac{r_P \frac{1}{2} (v_{g,P} + v_{g,N}) - r_S \frac{1}{2} (v_{g,P} + v_{g,S})}{\frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \Delta V \Delta t \quad (\text{F.318})$$

The scalar variables at the staggered velocity grid cell surface points is usually obtained by arithmetic interpolation. The scalar gradient terms in the staggered velocity cell volume are approximated by central difference expansions. The scalar properties at the staggered grid cell surface points coincide with the scalar grid central nodes:

$$\begin{aligned} (\mu_g)_P &= \frac{1}{2} (\mu_{g,P} + \mu_{g,S}) \\ \left( \frac{\partial \alpha_l}{\partial r} \right)_P &= \frac{(\alpha_l)_n - (\alpha_l)_s}{\frac{1}{2} (\delta r_{NP} + \delta r_{PS})} = \frac{\alpha_{l,P} - \alpha_{l,S}}{\frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \end{aligned} \quad (\text{F.319})$$

Term 2 on the RHS of the momentum equation is split into two parts, term 2a and term 2b:

$$\frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} v_g \right) = -v_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial v_g}{\partial z} \quad (\text{F.320})$$

Term 2a on the RHS of the momentum equation:

$$\begin{aligned} \iint_{\Delta t \Delta V} -v_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt \\ = -\frac{v_{g,P} \Delta V}{\frac{1}{2} (\delta z_{PW} + \delta z_{EP})} \left[ \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right)_e - \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right)_w \right] \end{aligned} \quad (\text{F.321})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,3} = -\frac{v_{g,P} \Delta V}{\frac{1}{2} (\delta z_{PW} + \delta z_{EP})} \left[ \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right)_e - \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right)_w \right] \quad (\text{F.322})$$

To approximate the scalar variables at the staggered velocity grid cell surface points, arithmetic interpolation is frequently applied. The derivatives are approximated by a central difference scheme:

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial z} \right)_e &= \frac{(\alpha_l)_E - (\alpha_l)_P}{\delta z_{EP}} = \frac{\frac{1}{2} (\alpha_{l,E} + \alpha_{l,SE}) - \frac{1}{2} (\alpha_{l,E} + \alpha_{l,SE})}{\delta z_{EP}} \\ \left( \frac{\partial \alpha_l}{\partial z} \right)_w &= \frac{(\alpha_l)_P - (\alpha_l)_W}{\delta z_{PW}} = \frac{\frac{1}{2} (\alpha_{l,P} + \alpha_{l,S}) - \frac{1}{2} (\alpha_{l,W} + \alpha_{l,SW})}{\delta z_{PW}} \end{aligned} \quad (\text{F.323})$$

$$(\mu_g)_e = \frac{1}{4}(\mu_{g,P} + \mu_{g,E} + \mu_{g,S} + \mu_{g,SE})$$

$$(\mu_g)_w = \frac{1}{4}(\mu_{g,P} + \mu_{g,W} + \mu_{g,S} + \mu_{g,SW})$$

Term 2b on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} -\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial v_g}{\partial z} dV dt = -\left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right)_P \frac{(v_{g,e} - v_{g,w})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \Delta V \Delta t \quad (F.324)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,4} = -(\mu_{g,t})_P \frac{\frac{\partial \alpha_l}{\partial z} \frac{1}{2}(v_{g,P} + v_{g,E}) - \frac{1}{2}(v_{g,P} + v_{g,W})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \Delta V \Delta t \quad (F.325)$$

where

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial z} \right)_P &= \frac{(\alpha_l)_e - (\alpha_l)_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \\ &= \frac{\frac{1}{4}(\alpha_{l,P} + \alpha_{l,E} + \alpha_{l,S} + \alpha_{l,SE}) - \frac{1}{4}(\alpha_{l,P} + \alpha_{l,W} + \alpha_{l,S} + \alpha_{l,SW})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \end{aligned} \quad (F.326)$$

Term 3 on the RHS of the momentum equation is split into two parts, term 3a and term 3b:

$$\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial r} v_g \right) = -\frac{v_g}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial v_g}{\partial r} \quad (F.327)$$

Term 3a on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} -\frac{v_g}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt = -\frac{v_{g,P}}{r_P^v} \left[ \frac{(r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r})_n - (r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r})_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \Delta V \Delta t \quad (F.328)$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,5} = -\frac{v_{g,P}}{r_P^v} \left[ \frac{r_P \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} (\frac{\partial \alpha_l}{\partial r})_n - r_S \frac{\mu_{g,t,S}}{\sigma_{\alpha_{g,t}}} (\frac{\partial \alpha_l}{\partial r})_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \Delta V \Delta t \quad (F.329)$$

where

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial r} \right)_n &= \frac{(\alpha_l)_N - (\alpha_l)_P}{\delta r_{NP}} = \frac{\frac{1}{2}(\alpha_{l,N} + \alpha_{l,P}) - \frac{1}{2}(\alpha_{l,P} + \alpha_{l,S})}{\delta r_{NP}} \\ \left( \frac{\partial \alpha_l}{\partial r} \right)_s &= \frac{(\alpha_l)_P - (\alpha_l)_S}{\delta r_{PS}} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) - \frac{1}{2}(\alpha_{l,S} + \alpha_{l,SS})}{\delta r_{PS}} \end{aligned} \quad (\text{F.330})$$

Term 3b on the RHS of the momentum equation:

$$\int_{\Delta t \Delta V} - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial v_g}{\partial r} dV dt = - \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \right)_P \left( \frac{\partial \alpha_l}{\partial r} \right)_P \frac{(v_{g,n} - v_{g,s})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \Delta V \quad (\text{F.331})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,6} = - \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \right)_P \left( \frac{\partial \alpha_l}{\partial r} \right)_P \frac{\frac{1}{2}(v_{g,N} + v_{g,P}) - \frac{1}{2}(v_{g,P} + v_{g,S})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \Delta V \Delta t \quad (\text{F.332})$$

The staggered grid variables are expressed in terms of the node values in the scalar grid:

$$\begin{aligned} (\mu_g)_P &= \frac{1}{2}(\mu_{g,P} + \mu_{g,S}) \\ \left( \frac{\partial \alpha_l}{\partial r} \right)_P &= \frac{(\alpha_l)_n - (\alpha_l)_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{\alpha_{l,P} - \alpha_{l,S}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \end{aligned} \quad (\text{F.333})$$

Term 4 on the RHS of the momentum equation is split into two parts, term 4a and term 4b:

$$\frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial r} w_g \right) = -w_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial w_g}{\partial z} \quad (\text{F.334})$$

Term 4a on the RHS of the momentum equation:

$$\int_{\Delta t \Delta V} -w_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt = -w_{g,P} \left[ \frac{\left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_e - \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right] \Delta V \Delta t \quad (\text{F.335})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,7} = -(w_g)_P \left[ \frac{\left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_e - \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right] \Delta V \Delta t \quad (\text{F.336})$$

The staggered grid variables are expressed in terms of the node values in the scalar grid:

$$(w_g)_P = \frac{1}{4}(v_{g,P} + v_{g,S} + v_{g,E} + v_{g,SE}) \quad (\text{F.337})$$

Term 4b on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} -\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial w_g}{\partial z} dV dt = -\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r}\right)_P \left[\frac{(w_g)_e - (w_g)_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})}\right] \Delta V \Delta t \quad (\text{F.338})$$

This term is implemented through the source term  $S_C$  as:

$$\begin{aligned} S_{C,8} &= -\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r}\right)_P \left[\frac{(w_g)_e - (w_g)_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})}\right] \Delta V \Delta t \\ &= -\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r}\right)_P \left[\frac{\frac{1}{2}(v_{g,E} + v_{g,SE}) - \frac{1}{2}(v_{g,P} + v_{g,S})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})}\right] \Delta V \Delta t \end{aligned} \quad (\text{F.339})$$

The 5th and 8th terms on the RHS of the radial component of the momentum equation for the gas phase are identical and discretized in the same way as the corresponding terms in the liquid phase equation, as discussed in Sect. F.4.4:

$$\int_{\Delta t} \int_{\Delta V} \frac{1}{r} \frac{\partial}{\partial r} \left( r \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial v_g}{\partial r} \right) dV dt = \frac{\Delta V \Delta t}{r_P^v} \left[ \frac{(r \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial v_g}{\partial r})_n - (r \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial v_g}{\partial r})_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \quad (\text{F.340})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,9} = \frac{\Delta V \Delta t}{r_P^v} \frac{r_P \alpha_{g,P} \mu_{g,P} (\frac{\partial v_g}{\partial r})_n - r_S \alpha_{g,S} \mu_{g,S} (\frac{\partial v_g}{\partial r})_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \quad (\text{F.341})$$

The scalar variables at the staggered grid surface are expressed in terms of the node values in the scalar grid. The derivatives of staggered grid variables are approximated by use of the central difference scheme:

$$\begin{aligned} \left(\frac{\partial v_g}{\partial r}\right)_n &= \frac{v_{g,N} - v_{g,P}}{\delta r_{NP}} \\ \left(\frac{\partial v_g}{\partial r}\right)_s &= \frac{v_{g,P} - v_{g,S}}{\delta r_{PS}} \end{aligned} \quad (\text{F.342})$$

The 6th and 9th terms on the RHS of the radial component of the momentum equation for the gas phase are identical and discretized in the same way as the corresponding terms in the liquid phase equation, as discussed in Sect. F.4.4.

$$-2 \int_{\Delta t} \int_{\Delta V} \frac{1}{r} \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{v_g}{r} dV dt = -2 \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \right)_P \frac{v_{g,P}}{r_P^2} \Delta V \Delta t$$

$$= -2 \times \frac{1}{2} \left( \alpha_{g,P} \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} + \alpha_{g,S} \frac{\mu_{g,t,S}}{\sigma_{\alpha_{g,t}}} \right) \frac{v_{g,P}}{r_P^{2,v}} \Delta V \Delta t \quad (\text{F.343})$$

This term is implemented through the source term  $S_P$  as:

$$S_{P,1} = -2 \times \frac{1}{2} \left( \alpha_{g,P} \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} + \alpha_{g,S} \frac{\mu_{g,t,S}}{\sigma_{\alpha_{g,t}}} \right) \frac{\Delta V \Delta t}{r_P^{2,v}} \quad (\text{F.344})$$

in which the scalar variables at the staggered grid surface are expressed in terms of the node values in the scalar grid.

Term 7 on the RHS of the radial momentum equation is discretized in the same way as the corresponding term in the liquid phase equation, as discussed in Sect. F.4.4. The formulation is not repeated here.

Term 10 on the RHS of the radial momentum equation is discretized in the same way as the corresponding term in the liquid phase equation, as discussed in Sect. F.4.4:

$$\begin{aligned} & \int \int \frac{\partial}{\partial z} \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial w_g}{\partial r} \right) dV dt \\ &= \frac{\Delta V \Delta t}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \left[ \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial w_g}{\partial r} \right)_e - \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial w_g}{\partial r} \right)_w \right] \\ &= \frac{\Delta V \Delta t}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \left[ \Gamma_e \frac{(w_{g,E} - w_{g,SE})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} - \Gamma_w \frac{(w_{g,P} - w_{g,S})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \end{aligned} \quad (\text{F.345})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,10} = \frac{\Delta V \Delta t}{S_{EW,P}} \left[ \Gamma_e \frac{(w_{g,E} - w_{g,SE})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} - \Gamma_w \frac{(w_{g,P} - w_{g,S})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \quad (\text{F.346})$$

in which the scalar variables at the staggered grid surface are expressed in terms of the node values in the scalar grid.

Term 11A on the RHS of the radial momentum equation is discretized in the same way as the corresponding term in the liquid phase equation, as discussed in Sect. F.4.4:

$$- \int \int \frac{\partial}{\partial r} \left( \frac{2}{3} \alpha_g \rho_g k \right) dV dt = - \frac{2}{3} \frac{\Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} ((\alpha_g \rho_g k)_n - (\alpha_g \rho_g k)_s) \quad (\text{F.347})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,11} = \frac{2}{3} \frac{\Delta V}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} [\alpha_{g,P} \rho_{g,P} k_P - \alpha_{g,S} \rho_{g,S} k_S] \quad (\text{F.348})$$

in which the scalar variables at the staggered grid surface are expressed in terms of the node values in the scalar grid.

Term 11B on the RHS of the radial momentum equation is discretized in the same way as the corresponding term in the liquid phase equation, as discussed in Sect. F.4.4:

$$\begin{aligned}
 & - \int_{\Delta t} \int_{\Delta V} \frac{\partial}{\partial r} \left( \frac{2}{3} \alpha_g \rho_g \frac{\mu_{g,t}}{\sigma_{\alpha g,t}} \frac{1}{r} \frac{\partial(rv_g)}{\partial r} \right) dV dt \\
 & = - \frac{2}{3} \frac{\Delta V}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \left( \frac{\alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha g,t}}}{r} \frac{\partial(rv_g)}{\partial r} \right)_n - \left( \frac{\alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha g,t}}}{r} \frac{\partial(rv_g)}{\partial r} \right)_s \right]
 \end{aligned} \tag{F.349}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,12} = - \frac{2}{3} \frac{\Delta V}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \frac{\alpha_{g,P} \frac{\mu_{g,t,P}}{\sigma_{\alpha g,t}}}{r_P} \left( \frac{\partial(rv_g)}{\partial r} \right)_n - \frac{\alpha_{g,W} \frac{\mu_{g,t,W}}{\sigma_{\alpha g,t}}}{r_S^*} \left( \frac{\partial(rv_g)}{\partial r} \right)_s \right] \tag{F.350}$$

where

$$\begin{aligned}
 \left( \frac{\partial(rv_g)}{\partial r} \right)_n &= \frac{(rv_g)_N - (rv_g)_P}{\delta r_{NP}} = \frac{r_N^v v_{g,N} - r_P^v v_{g,P}}{\delta r_{NP}} \\
 \left( \frac{\partial(rv_g)}{\partial r} \right)_s &= \frac{(rv_g)_P - (rv_g)_S}{\delta r_{PS}} = \frac{r_P^v v_{g,P} - r_S^v v_{g,S}}{\delta r_{PS}}
 \end{aligned} \tag{F.351}$$

Term 11C on the RHS of the radial momentum equation is discretized in the same way as the corresponding term in the liquid phase equation, as discussed in Sect. F.4.4:

$$\begin{aligned}
 & \int_{\Delta t} \int_{\Delta V} - \frac{\partial}{\partial r} \left( \frac{2}{3} \alpha_g \rho_g \frac{\mu_{g,t}}{\sigma_{\alpha g,t}} \frac{\partial w_g}{\partial z} \right) dV dt \\
 & = - \frac{2}{3} \frac{\Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha g,t}} \frac{\partial w_g}{\partial z} \right)_n - \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{\alpha g,t}} \frac{\partial w_g}{\partial z} \right)_s \right]
 \end{aligned} \tag{F.352}$$

This term is implemented through the source term  $S_C$  as:

$$\begin{aligned}
 S_{C,13} &= - \frac{2}{3} \frac{\Delta V}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \alpha_{g,P} \frac{\mu_{g,t,P}}{\sigma_{\alpha g,t}} \frac{(w_{g,E} - w_{g,P})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right] \\
 &+ \frac{2}{3} \frac{\Delta V}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \alpha_{g,W} \frac{\mu_{g,t,W}}{\sigma_{\alpha g,t}} \frac{(w_{g,P} - w_{g,W})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right]
 \end{aligned} \tag{F.353}$$

Term 13A on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r} \frac{\partial v_l}{\partial r} dV dt = \left( \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r} \frac{\partial v_l}{\partial r} \right)_P \Delta V \Delta t \tag{F.354}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,14} = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} + \frac{\mu_{l,t,S}}{\sigma_{\alpha_{l,t}}} \right) \left( \frac{\partial \alpha_l}{\partial r} \frac{\partial v_l}{\partial r} \right)_P \Delta V \Delta t \quad (\text{F.355})$$

The scalar variables at the staggered grid center node are obtained by arithmetic interpolation of the node values in the scalar grid. Moreover, the velocity gradient is approximated by use of the central difference scheme and the surface values are obtained by arithmetic interpolation of the node values in the staggered velocity grid:

$$\left( \frac{\partial v_l}{\partial r} \right)_P = \frac{v_{l,n} - v_{l,s}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{\frac{1}{2}(v_{l,P} + v_{l,N}) - \frac{1}{2}(v_{l,P} + v_{l,S})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \quad (\text{F.356})$$

Term 13B on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial v_l}{\partial z} dV dt = \Delta V \Delta t \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial v_l}{\partial z} \right)_P \quad (\text{F.357})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,15} = \Delta V \Delta t \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_P \frac{\frac{1}{2}(v_{l,E} + v_{l,P}) - \frac{1}{2}(v_{l,P} + v_{l,W})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \quad (\text{F.358})$$

where

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial z} \right)_P &= \frac{(\alpha_l)_e - (\alpha_l)_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \\ &= \frac{\frac{1}{4}(\alpha_{l,P} + \alpha_{l,E} + \alpha_{l,S} + \alpha_{l,SE}) - \frac{1}{4}(\alpha_{l,P} + \alpha_{l,W} + \alpha_{l,S} + \alpha_{l,SW})}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \end{aligned} \quad (\text{F.359})$$

Term 14 on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} v_l \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt = v_{l,P} \left[ \frac{(\mu_{l,t} \frac{\partial \alpha_l}{\partial r})_n - (\mu_{l,t} \frac{\partial \alpha_l}{\partial r})_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \Delta V \Delta t \quad (\text{F.360})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,16} = v_P \left[ \frac{\mu_{l,P}(\frac{\partial \alpha_l}{\partial r})_n - \mu_{l,S}(\frac{\partial \alpha_l}{\partial r})_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \Delta V \Delta t \quad (\text{F.361})$$

in which the scalar variables at the staggered grid center node are obtained by arithmetic interpolation of the node values in the scalar grid.

Term 15 on the RHS of the momentum equation:

$$\int_{\Delta t} \int_{\Delta V} w_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r} \right) dV dt = (w_l)_P \left[ \frac{(\frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r})_e - (\frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r})_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right] \Delta V \Delta t \quad (\text{F.362})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,17} = (w_l)_P \left[ \frac{(\mu_{l,t} \frac{\partial \alpha_l}{\partial r})_e - (\mu_{l,t} \frac{\partial \alpha_l}{\partial r})_w}{\frac{1}{2}(\delta z_{EP} + \delta z_{PW})} \right] \Delta V \Delta t. \quad (\text{F.363})$$

### Pressure force

The pressure force term is treated in the same way as described for the radial liquid velocity component.

### Added mass force

The added mass force term is treated in the same way as described for the radial liquid velocity component.

### Transversal force

The transversal force term is treated in the same way as described for the radial liquid velocity component.

### Steady drag force

The steady drag force term is treated in the same way as described for the radial liquid velocity component.

### Algebraic discretization equation

After dividing all the terms by  $\Delta t$ , the discretized equation can be written on the standard algebraic form:

$$a_P v_{g,P} = a_N v_{g,N} + a_S v_{g,S} + a_E v_{g,E} + a_W v_{g,W} + b_{v_g} \quad (\text{F.364})$$

The coefficients are defined by:

$$\begin{aligned}
 a_N &= D_n + \max[-C_n, 0] \\
 a_S &= D_s + \max[C_s, 0] \\
 a_E &= D_e + \max[-C_e, 0] \\
 a_W &= D_w + \max[C_w, 0] \\
 b &= \sum_m S_{C,m} + a_P^0 v_{g,P}^0 \\
 a_P &= \frac{\Delta V}{\Delta t} (\alpha_g \rho_g)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - \sum_q S_{P,q} \Delta V
 \end{aligned} \tag{F.365}$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity equation, as shown for the liquid phase equations. The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

$$\begin{aligned}
 b^* &= -m C_2 v_{g,P}^\nu + \sum_m S_{C,m,g} + a_P^0 v_{g,P}^0 \\
 a_P^* &= \frac{\Delta V}{\Delta t} (\alpha_g \rho_g)_P^0 + a_N + a_S + a_E + a_W + m C_1 - \sum_q S_{P,q,g} \Delta V
 \end{aligned} \tag{F.366}$$

#### F.4.7 The Gas Phase Axial Momentum Balance

The axial momentum balance for gas is given in (F.146).

$$\begin{aligned}
 &\frac{\partial}{\partial t} (\alpha_g \rho_g w_g) + \frac{1}{r} \frac{\partial}{\partial r} (r \alpha_g \rho_g v_g w_g) + \frac{\partial}{\partial z} (\alpha_g \rho_g w_g w_g) \\
 &= \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial r} w_g \right) + \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} w_g \right) \\
 &+ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} v_g \right) + \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} w_g \right) \\
 &+ \frac{1}{r} \frac{\partial}{\partial r} \left( r \alpha_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial w_g}{\partial r} \right) + \frac{\partial}{\partial z} \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial w_g}{\partial z} \right) \\
 &+ \frac{1}{r} \frac{\partial}{\partial r} \left( r \alpha_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial v_g}{\partial z} \right) + \frac{\partial}{\partial z} \left( \alpha_g \frac{\mu_{g,t}}{\sigma_{g,t}} \frac{\partial w_g}{\partial z} \right) \\
 &- \frac{\partial}{\partial z} \left( \frac{2}{3} \alpha_g \rho_g \left( k + \frac{\nu_{g,t}}{\sigma_{g,t}} \left( \frac{1}{r} \frac{\partial}{\partial r} (r v_g) + \frac{\partial w_g}{\partial z} \right) \right) \right) \\
 &- \alpha_g \frac{\partial p}{\partial z} + \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial r} \frac{\partial w_l}{\partial r} + \frac{\partial \alpha_l}{\partial z} \frac{\partial w_l}{\partial z} \right)
 \end{aligned}$$

$$\begin{aligned}
& + \left( v_l \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) + w_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) \right) \\
& + \alpha_g \rho_g g_z + F_{g,z}^C + \overline{F_{g,z}^{C'}}
\end{aligned}$$

The transient, convective and the diffusive terms are discretized just like the corresponding terms in the liquid phase as shown in Sect. F.4.5. Only the novel source terms found only in the axial gas phase momentum equation are considered in this section.

### The source terms

The source terms are approximated by the midpoint rule, in which  $S$  is considered an average value representative for the whole grid cell volume. The derivatives are represented by an abbreviated Taylor series expansion, usually a central difference expansion of second order is employed.

Term 1 on the RHS of the momentum equation is split into two parts, term 1a and term 1b:

$$\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial r} w_g \right) = - \frac{w_g}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial w_g}{\partial r} \quad (\text{F.367})$$

Term 1a on the RHS of the momentum equation:

$$\begin{aligned}
& - \int \int \frac{w_g}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right) dV dt \\
& = - \frac{w_{g,P} \Delta V \Delta t}{r_P \frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \left[ \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_n - \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \right)_s \right] \quad (\text{F.368})
\end{aligned}$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,1} = - \frac{w_{g,P} \Delta V \Delta t}{r_P \frac{1}{2} (\delta r_{NP} + \delta r_{PS})} \left[ r_N^v \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \right)_n \left( \frac{\partial \alpha_l}{\partial r} \right)_n - r_P^v \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \right)_s \left( \frac{\partial \alpha_l}{\partial r} \right)_s \right] \quad (\text{F.369})$$

where

$$\begin{aligned}
(\mu_{l,t})_n &= \frac{1}{4} (\mu_{l,P} + \mu_{l,N} + \mu_{l,W} + \mu_{l,NW}) \\
(\mu_{l,t})_s &= \frac{1}{4} (\mu_{l,P} + \mu_{l,S} + \mu_{l,W} + \mu_{l,SW}) \\
\left( \frac{\partial \alpha_l}{\partial r} \right)_n &= \frac{(\alpha_l)_N - (\alpha_l)_P}{\delta r_{NP}} = \frac{\frac{1}{2} (\alpha_{l,N} + \alpha_{l,NW}) - \frac{1}{2} (\alpha_{l,P} + \alpha_{l,W})}{\delta r_{NP}}
\end{aligned} \quad (\text{F.370})$$

$$\left(\frac{\partial \alpha_l}{\partial r}\right)_s = \frac{(\alpha_l)_P - (\alpha_l)_S}{\delta r_{PS}} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,W}) - \frac{1}{2}(\alpha_{l,S} + \alpha_{l,SW})}{\delta r_{PS}}$$

Term 1b on the RHS of the momentum equation:

$$-\int_{\Delta t \Delta V} \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r} \frac{\partial w_g}{\partial r} dV dt = -\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r}\right)_P \frac{(w_{g,n} - w_{g,s})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \Delta V \Delta t \quad (\text{F.371})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,2} = -\frac{1}{2} \left( \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} + \frac{\mu_{g,t,W}}{\sigma_{\alpha_{g,t}}} \right) \left( \frac{\partial \alpha_l}{\partial r} \right)_P \left[ \frac{\frac{1}{2}(w_P + w_N) - \frac{1}{2}(w_P + w_S)}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \right] \Delta V \Delta t \quad (\text{F.372})$$

where

$$\begin{aligned} \left(\frac{\partial \alpha_l}{\partial r}\right)_P &= \frac{(\alpha_l)_n - (\alpha_l)_s}{S_{NS,P}} \\ &= \frac{\frac{1}{4}(\alpha_{l,P} + \alpha_{l,N} + \alpha_{l,W} + \alpha_{l,NW}) - \frac{1}{4}(\alpha_{l,P} + \alpha_{l,S} + \alpha_{l,W} + \alpha_{l,SW})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \end{aligned} \quad (\text{F.373})$$

Term 2 on the RHS of the momentum equation is split into two parts, term 2a and term 2b:

$$\frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} w_g \right) = -w_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial w_g}{\partial z} \quad (\text{F.374})$$

Term 2a on the RHS of the momentum equation:

$$-\int_{\Delta t \Delta V} w_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = -w_{g,P} \left[ \frac{(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z})_e - (\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z})_w}{\delta z_{PW}} \right] \Delta V \Delta t \quad (\text{F.375})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,3} = -w_{g,P} \left[ \frac{\frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} (\frac{\partial \alpha_l}{\partial z})_e - \frac{\mu_{g,t,W}}{\sigma_{\alpha_{g,t}}} (\frac{\partial \alpha_l}{\partial z})_w}{\delta z_{PW}} \right] \Delta V \Delta t \Delta t \quad (\text{F.376})$$

where

$$\begin{aligned} \left( \frac{\partial \alpha_l}{\partial z} \right)_e &= \frac{(\alpha_l)_E - (\alpha_l)_P}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} = \frac{\frac{1}{2}(\alpha_{l,E} + \alpha_{l,P}) - \frac{1}{2}(\alpha_{l,P} + \alpha_{l,W})}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \\ \left( \frac{\partial \alpha_l}{\partial z} \right)_w &= \frac{(\alpha_l)_P - (\alpha_l)_W}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} = \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,W}) - \frac{1}{2}(\alpha_{l,W} + \alpha_{l,WW})}{\frac{1}{2}(\delta z_{PW} + \delta z_{EP})} \end{aligned} \quad (\text{F.377})$$

Term 2b on the RHS of the momentum equation:

$$- \int_{\Delta t \Delta V} \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial w_g}{\partial z} dV dt = - \left( \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right)_P \frac{(w_{g,e} - w_{g,w})}{\delta z_{PW}} \Delta V \Delta t \quad (\text{F.378})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,4} = - \frac{1}{2} \left( \frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} + \frac{\mu_{g,t,W}}{\sigma_{\alpha_{g,t}}} \right) \left( \frac{\partial \alpha_l}{\partial z} \right)_P \left[ \frac{\frac{1}{2}(w_{g,E} + w_{g,P}) - \frac{1}{2}(w_{g,P} + w_{g,W})}{\delta z_{PW}} \right] \Delta V \Delta t \quad (\text{F.379})$$

where

$$\left( \frac{\partial \alpha_l}{\partial z} \right)_P = \frac{(\alpha_l)_e - (\alpha_l)_w}{\delta z_{PW}} = \frac{(\alpha_l)_P - (\alpha_l)_W}{\delta z_{PW}} \quad (\text{F.380})$$

Term 3 on the RHS of the axial momentum equation is split into two parts, term 3a and term 3b:

$$\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} v_g \right) = -v_g \frac{\partial}{\partial r} \left( \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) - \frac{1}{r} \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial}{\partial r} (r v_g) \quad (\text{F.381})$$

Term 3a on the RHS of the momentum equation:

$$- \int_{\Delta t \Delta V} v_g \frac{\partial}{\partial r} \left( \frac{\mu_g}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = -(v_g)_P \left[ \left( \mu_g \frac{\partial \alpha_l}{\partial z} \right)_n - \left( \mu_g \frac{\partial \alpha_l}{\partial z} \right)_s \right] \frac{\Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \quad (\text{F.382})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,5} = -v_{g,P} \left[ \left( \mu_g \frac{\partial \alpha_l}{\partial z} \right)_n - \left( \mu_g \frac{\partial \alpha_l}{\partial z} \right)_s \right] \frac{\Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \quad (\text{F.383})$$

where

$$(v_g)_P = \frac{1}{4}(v_{g,P} + v_{g,N} + v_{g,W} + v_{g,NW}) \quad (\text{F.384})$$

$$(\mu_{l,t})_n = \frac{1}{4}(\mu_{l,P} + \mu_{l,N} + \mu_{l,W} + \mu_{l,NW})$$

$$\begin{aligned}
(\mu_{l,t})_s &= \frac{1}{4}(\mu_{l,P} + \mu_{l,S} + \mu_{l,W} + \mu_{l,SW}) \\
\left(\frac{\partial \alpha_l}{\partial z}\right)_n &= \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,N}) - \frac{1}{2}(\alpha_{l,W} + \alpha_{l,NW})}{\delta z_{PW}} \\
\left(\frac{\partial \alpha_l}{\partial z}\right)_s &= \frac{\frac{1}{2}(\alpha_{l,P} + \alpha_{l,S}) - \frac{1}{2}(\alpha_{l,W} + \alpha_{l,SW})}{\delta z_{PW}}
\end{aligned}$$

Term 3b on the RHS of the axial momentum equation:

$$-\int_{\Delta t} \int_{\Delta V} \frac{1}{r} \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial}{\partial r} (rv_g) dV dt = -\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial r}\right)_P \left[\frac{(rv_l)_n - (rv_l)_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})}\right] \Delta V \Delta t \quad (\text{F.385})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,6} = -\frac{\frac{1}{2}\left(\frac{\mu_{g,t,P}}{\sigma_{\alpha_{g,t}}} + \frac{\mu_{g,t,S}}{\sigma_{\alpha_{g,t}}}\right)}{r_P} \left(\frac{\partial \alpha_l}{\partial r}\right)_P \left[\frac{\frac{1}{2}(v_N + v_{NW}) - \frac{1}{2}(v_P + v_W)}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})}\right] \Delta V \Delta t \quad (\text{F.386})$$

where

$$\begin{aligned}
\left(\frac{\partial \alpha_l}{\partial r}\right)_P &= \frac{(\alpha_l)_n - (\alpha_l)_s}{\delta r_{NP} + \delta r_{PS}} \\
&= \frac{\frac{1}{4}(\alpha_{l,P} + \alpha_{l,N} + \alpha_{l,W} + \alpha_{l,NW}) - \frac{1}{4}(\alpha_{l,P} + \alpha_{l,S} + \alpha_{l,W} + \alpha_{l,SW})}{(\delta r_{NP} + \delta r_{PS})}
\end{aligned} \quad (\text{F.387})$$

Term 4 on the RHS of the axial momentum equation is split into two parts, term 4a and term 4b:

$$\frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_g}{\partial z} w_g \right) = -w_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) - \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \frac{\partial w_g}{\partial z} \quad (\text{F.388})$$

Term 4a on the RHS of the momentum equation:

$$-\int_{\Delta t} \int_{\Delta V} w_g \frac{\partial}{\partial z} \left( \frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = -w_{g,P} \left[ \frac{\left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z}\right)_e - \left(\frac{\mu_{g,t}}{\sigma_{\alpha_{g,t}}} \frac{\partial \alpha_l}{\partial z}\right)_w}{\delta z_{PW}} \right] \Delta V \Delta t \quad (\text{F.389})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,7} = -w_{g,P} \left[ \frac{(\frac{\mu_{g,t,P}}{\sigma_{\alpha g,t}} \frac{\partial \alpha_l}{\partial z})_e - (\frac{\mu_{g,t,W}}{\sigma_{\alpha g,t}} \frac{\partial \alpha_l}{\partial z})_w}{\delta z_{PW}} \right] \Delta V \Delta t \quad (\text{F.390})$$

Term 4b on the RHS of the momentum equation:

$$-\int_{\Delta t} \int_{\Delta V} \frac{\mu_{g,t}}{\sigma_{\alpha g,t}} \frac{\partial \alpha_l}{\partial z} \frac{\partial w_g}{\partial z} dV dt = -\left( \frac{\mu_{g,t}}{\sigma_{\alpha g,t}} \frac{\partial \alpha_l}{\partial z} \right)_P \left[ \frac{w_{g,e} - w_{g,w}}{\delta z_{PW}} \right] \Delta V \Delta t \quad (\text{F.391})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,8} = -\frac{1}{2}(\mu_{g,P} + \mu_{g,W}) \left( \frac{\partial \alpha_l}{\partial z} \right)_P \left[ \frac{\frac{1}{2}(w_{g,E} + w_{g,P}) - \frac{1}{2}(w_{g,P} + w_{g,W})}{\delta z_{PW}} \right] \Delta V \Delta t \quad (\text{F.392})$$

The 5th to 9th terms on the RHS of the axial component of the gas momentum equation are discretized in the same way as the corresponding equations in the liquid phase equation, discussed in Sect. F.4.5.

Term 11A on the RHS of the axial momentum equation:

$$\int_{\Delta t} \int_{\Delta V} \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r} \frac{\partial w_l}{\partial r} dV dt = \left( \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial r} \frac{\partial w_l}{\partial r} \right)_P \Delta V \Delta t \quad (\text{F.393})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,14} = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha l,t}} + \frac{\mu_{l,t,W}}{\sigma_{\alpha l,t}} \right) \left( \frac{\partial \alpha_l}{\partial r} \right)_P \left( \frac{\partial w_l}{\partial r} \right)_P \Delta V \Delta t \quad (\text{F.394})$$

where

$$\left( \frac{\partial w_l}{\partial r} \right)_P = \frac{w_{l,n} - w_{l,s}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{\frac{1}{2}(w_{l,P} + w_{l,N}) - \frac{1}{2}(w_{l,P} + w_{l,S})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \quad (\text{F.395})$$

Term 11B on the RHS of the axial momentum equation:

$$\int_{\Delta t} \int_{\Delta V} \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial z} \frac{\partial w_l}{\partial z} dV dt = \left( \frac{\mu_{l,t}}{\sigma_{\alpha l,t}} \frac{\partial \alpha_l}{\partial z} \frac{\partial w_l}{\partial z} \right)_P \Delta V \Delta t \quad (\text{F.396})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,15} = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha l,t}} + \frac{\mu_{l,t,W}}{\sigma_{\alpha l,t}} \right) \left( \frac{\partial \alpha_l}{\partial z} \right)_P \left( \frac{\partial w_l}{\partial z} \right)_P \Delta V \Delta t \quad (\text{F.397})$$

Term 12 on the RHS of the axial component of the momentum equation:

$$\int \int_{\Delta t \Delta V} v_l \frac{\partial}{\partial r} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = \frac{(v_l)_P \Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_n - \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_s \right] \quad (\text{F.398})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,16} = \frac{(v_l)_P \Delta V \Delta t}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \left[ \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial r} \right)_n - \frac{\mu_{l,t,S}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial r} \right)_s \right] \quad (\text{F.399})$$

Term 13 on the RHS of the axial component of the momentum equation:

$$\int \int_{\Delta t \Delta V} w_l \frac{\partial}{\partial z} \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right) dV dt = \frac{w_{l,P} \Delta V \Delta t}{\delta z_{PW}} \left[ \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_e - \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \frac{\partial \alpha_l}{\partial z} \right)_w \right] \quad (\text{F.400})$$

This term is implemented through the source term  $S_C$  as:

$$S_{C,17} = \frac{w_{l,P} \Delta V}{\delta z_{PW}} \left[ \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial z} \right)_e - \frac{\mu_{l,t,W}}{\sigma_{\alpha_{l,t}}} \left( \frac{\partial \alpha_l}{\partial z} \right)_w \right]. \quad (\text{F.401})$$

### Pressure force term

The pressure force term in the axial component of the gas momentum equation is discretized in the same way as described when considering the liquid momentum equation in Sect. [F.4.5](#).

### Gravity force term

The gravity force term in the gas momentum equation is discretized in the same way as described when considering the liquid momentum equation in Sect. [F.4.5](#).

### Virtual mass force term

The virtual mass force term in the gas momentum equation is discretized in the same way as described when considering the liquid phase momentum equation in Sect. [F.4.5](#).

### Steady drag force term

The steady drag force term in the axial component of the gas momentum equation is treated in the same way as described when considering the liquid momentum equation, as discussed in Sect. [F.4.5](#).

### Algebraic discretization equation

After dividing all the terms by  $\Delta t$ , the discretized equation can be written on the standard algebraic form:

$$a_P w_{g,P} = a_N w_{g,N} + a_S w_{g,S} + a_E w_{g,E} + a_W w_{g,W} + b_{w_g} \quad (\text{F.402})$$

The coefficients are defined by:

$$\begin{aligned} a_N &= D_n + \max[-C_n, 0] \\ a_S &= D_s + \max[C_s, 0] \\ a_E &= D_e + \max[-C_e, 0] \\ a_W &= D_w + \max[C_w, 0] \\ b &= \sum_m S_{C,m} + a_P^0 w_{g,P}^0 \\ a_P &= \frac{\Delta V}{\Delta t} (\alpha_g \rho_g)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - \sum_q S_{P,q} \Delta V \end{aligned} \quad (\text{F.403})$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity equation, as shown for the liquid phase equations. The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

$$\begin{aligned} b^* &= -m C_2 w_{g,P}^\nu + \sum_m S_{C,m,g} + a_P^0 w_{g,P}^0 \\ a_P^* &= \frac{\Delta V}{\Delta t} (\alpha_g \rho_g)_P^0 + a_N + a_S + a_E + a_W + m C_1 - \sum_q S_{P,q,g} \Delta V. \end{aligned} \quad (\text{F.404})$$

### F.4.8 Turbulent Kinetic Energy

The equation for the turbulent kinetic energy is discretized in accordance with the generalized equation in Sect. F.4.3, with  $\psi = k$  and phase  $k = l$ .

#### The source terms

The source terms are approximated by the midpoint rule, in which  $\langle S \rangle$  is considered an average value representative for the whole grid cell volume. The derivatives are represented by an abbreviated Taylor series expansion, usually a central difference expansion of second order is employed.

$$\int_{\Delta t} \int_{\Delta V} \alpha_l (P_k + P_b - \rho_l \varepsilon) dV dt = \alpha_l (P_k + P_b - \rho_l \varepsilon) \Delta V \Delta t \quad (\text{F.405})$$

where

$$S_{C,1} \Delta V \Delta t = [\alpha_{l,P} P_k \Delta V + \alpha_{l,P} P_b] \Delta V \Delta t \quad (\text{F.406})$$

$$S_{p,1} \Delta V \Delta t = \alpha_{l,P} \rho_{l,P} \varepsilon \Delta V \Delta t \quad (\text{F.407})$$

The production terms are approximated as:

$$P_k = \mu_{l,t,P} (2[(\frac{\partial v_l}{\partial r})_P^2 + (\frac{\partial w_l}{\partial z})_P^2 + (\frac{v_l}{r})_P^2] + (\frac{\partial v_l}{\partial z} + \frac{\partial w_l}{\partial r})_P^2)$$

where

$$\begin{aligned} \left(\frac{\partial v_l}{\partial r}\right)_P &= \frac{(v_l)_n - (v_l)_s}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} = \frac{v_{l,N} - v_{l,S}}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \\ \left(\frac{\partial w_l}{\partial z}\right)_P &= \frac{(w_l)_e - (w_l)_w}{\frac{1}{2}(\delta_{PW} + \delta_{EP})} = \frac{w_{l,E} - w_{l,P}}{\frac{1}{2}(\delta_{PW} + \delta_{EP})} \\ \left(\frac{v_l}{r}\right)_P &= \frac{\frac{1}{2}(v_{l,P} + v_{l,N})}{\frac{1}{2}(r_P^v + r_N^v)} \\ \left(\frac{\partial v_l}{\partial z}\right)_P &= \frac{\frac{1}{4}(v_{l,P} + v_{l,E} + v_{l,N} + v_{l,NE}) - \frac{1}{4}(v_{l,P} + v_{l,W} + v_{l,N} + v_{l,NW})}{\frac{1}{2}(\delta_{PW} + \delta_{EP})} \\ \left(\frac{\partial w_l}{\partial r}\right)_P &= \frac{\frac{1}{4}(w_{l,P} + w_{l,E} + w_{l,N} + w_{l,NE}) - \frac{1}{4}(w_{l,P} + w_{l,W} + w_{l,N} + w_{l,NW})}{\frac{1}{2}(\delta r_{NP} + \delta r_{PS})} \end{aligned} \quad (\text{F.408})$$

and

$$\begin{aligned} P_b &= C_d [F_{D,z}((w_g)_P - (w_l)_P) + F_{D,r}((v_g)_P - (v_l)_P)] \\ &= C_d \left[ F_{D,z} \left( \frac{1}{2}(w_{g,P} + w_{g,E}) - \frac{1}{2}(w_{l,P} + w_{l,E}) \right) \right. \\ &\quad \left. + F_{D,r} \left( \frac{1}{2}(v_{g,P} + v_{g,N}) - \frac{1}{2}(v_{l,P} + v_{l,N}) \right) \right]. \end{aligned} \quad (\text{F.409})$$

### Algebraic discretization equation

After dividing all the terms by  $\Delta t$ , the discretized equation can be written on the standard algebraic form:

$$a_P k_{l,P} = a_N k_{l,N} + a_S k_{l,S} + a_E k_{l,E} + a_W k_{l,W} + b_{k_l} \quad (\text{F.410})$$

The coefficients are defined by:

$$\begin{aligned}
 a_N &= D_n + \max[-C_n, 0] \\
 a_S &= D_s + \max[C_s, 0] \\
 a_E &= D_e + \max[-C_e, 0] \\
 a_W &= D_w + \max[C_w, 0] \\
 b &= \sum_m S_{C,m} + a_P^0 k_{l,P}^0 \\
 a_P &= \frac{\Delta V}{\Delta t} (\alpha_l \rho_l)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - \sum_q S_{P,q} \Delta V
 \end{aligned} \tag{F.411}$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity equation, as shown for the liquid phase velocity equations. The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

$$\begin{aligned}
 b^* &= -m C_2 k_{l,P}' + \sum_m S_{C,m} + a_P^0 k_{l,P}^0 \\
 a_P^* &= \frac{\Delta V}{\Delta t} (\alpha_l \rho_l)_P^0 + a_N + a_S + a_E + a_W + m C_1 - \sum_q S_{P,q,l} \Delta V
 \end{aligned} \tag{F.412}$$

The convective and diffusive fluxes are approximated in the following way:

$$\begin{aligned}
 C_n &= A_n (\alpha_l \rho_l v_r)_n = A_n \frac{1}{2} (\alpha_N \rho_N + \alpha_P \rho_P) v_{r,N} \\
 C_s &= A_s (\alpha_l \rho_l v_r)_s = A_s \frac{1}{2} (\alpha_P \rho_P + \alpha_S \rho_S) v_{r,P} \\
 C_e &= A_e (\alpha_l \rho_l v_z)_e = A_e \frac{1}{2} (\alpha_E \rho_E + \alpha_P \rho_P) v_{z,E} \\
 C_w &= A_w (\alpha_l \rho_l v_z)_w = A_w \frac{1}{2} (\alpha_P \rho_P + \alpha_W \rho_W) v_{z,P} \\
 D_n &= \frac{A_n \Gamma_n}{\delta r_{NP}} \\
 D_s &= \frac{A_s \Gamma_s}{\delta r_{PS}} \\
 D_e &= \frac{A_e \Gamma_e}{\delta z_{EP}} \\
 D_w &= \frac{A_w \Gamma_w}{\delta z_{PW}} \\
 \Gamma_n &= \left( \frac{\mu_{l,eff}}{\sigma_k} \right)_n = \frac{1}{2\sigma_k} (\alpha_N \mu_N + \alpha_N \mu_N) \\
 \Gamma_s &= \left( \frac{\mu_{l,eff}}{\sigma_k} \right)_s = \frac{1}{2\sigma_k} (\alpha_P \mu_P + \alpha_S \mu_S) \\
 \Gamma_w &= \left( \frac{\mu_{l,eff}}{\sigma_k} \right)_w = \frac{1}{2\sigma_k} (\alpha_W \mu_W + \alpha_P \mu_P) \\
 \Gamma_e &= \left( \frac{\mu_{l,eff}}{\sigma_k} \right)_e = \frac{1}{2\sigma_k} (\alpha_P \mu_P + \alpha_W \mu_W).
 \end{aligned} \tag{F.413}$$

### F.4.9 Turbulent Kinetic Energy Dissipation Rate

The equation for the turbulent energy dissipation rate is discretized in accordance with the generalized equation in Sect. F.4.3, with  $\psi = \epsilon$  and phase  $k = l$ .

#### The source term

The source terms in the equation for the turbulent kinetic energy dissipation rate are implemented through the source terms  $S_P$  and  $S_C$  in the following way:

$$\int_{\Delta t} \int_{\Delta V} \alpha_l \frac{\epsilon}{k} (C_1(P_k + P_b) - C_2 \rho_l \epsilon) dV dt = [\alpha_l \frac{\epsilon}{k} (C_1(P_k + P_b) - C_2 \rho_l \epsilon)]_P \Delta V \Delta t \quad (\text{F.414})$$

where

$$S_{C,1} \Delta V \Delta t = [\alpha_l \frac{\epsilon}{k} C_1 P_k + \alpha_l \frac{\epsilon}{k} C_1 P_b]_P \Delta V \Delta t \quad (\text{F.415})$$

$$S_{p,1} \Delta V \Delta t = [\alpha_l \rho_l C_2 \frac{\epsilon}{k}]_P \Delta V \Delta t \quad (\text{F.416})$$

The production terms  $P_k$  and  $P_b$  are defined in Sect. F.4.8.

#### Algebraic discretization equation

After dividing all the terms by  $\Delta t$ , the discretized equation can be written on the standard algebraic form:

$$a_P \varepsilon_{l,P} = a_N \varepsilon_{l,N} + a_S \varepsilon_{l,S} + a_E \varepsilon_{l,E} + a_W \varepsilon_{l,W} + b_{\varepsilon_l} \quad (\text{F.417})$$

The coefficients are defined by:

$$\begin{aligned} a_N &= D_n + \max[-C_n, 0] \\ a_S &= D_s + \max[C_s, 0] \\ a_E &= D_e + \max[-C_e, 0] \\ a_W &= D_w + \max[C_w, 0] \\ b &= \sum_m S_{C,m} + a_P^0 k_{l,P}^0 \\ a_P &= \frac{\Delta V}{\Delta t} (\alpha_l \rho_l)_P + a_N + a_S + a_E + a_W + C_n - C_s + C_e - C_w - \sum_q S_{P,q} \Delta V \end{aligned} \quad (\text{F.418})$$

To avoid negative coefficients, the relation for the coefficient  $a_P$  can be modified using the continuity equation, as shown for the liquid phase velocity equations. The alternative  $a_P^*$  and  $b^*$  coefficients are defined by:

$$\begin{aligned} b^* &= -mC_2\varepsilon_{l,P}^\nu + \sum_m S_{C,m} + a_P^0\varepsilon_{l,P}^0 \\ a_P^* &= \frac{\Delta V}{\Delta t}(\alpha_l\rho_l)_P^0 + a_N + a_S + a_E + a_W + mC_1 - \sum_q S_{P,q,l}\Delta V \end{aligned} \quad (F.419)$$

The convective and diffusive fluxes are approximated in the following way:

$$\begin{aligned} C_n &= A_n(\alpha_l\rho_l v_r)_n = A_n\frac{1}{2}(\alpha_N\rho_N + \alpha_P\rho_P)v_{r,N} \\ C_s &= A_s(\alpha_l\rho_l v_r)_s = A_s\frac{1}{2}(\alpha_P\rho_P + \alpha_S\rho_S)v_{r,P} \\ C_e &= A_e(\alpha_l\rho_l v_z)_e = A_e\frac{1}{2}(\alpha_E\rho_E + \alpha_P\rho_P)v_{z,E} \\ C_w &= A_w(\alpha_l\rho_l v_z)_w = A_w\frac{1}{2}(\alpha_P\rho_P + \alpha_W\rho_W)v_{z,P} \\ D_n &= \frac{A_n\Gamma_n}{\delta r_{NP}} \\ D_s &= \frac{A_s\Gamma_s}{\delta r_{PS}} \\ D_e &= \frac{A_e\Gamma_e}{\delta z_{EP}} \\ D_w &= \frac{A_w\Gamma_w}{\delta z_{PW}} \\ \Gamma_n &= \left(\frac{\mu_l^{eff}}{\sigma_\epsilon}\right)_n = \frac{1}{2\sigma_\epsilon}(\alpha_N\mu_N + \alpha_P\mu_P) \\ \Gamma_s &= \left(\frac{\mu_l^{eff}}{\sigma_\epsilon}\right)_s = \frac{1}{2\sigma_\epsilon}(\alpha_P\mu_P + \alpha_S\mu_S) \\ \Gamma_w &= \left(\frac{\mu_l^{eff}}{\sigma_\epsilon}\right)_w = \frac{1}{2\sigma_\epsilon}(\alpha_W\mu_W + \alpha_P\mu_P) \\ \Gamma_e &= \left(\frac{\mu_l^{eff}}{\sigma_\epsilon}\right)_e = \frac{1}{2\sigma_\epsilon}(\alpha_P\mu_P + \alpha_W\mu_W). \end{aligned} \quad (F.420)$$

#### F.4.10 Volume Fraction

The gas volume fraction is calculated from the continuity equation for phase  $k$  which is discretized by the scheme proposed by Spalding [93].

The continuity equation for phase  $k$  ( $k = l, g$ ) is derived in Appendix F:

$$\begin{aligned} &\frac{\partial}{\partial t}(\alpha_k\rho_k) + \frac{1}{r}\frac{\partial}{\partial r}(r\alpha_k\rho_k v_{k,r}) + \frac{\partial}{\partial z}(\alpha_k\rho_k v_{k,z}) \\ &= \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\mu_{k,t}}{\sigma_{\alpha_k,t}}\frac{\partial\alpha_k}{\partial r}\right) + \frac{\partial}{\partial z}\left(\frac{\mu_{k,t}}{\sigma_{\alpha_k,t}}\frac{\partial\alpha_k}{\partial z}\right) + S \end{aligned}$$

In the FEM, this equation is integrated in time and over a grid cell volume. The resulting terms are then approximated in accordance with the approach presented for the generalized equation. The derivatives of the volume fraction in the diffusive terms

are approximated by central differences and for the convection terms the upwind scheme is employed.

The discretized liquid phase continuity equation ( $k = l$ ) can then be expressed as:

$$\begin{aligned} & \alpha_{l,P} \left[ \frac{\rho_l \Delta V}{\Delta t} + (\max[C_n, 0] + D_n) + (\max[-C_s, 0] + D_s) \right. \\ & \quad \left. + (\max[C_e, 0] + D_e) + (\max[-C_w, 0] + D_w) \right] \\ &= \frac{(\alpha_l \rho_l)_P^o \Delta V}{\Delta t} + \alpha_{l,N} (\max[-C_n, 0] + D_n) + \alpha_{l,S} (\max[C_s, 0] + D_s) \\ & \quad + \alpha_{l,E} (\max[-C_e, 0] + D_e) + \alpha_{l,W} (\max[C_w, 0] + D_w) + S \Delta V \quad (\text{F.421}) \end{aligned}$$

where

$$\begin{aligned} C_n &= A_n F_n = A_n (\rho_l v_l)_n = A_n v_{r,N} \frac{1}{2} (\rho_{l,P} + \rho_{l,N}) \\ C_s &= A_s F_s = A_s (\rho_l v_l)_s = A_s v_{r,P} \frac{1}{2} (\rho_{l,P} + \rho_{l,S}) \\ C_e &= A_e F_e = A_e (\rho_l w_l)_e = A_e w_{l,E} \frac{1}{2} (\rho_{l,P} + \rho_{l,E}) \\ C_w &= A_w F_w = A_w (\rho_l w_l)_w = A_w w_{l,P} \frac{1}{2} (\rho_{l,P} + \rho_{l,W}) \end{aligned} \quad (\text{F.422})$$

and

$$\begin{aligned} D_n &= \frac{A_n \Gamma_n}{\delta r_{NP}} \\ D_s &= \frac{A_s \Gamma_s}{\delta r_{PS}} \\ D_e &= \frac{A_e \Gamma_e}{\delta z_{EP}} \\ D_w &= \frac{A_w \Gamma_w}{\delta z_{PW}} \\ \Gamma_n &= \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \right)_n = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} + \frac{\mu_{l,t,N}}{\sigma_{\alpha_{l,t}}} \right) \\ \Gamma_s &= \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \right)_s = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} + \frac{\mu_{l,t,S}}{\sigma_{\alpha_{l,t}}} \right) \\ \Gamma_w &= \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \right)_w = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} + \frac{\mu_{l,t,W}}{\sigma_{\alpha_{l,t}}} \right) \\ \Gamma_e &= \left( \frac{\mu_{l,t}}{\sigma_{\alpha_{l,t}}} \right)_e = \frac{1}{2} \left( \frac{\mu_{l,t,P}}{\sigma_{\alpha_{l,t}}} + \frac{\mu_{l,t,E}}{\sigma_{\alpha_{l,t}}} \right) \end{aligned} \quad (\text{F.423})$$

For convenience two new variables  $m$  and  $S_{l,1}$  are introduced, hence the equation can be written in a more compact form:

$$\alpha_{l,P} \sum_i m_{l,i,ovt} - \sum_i \alpha_{l,i,in} m_{l,i,in} - S_{l,1} = R_l = 0 \quad (\text{F.424})$$

where

$$\begin{aligned}
\sum_i m_{l,i,ovt} &= \frac{\rho_l \Delta V}{\Delta t} + (\max[C_n, 0] + D_n) + (\max[-C_s, 0] + D_s) \\
&\quad + (\max[C_e, 0] + D_e) + (\max[-C_w, 0] + D_w) \\
\sum_i \alpha_{l,i,in} m_{l,i,in} &= \alpha_{l,N} (\max[-C_n, 0] + D_n) + \alpha_{l,S} (\max[C_s, 0] + D_s) \\
&\quad + \alpha_{l,E} (\max[-C_e, 0] + D_e) + \alpha_{l,W} (\max[C_w, 0] + D_w) \\
S_{l,1} &= \frac{(\alpha_l \rho_l)_P^o \Delta V}{\Delta t} \tag{F.425}
\end{aligned}$$

A similar equation can be obtained for the gas phase as well. If both equations are solved for  $\alpha_P$  yields:

$$\alpha_{l,P} + \alpha_{g,P} = \frac{\sum_i \alpha_{l,i,in} m_{l,i,in} + S_l}{\sum_i m_{l,i,ovt}} + \frac{\sum_i \alpha_{g,i,in} m_{g,i,in} + S_g}{\sum_i m_{g,i,ovt}} = 1 \tag{F.426}$$

With minor manipulation of the equation, we get:

$$\begin{aligned}
&\sum_i m_{l,i,ovt} \\
&= \frac{(\sum_i \alpha_{l,i,in} m_{l,i,in} + S_l) \sum_i m_{g,i,ovt} + (\sum_i \alpha_{g,i,in} m_{g,i,in} + S_g) \sum_i m_{l,i,ovt}}{\sum_i m_{g,i,ovt}} \tag{F.427}
\end{aligned}$$

This relation is used to substitute for the  $\sum_i m_{l,i,ovt}$  term in (F.424), hence we get:

$$\begin{aligned}
&\alpha_{l,P} \left[ \frac{(\sum_i \alpha_{l,i,in} m_{l,i,in} + S_l) \sum_i m_{g,i,ovt} + (\sum_i \alpha_{g,i,in} m_{g,i,in} + S_g) \sum_i m_{l,i,ovt}}{\sum_i m_{g,i,ovt}} \right] \\
&= \sum_i \alpha_{l,i,in} m_{l,i,in} + S_l. \tag{F.428}
\end{aligned}$$

### Algebraic discretization equation

The algebraic equation that must be solved for the gas volume fraction variable can thus be written as:

$$a_P \alpha_{l,P} = a_N \alpha_{l,N} + a_S \alpha_{l,S} + a_E \alpha_{l,E} + a_W \alpha_{l,W} + S_l \tag{F.429}$$

The coefficients are defined as follows:

$$\begin{aligned}
a_N &= D_n + \max[-C_n, 0] \\
a_S &= D_s + \max[C_s, 0]
\end{aligned}$$

$$\begin{aligned}
a_E &= D_e + \max[-C_e, 0] \\
a_W &= D_w + \max[C_w, 0] \\
S_C &= \frac{(\alpha_l \rho_l)_P \Delta V}{\Delta t} + S \Delta V \\
a_P &= \frac{(\sum_i \alpha_{l,i,in} m_{l,i,in} + S_l) \sum_i m_{g,i,out} + (\sum_i \alpha_{g,i,in} m_{g,i,in} + S_g) \sum_i m_{l,i,out}}{\sum_i m_{g,i,out}}
\end{aligned} \tag{F.430}$$

#### F.4.11 The Pressure-Velocity Correction Equations

The pressure correction equation is derived from the liquid continuity equation and the liquid velocity correction equation formulas. The SIMPLE Consistent (SIMPLEC) -approximation proposed by van Doormal and Raithby [29] is used to derive the velocity correction formulas.

The continuity equation for the liquid phase is given in appendix F. The discretization of this equation is discussed in Sect. F.4.10. The discretized form of the continuity equation thus yields:

$$\begin{aligned}
& \frac{[(\alpha_l \rho_l)_P - (\alpha_l \rho_l)_P^0] \Delta V}{\Delta t} + A_n(\alpha_l \rho_l v_{l,r})_n \\
& - A_s(\alpha_l \rho_l v_{l,r})_s + A_e(\alpha_l \rho_l v_{l,z})_e - A_w(\alpha_l \rho_l v_{l,z})_w \\
& = D_n(\alpha_{l,N} - \alpha_{l,P}) - D_s(\alpha_{l,P} - \alpha_{l,S}) + D_e(\alpha_{l,E} - \alpha_{l,P}) \\
& - D_w(\alpha_{l,P} - \alpha_{l,W}) + S \Delta V
\end{aligned} \tag{F.431}$$

The pressure correction is given by the difference between the correct pressure,  $p$ , and the guessed pressure,  $p^*$ . The velocity correction  $v'$  is given by the difference between the correct velocity,  $v$ , and the guessed velocity  $v^*$ :

$$\begin{aligned}
p &= p^* + p' \\
v &= v^* + v'
\end{aligned} \tag{F.432}$$

The relationship between the liquid velocity correction at the grid cell surface  $e$  and the pressure corrections, i.e., the velocity correction formula, is given as:

$$w'_{l,e} = \frac{A_e \alpha_{l,e} (p'_P - p'_E)}{a_{l,e} - \sum_{nb} a_{nb}} = d_e (p'_P - p'_E) \tag{F.433}$$

where

$$d_e = \frac{A_e \alpha_{l,e}}{a_{l,e} - \sum_{nb} a_{l,nb}} \tag{F.434}$$

The correction formulas for the liquid velocity components in the other directions, as well as the corresponding correction formulas for the gas phase, can be deduced in a similar manner.

### Algebraic discretization equation

The transport equation for the pressure corrections is obtained substituting all the velocity components in (F.431) by the sum of the guessed and corrected velocities, and then substituting the velocity corrections by the corresponding pressure corrections employing the liquid phase velocity correction formulas. The resulting algebraic equation to be solved is written:

$$a_P p'_P = a_N p'_N + a_S p'_S + a_E p'_E + a_W p'_W + b \quad (\text{F.435})$$

The coefficients are given as:

$$\begin{aligned} a_N &= A_n(\alpha_l \rho_l)_n d_n = A_n d_n \frac{1}{2} (\alpha_{l,P} \rho_{l,P} + \alpha_{l,N} \rho_{l,N}) \\ a_S &= A_s(\alpha_l \rho_l)_s d_s = A_s d_s \frac{1}{2} (\alpha_{l,P} \rho_{l,P} + \alpha_{l,S} \rho_{l,S}) \\ a_E &= A_e(\alpha_l \rho_l)_e d_e = A_e d_e \frac{1}{2} (\alpha_{l,P} \rho_{l,P} + \alpha_{l,E} \rho_{l,E}) \\ a_W &= A_w(\alpha_l \rho_l)_w d_w = A_w d_w \frac{1}{2} (\alpha_{l,P} \rho_{l,P} + \alpha_{l,W} \rho_{l,W}) \\ a_P &= a_N + a_S + a_E + a_W \\ b &= \frac{((\alpha_l \rho_l)_P - (\alpha_l \rho_l)_P^o) \Delta V}{\Delta t} - A_n(\alpha_l \rho_l v_{l,r}^*)_n + A_s(\alpha_l \rho_l v_{l,r}^*)_s - A_e(\alpha_l \rho_l v_{l,z}^*)_e \\ &\quad + A_w(\alpha_l \rho_l v_{l,z}^*)_w + D_n(\alpha_{l,N} - \alpha_{l,P}) - D_s(\alpha_{l,P} - \alpha_{l,S}) + D_e(\alpha_{l,E} - \alpha_{l,P}) \\ &\quad - D_w(\alpha_{l,P} - \alpha_{l,W}) + S_C \Delta V. \end{aligned} \quad (\text{F.436})$$
